The equilibrium constants K = [paramagnetic form]/[diamagnetic form] have been calculated from values of magnetic susceptibility. The plots of log K against $1/T$ give a minimum which demonstrates an inversion of sign in the enthalpy of values of the equilibrium.

The possibility that the paramagnetism of the molten compounds can result from dissociation of the complexes into free Ni^{++} ions and chelate molecules has been excluded by measurements of electrical conductivity made on these complexes in the molten state.

THE STRUCTURE OF ETAMYCIN

Sir:

This communication reports the complete structure of the antibiotic Etamycin[1] (Viridogrisein[2]), the isolation of which recently was described independently and simultaneously by two groups.[1,2] The antibiotic possesses interesting activity against Gram-positive organisms, and in addition causes a reversible leucopenia in dogs. Etamycin is a surprisingly lipophilic peptide (soluble in benzene and carbon tetrachloride) with a molecular weight in the range 800–900. The presence of 3-hydroxypicolinic acid, L-alanine, *allo*-hydroxy-D-proline, D-leucine and threonine was reported.[1,2] We have now shown Etamycin to be a macrocyclic lactone (22-membered ring) which contains in addition to the above-mentioned components sarcosine, α-

Digitized by Arya Samaj Foundation Chennai and eGangotri

phenylsarcosine (PheSar) and β,N-dimethylleucine (DiMeLeu, I), the latter two of which have not been encountered previously in a natural product.

The presence of N-methylamino acids was indicated by color tests[3] on hydrolysates, and confirmed by an N-methyl determination, which demonstrated the presence of three N-methyl groups per molecule of Etamycin. For the isolation of the three N-methylamino acids, an Etamycin total hydrolysate was deaminated to destroy threonine, alanine and leucine and subjected to preparative paper chromatography.

One of the amino acids was identified as sarcosine by conversion to the dinitrophenyl derivative, m.p. 185–186°, undepressed upon admixture with an authentic sample.

The second amino acid, $C_9H_{11}NO_2$, m.p. 245–246° (sublimes) (Found: C, 65.30; H, 6.66; N, 8.57) had infrared and ultraviolet spectra indicating the presence of a benzene ring. It was proved to be identical with synthetic D,L-α-phenylsarcosine, m.p. 246–247° (sublimes), by infrared and ultraviolet spectra and chromatographic behavior. The optical inactivity is expected since optically active α-phenylglycine is known[4] to racemize rapidly with hot 10% hydrochloric acid.

The third amino acid, $C_8H_{17}NO_2$, m.p. 315–316° dec., (Found: C, 60.12; H, 10.47; N, 8.77) was optically active, $[\alpha]^{28}D$ +36.2° (*c*, 2.4 in 5*N* HCl). Hypochlorite degradation[5] gave methylamine, identified as the dinitrophenyl derivative, and the isopropylmethylacetaldehyde, isolated as the 2,4-dinitrophenylhydrazone, m.p. 125.2–126.0°, $[\alpha]^{28}D$ −38.7° (*c*, 1.5 in $CHCl_3$), which was identical (m.p., mixed m.p., infrared spectra) with a sample of the DNPH of (−)-isopropylmethylacetaldehyde obtained by ozonolysis[6] of ergosterol.[7] Thus, the third amino acid is β,N-dimethylleucine (I). It may be significant that the new amino acid and ergosterol have a common structural unit.

Etamycin contains only one each of the eight components according to quantitative paper chromatography and analyses of Etamycin, $C_{44}H_{62}N_8O_{10}$ (Found: C, 59.95; H, 7.40; N, 13.07; dried at 135° (0.01 mm.) and Etamycin hydrate, $C_{44}H_{62}N_8O_{10}\cdot H_2O$ (Found: C, 58.96; H, 7.17; N, 12.54; N-CH_3, 4.63; eq. wt., 890; dried at 110° (0.01 mm.).

Evidence that Etamycin contains a lactone structure was obtained as follows. On treatment with 0.1 *N* sodium hydroxide at room temperature it is converted into an antibiotically inactive acid, which contains the hydroxypicolinic acid and all amino acids. In Etamycin the threonine resists oxidation with chromic acid, whereas under the same conditions, in Etamycin acid the threonine is destroyed to the extent of 80%. Consequently the lactone link must involve the C-terminal carboxyl group and the hydroxyl group of threonine.

The absence of a terminal free amino group and the presence of unusual amino acids presented difficulties in the application of the conventional chemical and enzymatic methods of peptide sequence determination. However, catalytic hydrogenation of the obviously N-terminal hydroxypicolinic acid provided a secondary amino function, and alkali treatment gave a terminal carboxyl group, thus making possible the application of the Edman method.[8] Seven successive degradations revealed the sequence as hydroxypicolinic acid—Thr–D-Leu–D–aHyPro–Sar–DiMeLeu–L–Ala(?)–(PheSar). The course of the degradation was followed by paper chromatography of the phenylthiohydantoins,[9] dinitrophenylation and hydrolysis of each successive peptide, followed by paper chromatography of the resulting DNP-amino acids,[10] and by quantitative estimation of the amino acid content of each successive peptide after total hydrolysis and two dimensional paper chromatography. The sequence was completed by degradation from the carboxyl end with hydrazine,[11] which established phenylsarcosine as C-terminal. The structure of Etamycin is represented by II.

NOTE ADDED IN PROOF.—Comparison of the rotation of the DiMeLeu in neutral and acid solution has shown it to be in the L-series. Another isolation after mild hydrolysis gave PheSar having $[\alpha]^{31}D$ + 118° (*c*, 4.8 in *N* HCl), from which it can be deduced that it probably is in the L-series.

We are indebted to Bristol Laboratories of Syracuse, N. Y., for our supply of Etamycin, for microbiological assays and for some financial aid.

BOOK REVIEWS

Modern Instruments in Chemical Analysis. First Edition. By FRANK M. BIFFEN, B.Sc., F.R.I.C., Research Specialist, Johns–Manville Corporation, and WILLIAM SEAMAN, M.S., Ph.D., Research Fellow, American Cyanamid Company. McGraw–Hill Book Company, Inc., 330 West 42nd St., New York 36, N. Y. 1956. ix + 333 pp. 16 × 23.5 cm. Price, $7.50.

The announced objective of the authors is to provide information for the general analytical chemist, and for others, regarding many of the leading physical principles and the instruments that are very frequently employed in chemical analysis. In spite of the somewhat different purposes and orientation, this book compares very favorably, as to scope and manner of treatment, with the three leading books of similar character that are more specifically aimed toward instruction in university courses.

The authors have concentrated their attention primarily upon photometric methods, electrical techniques and radioactive measurements.

After a brief consideration of the electromagnetic spectrum, chapter 1, the succeeding seven chapters deal, respectively, with: 2. Emission spectrographic methods. 3. Flame photometry. 4. Visible and ultraviolet absorptiometric methods. 5. Infrared spectroscopy. 6. Raman spectroscopy. 7. Mass spectrometry. 8. X-Ray diffraction. Five of the remaining chapters deal with electrical methods: 9. Survey of electroanalysis. 10. Polarography and amperometric titrations. 11. Potentiometric analysis. 12. Conductometric analysis, including the high-frequency method. 13. Coulometric analysis. The concluding chapter is: 14. Radioactivity.

Some topics that might have been expected have been omitted, as for example, fluorimetry as applied to solutions and solids, thermal methods such as enthalpy (thermometric) titrations and thermal conductance measurements. The latter topic has become of great importance in connection with vapor-phase chromatography.

In general, each chapter and each major topic is treated briefly and clearly, with generous use of line drawings and photographs of major features of the instruments. A good selection of reference books and selected journal articles is included in a rather extensive bibliography at the end of each chapter. This feature will enable the technical man to go fully into the more detailed aspects of any of the subjects that are treated.

The book is very readable, and the general composition is very good and quite free from misprints and other defects of manufacture.

FRICK CHEMICAL LABORATORY
PRINCETON UNIVERSITY
PRINCETON, N. J. N. H. FURMAN

Ion Exchange and Its Applications. Papers read at the Conference in the William Beveridge Hall, London University, 5th–7th April, 1954, with the discussions that followed. Society of Chemical Industry. The Macmillan Company, 60 Fifth Avenue, New York 11, N. Y. 1956. 173 pp. 22 × 28 cm. Price, $7.50.

This book is a set of some twenty review papers, each on somewhat different aspects of the field and written by different authors, with apparently no or little editing. Inevitably then, one encounters a considerable amount of duplication; the space allotted to each topic is often not commensurate with its extent or importance, and the contributions are of rather uneven quality.

The first section on *theoretical aspects* begins with a paper on the synthesis and general properties of resins; this is the best, short discussion of the topic this reviewer has seen. The paper on ion-exchange equilibria appears to skim over the more fundamental concepts, concentrating too much on the more formal but less informative contributions. Little information is given for the reader interested primarily in practical applications. Ion-exchange kinetics are discussed briefly and in general terms. The chromatographic column operations is essentially a review of the elegant contributions of its author, but does not mention the more simple treatments of other authors which lead to equally good values for calculated theoretical plate heights. The practical aspects of rate phenomena are, unfortunately, ignored.

The section on *industrial applications* includes two papers on water treatment and demineralization, both of which are so vague and general as to be of little practical value. The following two papers on the recovery of copper and on metallurgical applications contain interesting information, but are too brief and too general in nature.

The section on *inorganic and analytical applications* contains an introductory paper on analytical aspects, one which is entirely vague and often misleading. An article on the recovery of gold from cyanide solution is excellent. It shows how to attack the problem of the separation of a complex system, going from the laboratory through the pilot plant to plant operation. An article on the use of resins for concentrating traces of dissolved metals for analytical purposes is interesting, but its subject matter is so limited that it does not merit the accorded space. This section continues with an excellent review of continuous ion-exchange processes, presented in an authoritative and well documented manner. The subsequent article on the use of resins in the study of complex ions, where the resin is used either as a sorbent for an ion or for one of its complexes, is similarly authoritative. A much too brief summary of the use of membranes for desalting purposes concludes the section.

The section on *organic and biochemical applications* starts with a contribution dealing with amino acids, peptides and proteins, one which summarizes the older work well but devotes only a short section to the recent and most successful methods. Two brief and excellent reviews of applications to the wine industry and to medical practice follow. The summary of cation-exchange processes in soils does not attempt to relate these phenomena with other, related topics in the book.

This section is concluded with three papers: the first an excellent review on the separation of nucleic acid degradation products; the second a short description of dye purification processes making use of the "sieve" effect; the third a résumé of ion-exchange methods for the separation of alkaloids.

Each paper is followed by its discussion. It is here that the lack of editing is particularly felt, because so much of the discussion centered on questions to which there was no answer.

These papers understandably stress British contributions in this field, but space limitations mean that this is often done at the expense of equally valuable work by others. Further, most of the contributors devote entirely too much space to historical introductions and to material covered by other papers, with the result that about one-third of the available space is wasted. This being the case, the price of this book seems too high.

BROOKLYN 1, NEW YORK

Tables of Chemical Kinetics, Homogeneous Reactions. National Bureau of Standards Circular 510, Supplement 1. National Bureau of Standards, Office of Technical Information, Washington 25, D. C. Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. xiv + 472 pp. 23 × 29 cm. Price, $3.25.

This present supplement to "Tables of Chemical Kinetics" covers work up to 1953 on Rearrangements, Isomerizations, Condensations and Solvolyses, including much work published prior to 1951 but not presented in the original volume. Exhaustive search of American and British journals only is claimed, but since articles cited in these are also included, the coverage is actually much wider. To each table is appended a section of comments which amplify and explain the data given in the table. These com-

ments are usually very much to the point and make it clear that this is not an uncritical compilation of published data.

The problem of devising a suitably flexible and rational system of classification for a work such as this is a formidable one. The task is made doubly difficult by the frequent failure of authors to ascertain the products of the reactions they study kinetically. On the whole, the present system is a reasonable one although it occasionally results in unusual juxtapositions and, conversely, sometimes separates reactions that belong together. One finds, for example, that "Ester Solvolysis" includes displacements effected by added reagents or by the conjugate base of the solvent. In contrast to this, the ethanolysis and acetolysis of sulfonate esters are tabulated separately under "Ester Solvolysis" and "Ester Exchange," respectively. The classification of alkyl halides as "esters" is somewhat distressing to an organic chemist. Indeed, the section on "Ester Solvolysis" could stand a considerable overhaul in organization, since in its present form it covers a very large and rapidly expanding field.

The above comments are intended mainly to warn the reader that he may not always find what he seeks where he expects to find it. Obviously, no conceivable system of classification would please everyone. Many possible objections could be met by an alphabetical index expanded to include extensive cross listings according to type of reaction, of reactant(s) and of product(s). One hesitates to suggest additional work to the authors, who are to be congratulated for their willingness to undertake the arduous task of compiling this work, but such an index should add greatly to the usefulness of the "Tables."

DEPARTMENT OF CHEMISTRY
UNIVERSITY OF ROCHESTER WILLIAM H. SAUNDERS, JR.
ROCHESTER 20, NEW YORK

Rauwolfia: Botany, Pharmacognosy, Chemistry and Pharmacology. By ROBERT E. WOODSON, JR., Ph.D., Professor of Botany, Washington University, Senior Taxonomist, Missouri Botanical Garden, HEBER W. YOUNGKEN, Ph.D., Sc.D., Phm.D., Research Professor of Pharmacognosy and Botany, Massachusetts College of Pharmacy, EMIL SCHLITTLER, Ph.D., Director of Research, CIBA Pharmaceutical Products Inc., Summit, New Jersey, and JURG A. SCHNEIDER, M.D., Director of Physiology Research, CIBA Pharmaceutical Products Inc., Summit, New Jersey. Little, Brown and Company, 34 Beacon Street, Boston 6, Massachusetts. 1957. xii + 149 pp. 16 × 24 cm. Price, $5.50.

In the fourth edition (1949) of Henry's "The Plant Alkaloids" 5 pages and 49 references sufficed for presenting the chemistry and pharmacology of the seven rauwolfia alkaloids known at that time. Except for rauwolscine, which had been identified as a yohimbine isomer, their structure chemistry was as yet uncharted territory. Their pharmacology was on the whole unexciting and held little promise of therapeutic utility. While extracts of *Rauwolfia serpentina* were known to exert hypotensive and sedative effects, it was not clear whether these were due to an alkaloidal constituent. In the intervening 8 years, and particularly since the discovery of reserpine by Mueller, Schlittler and Bein (1952), this picture has changed radically. More than 40 alkaloids isolated from Rauwolfia species are now on record, and the structures of a great majority of these have been elucidated. Only last year we have seen these achievements culminate in Woodward's brilliantly conceived and executed synthesis of reserpine. There was a commensurate expansion of pharmacological research, most of it concerned with analyzing the unique combination of properties exhibited by reserpine, as well as revival of interest in the botany and pharmacognosy of the genus.

Obviously the time was ripe for reviewing the various aspects of the field anew in the light of these recent advances. The authors of "Rauwolfia," each of whom has in his area of competence made important contributions to the present state of knowledge, have succeeded admirably in imparting the new look on the topic. The four chapters of the little book are written in the manner of brief review articles. There is no attempt to bring in technical detail, except in the chapters on the botany (R. E. Woodson) and on the pharmacognosy (H. W. Youngken), where much of the space is naturally given over to the description and visualization of morphological subject matter. While the chemist interested in the Rauwolfia alkaloids will rarely have need for this kind of information, he will be well advised to read the initial sections in the botanical chapter which deal with the taxonomy, synonomy, geographical distribution of the species, and their culture and propagation. For instance, it may be new to him that *R. tetraphylla*, *canescens*, *heterophylla* and *hirsuta* are not, as he may have been led to believe by the chemical literature, different species. and that according to the nomenclature rules *tetraphylla* deserves preference. Likewise, he may be unaware of the fact that *R. canescens* is not indigenous in India, but was transplanted there a century ago from the West Indies.

The chemical chapter, by E. Schlittler, opens with a very useful set of tables listing the alkaloids so far isolated from the various species, together with their melting points, rotations and references to the papers reporting their discovery. In the following exposition of their structure chemistry some order is brought into the chaos of names by grouping the compounds according to certain structural criteria (anhydronium bases, indoline types, tertiary bases with heterocyclic, or alicyclic, ring E). The numerous more "conventional" representatives (yohimbine types) of the last-named group are treated somewhat cursorily, to allow fuller discussion in the following section of its most important members, reserpine and its two congeners, deserpidine and rescinnamine. That the proof of structure and the elucidation of the stereochemistry of these compounds should have received authoritative and lucid treatment by the originator of this whole line of research was only to be expected. In the stereochemical argument one could perhaps disagree with the author on one or two points in his evaluation of the evidence. Thus, this reviewer was a little surprised to find one of the early proofs for the *cis*-fusion of rings D and E, the formation of a quaternary N-4 tosylate from methyl reserpate 18-tosylate on treatment with collidine, discussed not in this context, but in connection with the configuration of C-17, on which this observation bears only indirectly. The chapter ends with a brief review of the synthetic studies so far on record, including the Woodward synthesis of reserpine, which is conveniently outlined in a flow sheet.

The present status of pharmacological knowledge is ably summarized by J. A. Schneider in the last chapter. It opens with an introductory section dealing with the historical aspects and the effects of crude extracts from various species. The pharmacodynamic properties of the individual alkaloids, grouped for this purpose as in the chemical chapter, are then reviewed. It is, of course, the subsection on reserpine which gives real substance to the chapter. Here the author could draw on a comparative wealth of recently published material which lent itself to classification according to pharmacological criteria and more detailed discussion in terms of specific effects.

In brief, the booklet provides all the essential information on Rauwolfia in highly condensed, yet readable form. It will be equally useful to the expert as a source of references and to the newcomer who needs orientation in one or the other aspect of the field.

The Thermal Denaturation of Desoxyribose Nucleic Acid

BY STUART A. RICE AND PAUL DOTY

RECEIVED SEPTEMBER 19, 1956

Several samples of thymus desoxyribose nucleic acid in saline solutions have been studied by light scattering, viscosity and sedimentation methods after exposure to a series of elevated temperatures. For exposure times of one hour, changes are noticed at temperatures above 89° for two of the samples and above somewhat lower temperatures for the others. From this characteristic temperature up to 100° the viscosity falls about 12-fold (as Zamenhof first noted), the mean end-to-end length decreases by about 15-fold and the molecular weight remains unchanged according to light scattering studies. Sedimentation measurements reveal a broadening of the distribution of sedimentation constants but no significant change in the average value. Typical denaturing agents lower the temperature range in which these changes occur by 10–20° but have no effect at room temperature. It appears that the changes at the elevated temperatures are due to the melting out of regions of hydrogen-bonded structure within DNA molecules and this coöperative breakdown of the highly organized, native structure is termed denaturation. At a given elevated temperature the viscosity quickly reaches an equilibrium value but it cannot be decided whether this indicates existence of a true equilibrium between native and denatured regions of the DNA molecules or a distribution of denaturation temperatures for different regions. It is shown that the completely denatured state can be achieved without chain degradation and it is surmised that in this state the polynucleotide strands are held together by remaining or reformed hydrogen bonds.

During the last three years it has become increasingly clear that desoxypentose nucleic acids (DNA) possess a uniquely ordered structure which is maintained in aqueous salt solutions but which can be irreversibly disordered by exposure to acid, alkali, heat and other agents. This breakdown of a specific structure is accompanied by a drastic fall in viscosity, a substantial rise in optical density in the ultraviolet and a shift to a different titration curve. Since the advent of the Watson–Crick structure for DNA it has been suggested frequently that this configurational change be identified with the breakdown of hydrogen bonding between the base pairs of the two polynucleotide chains.

When dissolved in 0.2 *M* NaCl, DNA can be exposed to *p*H values as low as 2.6 for several hours without significant chemical degradation. A study of the physical changes[1] showed that when brought to this *p*H the DNA molecules contracted without change in molecular weight. In this acid condition, the optical density at 258 mμ is raised about 32%.[2] A recent analysis of the titration curves of such acid–treated DNA shows that essentially all the original hydrogen bonds are broken if the temperature is 25° but that only about half are broken at low temperatures (0.4°).[3] It also has been shown that prolonged exposure to *p*H 2.6 at 25° leads to detectable chemical degradation: purines are liberated in substantial numbers, the polynucleotide chains undergo slow scission and the remaining hydrogen bonded areas disappear.[4]

The study reported here began in 1953 as a parallel investigation of the changes brought about in DNA by heat. Since the occurrence of a sharp fall in viscosity in a critical temperature range was readily apparent,[5] our first concern was to establish whether this was purely a configurational change as in the case of acid treatment or whether a molecular weight change was involved. In addition, we were concerned with characterizing the heat-treated DNA and elucidating the mechanism of the thermally induced transition. Further, these considerations led to an exploration of the problem of the separation of the two polynucleotide strands in DNA. Some results have been given in a preliminary note.[6]

Experimental

Samples.—Four preparations of calf thymus DNA were employed. Two of these have been described before in an earlier publication.[7] The sample listed there as Simmons B is designated here as SB-1 and the one listed as Varin is designated here as V-1. The third sample was prepared by Dr. Norman Simmons (University of California, Los Angeles) and is designated as SC-1. The fourth sample, on which most work was done, was prepared according to Simmons Method B and is designated SB-11. Briefly, this preparative procedure involves multiple extractions of minced thymus in saline–citrate (0.015 *M* sodium citrate and 0.15 *M* NaCl) by blending and centrifuging to obtain a sediment containing the nucleoprotein. 30% sodium *p*-xylene sulfonate is used to deproteinize the nucleoprotein. The protein is then precipitated upon dilution and filtered off. The DNA in solution is precipitated with isopropyl alcohol, redissolved and precipitated several times.

The molecular weight and radii of gyration as determined by light scattering are listed in Table I together with the intrinsic viscosity at zero gradient. The higher values for sample SB-11 are thought to be due to instantaneous transfer of the thymus gland from the freshly killed animal to Dry Ice and its remaining at this low temperature until blended in cold saline–citrate.

TABLE I

SUMMARY OF MOLECULAR PROPERTIES OF DNA SAMPLES

Sample	Mol. wt.	Radius of gyration, Å.	Intrinsic viscosity, 100 cc./g.
V-1	6,850,000	2050	48
SB-1	5,850,000	2000	53
SC-1	6,600,000	2700	62
SB-11	8,200,000	3000	72

Analytical Constants and Experimental Techniques.—The values of the extinction coefficient, refractive index increment, etc., are the same as those previously employed[7] and the techniques of light scattering and viscosity measurement are the same as described before.[7] In particular any viscosity measurement quoted implies that if gradient dependence were present, measurements in the range of 30 to 100 sec.$^{-1}$ were extrapolated to zero gradient to yield the value listed. Gradient dependence was found to disappear at intrinsic viscosities of about 10. Sedimentation measurements were made in a Spinco Model E ultracentrifuge using 30 mm. cells. Bar angles as low as 5° were used for the most dilute solutions. The saline–citrate solvent mentioned above (0.015 *M* sodium citrate and 0.15 *M* NaCl) was used throughout.

Experimental Results

Viscosity.—Preliminary measurements on all of the DNA samples confirmed Zamenhof's[5,8] observation that the viscosity of DNA solutions in physiological saline falls rapidly in the vicinity of 80°. A systematic study was carried out as follows. DNA solutions were made by dissolving the sample in water in the cold room to yield a concentration of about 40 mg./dl. This was adjusted to the standard saline–citrate solvent and a concentration of 4 to 7 mg./dl. Aliquots of this stock solution were heated at various temperatures by immersion in thermostats for one hour. The aliquots were then placed in ice and the viscosities measured within a day at 25°.

Results for samples V-1 and SB-11 are shown in Fig. 1. It is seen that the intrinsic viscosity of V-1 begins to fall at about 70° and reaches half its original value at 89°. Sample SB-1 showed a similar behavior. However, for sample SB-11 (and SC-1, not shown) the viscosity did not begin to fall until 85° and it reached half its value only at 94°. All samples reached about the same value of intrinsic viscosity at 100°, that is, 4.5 ± 1.5. The uncertainty is large here because of the high dilution employed in these particular measurements.

The relative sharpness of the viscosity fall in all four samples is indicative of a configurational change having the characteristics of a melting or denaturation of a periodic intramolecular structure. At first thought it appears that the process may involve only the passage of the individual DNA molecules from the original state of high viscosity to the final state of low viscosity. If it is assumed that the transition consists of a single first-order process, the data in Fig. 1 may be used to derive the temperature dependence of the first-order rate constant. When this is done, an activation energy of 35–40 kcal./mole is found for samples V-1 and SB-1 and a value of 93 kcal./mole for samples SB-11 and SC-1. Corresponding entropies of activation are calculated to be in the range of 63–75 entropy units for the first two samples and 220 e.u. for the SB-11 and SC-1 samples. These values are comparable with those found in protein denaturation studies and indicate that a highly ordered structure is being irreversibly broken down. Insofar as the term *denaturation* denotes the disappearance of a periodic structure by a rate process grossly characterized by a high entropy and high energy of activation, the transition described here can be termed denaturation.

The nature of the denaturation process was examined in more detail by observing the change in viscosity as a function of the time of exposure to elevated temperatures. Several results are shown in Fig. 2. The striking feature of these results is that they show that the viscosity falls rapidly and levels out at a plateau which is lower the higher the temperature. While it was not to be expected that the viscosity would measure precisely the extent of denaturation, except in the event of all-or-none reactions within individual DNA molecules, it clearly should give a qualitative indication of the progress of the reaction. Hence the leveling off of these curves demonstrates that the denaturation essentially comes to a stop short of completion by an amount dependent on the temperature. The implications which this observation carries are discussed later. However, at this point it is clearly evident that this observation invalidates the interpretation offered in the preceding paragraph.

The temperature range in which thermal denaturation occurs rapidly would be expected to be lowered by substances which are effective in denaturing proteins, as a consequence, measurements of the viscosity at 25° of a series of DNA solutions which had been heated at various temperatures for 1 hour were carried out in the presence of typical denaturing agents. The results for 8 *M* urea, 3.2 *M* guanidine hydrochloride and 0.8 *M* sodium salicylate are shown in Fig. 3 for sample SB-11. It is seen that the viscosity plots are approximately shifted to lower temperatures by these agents. The temperature at which the viscosity has fallen

by half is lowered 19, 14 and 8°, respectively, for the urea, guanidine hydrochloride and sodium salicylate. However, because of the difference in concentrations the molar efficiency of these agents is in the reverse order, similar to that usually found for proteins. It is also apparent that the viscosity of the denatured material is different in these various

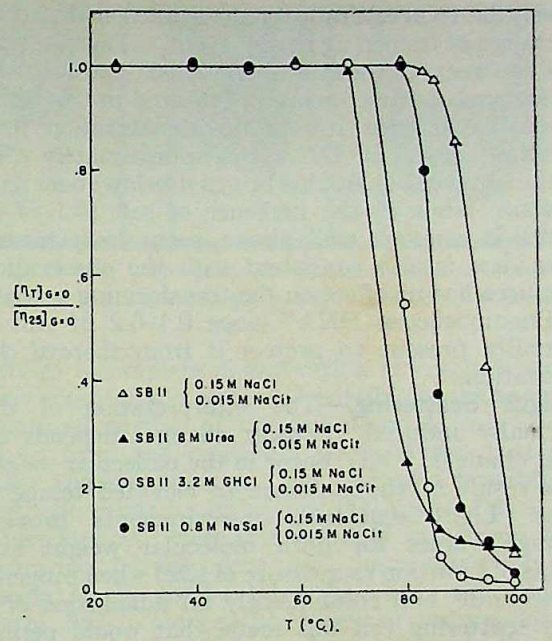

Fig. 3.—Intrinsic viscosity of sample SB-11 in the presence of hydrogen bond breaking agents as a function of the temperature of one hour heating.

solvents. It is lowest in the guanidine hydrochloride; this is probably due at least in part to the suppression of the electrostatic repulsions among the phosphate groups by the guanidinium ion. Separate experiments have also established that the molecular weight of DNA after exposure to 3.2 *M* guanidine hydrochloride at 100° for one hour is lowered to 940,000, which, as we shall subsequently see, is markedly lower than after comparable treatment in the absence of any denaturing agent. It is important to note that the DNA solutions employed here always contained 0.15 *M* NaCl and 0.015 *M* sodium citrate before the denaturing agent was added. The addition of any of these denaturing agents did not significantly change the intrinsic viscosity, 72. Hence the only observed effect of these agents, provided that they are added to saline solutions of DNA, is to lower by as much as 20° the denaturation temperature range of DNA. They have no effect at room temperature.

These conclusions stand in apparent conflict with the investigations of Conway[9] for he has found that 6 *M* urea raises the intrinsic viscosity (at zero shear) of aqueous solutions of DNA and lowers it substantially in the presence of 0.1 *M* NaCl. Since these observations appear reliable and the intrinsic viscosity of the DNA sample, 45, is high enough to ensure that it is not seriously denatured, it appears that the fall in viscosity in the presence of 0.1 *M* NaCl could only have come about if the urea was added before the salt. From the work of Thomas[2] and that of M. Litt[10] in this Laboratory it is clear that the denaturation temperature range is lowered markedly as the ionic strength is reduced so that in the absence of added salt and at rather high dilution denaturation takes place in the vicinity of room temperature. The effect of adding urea and other denaturing agents under this condition will

clearly be to accelerate the denaturation that is on the verge of occurring in any event. Thus the conflict between Conway's observations and our own is removed if our conclusion is stated in this form; concentrated urea lowers the denaturation temperature range of DNA by approximately 20°. In the absence of salt this brings it below room temperature while in the presence of salt (0.1 *M* or more) it remains well above room temperature. This view is also consistent with the observation that urea has no effect on the transforming activity of Pneumococcus DNA[11] since 0.1–0.2 *M* salt is generally present to protect it from thermal denaturation.

Light Scattering.—The interpretation of the thermally induced viscosity changes depends on what changes, if any, occur in the molecular weight as a result of the exposure to elevated temperatures. Light scattering measurements provide average values for both molecular weight and radius of gyration (a measure of size) when properly carried out[7] and consequently an adaptation of a light scattering cell was made that would permit angular intensity measurements to be made on the same DNA solution before and after heating without removal from the cell. This was done by sealing a sintered glass frit (ultra-fine) to a tapered glass joint (female) which could then be fitted onto the joint at the top of the light scattering cell which was itself shaped like an erlenmeyer flask. The glass frit prevented dust from entering the cell during the adjustment of pressure that took place on heating and cooling.

Solutions of about 6 mg./dl. DNA (sample SB-11) in the saline–citrate solvent were then measured at 25° as a function of time exposed to temperatures of 84, 94 and 100°, respectively. In this concentration range the scattering is proportional to the concentration so that the molecular weight can be obtained from measurements at a single concentration. The temperature of 84° induced no change in scattering (and hence no change in molecular weight or size) until after 10 hr. (At 21 hr. the molecular weight had fallen to one-half and the radius of gyration had diminished about 25%.) This display of thermal stability was not unexpected since the viscosity had not fallen after one hour at this temperature. At 94 and 100°, however, substantial changes occurred as shown in Figs. 4 and 5 where the reciprocal scattering envelopes (Kc/R_θ) are plotted as a function of $\sin^2(\theta/2)$ (θ is the scattering angle and R_θ the reduced intensity of light scattered at θ). In both cases the slope of the plot falls abruptly while maintaining essentially the same intercept showing thereby that the molecular size is greatly diminished while the molecular weight remains approximately con-

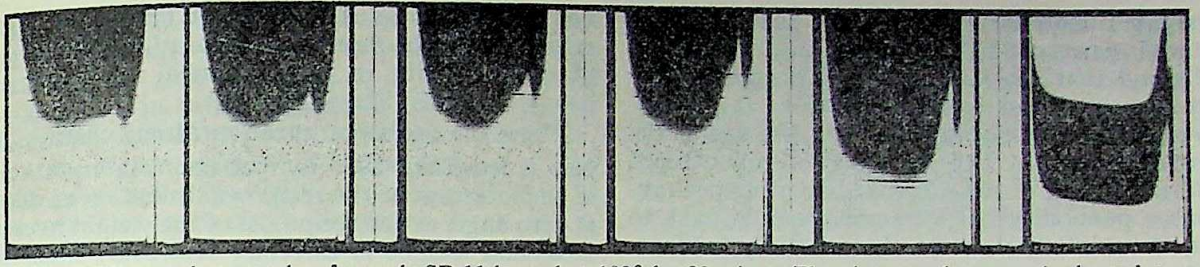

Fig. 6.—Schlieren photographs of sample SB-11 heated at 100° for 20 min. The photographs are at 4 minute intervals, the rotor speed is 37020 r.p.m. and the bar angle is 15, 7.5, 5, 5, 5 and 5° reading from right to left. The DNA concentration is 0.0429%.

stant. At longer times the molecular weight does decrease as shown by the upward trend of the intercepts.

These results show that thermal denaturation, like the case of acid denaturation summarized in the Introduction, consists of a substantial contraction of the molecule without a change in molecular (or particle) weight. In keeping with the viscosity results shown in Fig. 2 the radius of gyration falls from 2800 Å. to an intermediate and essentially constant value of 1250 Å. at 94° whereas at 100° it falls quickly to a lower value of 1000 Å. At both temperatures two hour exposures cause degradation to an average molecular weight of about 3 million and a radius of gyration of about 750 Å. Thus thermal denaturation appears to reach its final extent at a given temperature rather quickly and is then followed by a slow degradation.

In this case as in that of acid denaturation, there is no evidence of a lowering of the molecular weight to one-half as might be expected if the two polynucleotide strands separated. This indicates that either the breakdown of the hydrogen bonding is incomplete or that other types of bonds form which prevent the separation. Further consideration of this problem is taken up in a later section.

The attainment of a stable, intermediate value of both viscosity and size from light scattering when the solutions are exposed to temperatures lower than that required to produce the maximum effect raises a fundamental question. Have all the DNA molecules partially denatured or have some become completely denatured and others remained unaffected? In other words, do different parts of the individual DNA molecules have different resistances to thermal denaturation or is there a spectrum of melting temperatures among the population of DNA molecules?

In an attempt to answer this question and to characterize further the denatured state, some sedimentation studies were undertaken.

Sedimentation.—The sedimentation experiments were carried out in a manner similar to the light scattering experiments except that concentrations of 35 mg./dl. rather than 10 mg./dl. were employed. After heating at various times up to six hours at 84° no change in the sedimentation pattern or rate was observed over that of the unheated material. Heating at 94° for one hour brought about a slight broadening in the sedimentation pattern but it still remained hypersharp. The observed sedimentation constants (11.8 S. at 35 mg./dl. and 8.5 at 70 mg./dl.) are not much different than for the unheated material. In view of the previous evidence that a state of incomplete denaturation is reached under these conditions it appeared possible that the more denatured portion of the sample could not be resolved from the relatively undenatured material under these conditions. To test this possibility, synthetic mixtures of native DNA and DNA denatured at 100° were mixed and it was found that separation did not occur until the relative concentration of the native DNA had been reduced to nearly 10%. Hence the observed sedimentation diagrams of the 94° material could not discriminate between the two possibilities mentioned at the end of the preceding section.

When DNA solutions exposed to 100° for 15 or 20 minutes were examined it was found that half of the material appeared as a rather sharp, but not hypersharp, peak and that the remainder sedimented faster as a very diffuse shoulder that eventually separated (see Fig. 6). The pattern did not differ significantly over the concentration range of 35 to 53 mg./dl. In each case the sedimentation rate of the sharper peak was about 21 ± 2 and the diffuse peak extended from about 25 to 40 S.

The appearance of two differently sedimenting species in solutions in which it was thought that denaturation had gone essentially to completion posed a difficult problem. We had originally interpreted it as incomplete denaturation and associated the diffuse peak with the completely denatured material. This was the basis of the assignment of 30 as the sedimentation constant of the denatured DNA in the preliminary note.[6] However, quite recently, Dr. K. V. Shooter and Professor J. A. V. Butler have examined our sample SB-11 by ultraviolet optics in the ultracentrifuge[12,13] and found that the distribution of sedimentation coefficients broadened but remained single-peaked at 21 S. when heated at 100° for 15 min. at a concentration of 10 mg./dl.

Now it is well known that when DNA is thermally denatured at higher concentrations (>100 mg./dl.) the initial fall in viscosity is gradually restored and even surpassed. This presumably is due to the formation of intermolecular hydrogen bonds making use of the large number of sites opened up in the denaturation process. When this is taken together with the absence of the double peak at 10 mg./dl. it appears possible that our observation at intermediate concentrations was made on partially

aggregated material; that is, the faster, diffuse material corresponded to aggregated denatured DNA and that the sharper peak was still molecularly dispersed and corresponds to what was observed at lower concentration with the aid of the ultraviolet optics. The possibility of undenatured material staying in the slower sedimenting peak remains a possibility but its amount would have to be quite small because of the relatively low viscosity.

The Denatured State

Molecular Weight.—From the results presented in Figs. 4 and 5 it appears that the exposure of DNA in saline solution to temperatures of 94 and 100° produces denaturation (as seen in the lowering of the slopes) followed by the gradual onset of chemical degradation (as seen in the eventual rise in intercepts). At 94° the slope, and hence the radius of gyration, is not lowered as much as at 100° in keeping with the viscosity results (Fig. 2) which shows that denaturation proceeds only to an intermediate point at 94°. The fact that there is a delay in the onset of the fall in molecular weight after completion of the denaturation is seen in Fig. 7 where the light scattering molecular weight results for samples SB-11 and V-1 are plotted as a function of time. The denaturation, judged either in terms of viscosity or light scattering, is essentially complete at 15 min. but the initial fall in molecular weight is not evident until about 45 min. The fall in molecular weight continues as long as the sample is held at the elevated temperature, and it exhibits no leveling off at any particular value.

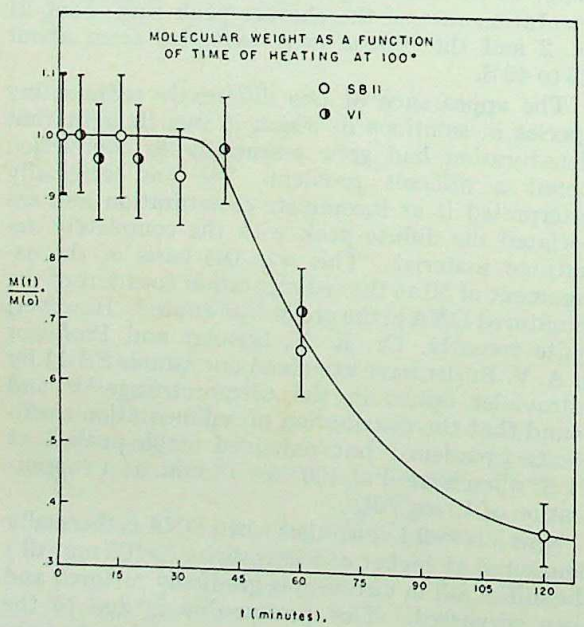

Fig. 7.—Molecular weight (from light scattering) as a function of time of heating at 100°.

In the case of thermal denaturation studied here as well as in the case of acid denaturation[1] the denatured material, prior to its eventual degradation, exhibits the same intercept in the light scattering plots as the original sample. Although we do interpret this as showing that denaturation occurs without change in molecular weight, the conclusion is not as obvious as it appears at first sight. The reason lies in the recent demonstration[14] of the role of polydispersity in the reciprocal scattering envelopes of chain-like molecules.

When the radius of gyration of the chain molecule is less than 1000 Å., the usual interpretation of the intercept of the reciprocal radiation envelope at zero angle as the reciprocal of the weight average molecular weight is correct. However, when the radius of gyration exceeds 1000 Å., the reciprocal scattering envelope that is experimentally accessible will not yield the weight average molecular weight unless the molecular weight distribution happens to be the most probable (*i.e.*, one in which the various molecular weight averages stand in the ratios $M_z:M_w:M_n = 3:2:1$). When the molecular weight distribution is not of this form, the interpretation of the experimental data must be modified. For these other cases, the reciprocal radiation envelope will either approach or coincide with an asymptote whose intercept on the ordinate provides the reciprocal of two times the number average molecular weight, M_n. The implications of this possibility of ambiguity in assigning the type of average that is being determined by light scattering measurements on DNA is discussed elsewhere.[15] It is sufficient to say here that several lines of evidence indicate that the distribution of molecular weights in DNA does correspond roughly to that of the most probable distribution. If we call the molecular weight obtained from the scattering measurements in the usual angular range the "light scattering" molecular weight, we may conclude that in the present case the weight average molecular weight of denatured DNA is within probable experimental error equal to the light scattering average molecular weight for undenatured DNA.

Sedimentation Constant and Intrinsic Viscosity of Denatured DNA.—The intrinsic viscosity of thermally denatured DNA has been found in this study to be 4.5 ± 1.5. This is in need of more accurate and precise determination, but it is sufficiently reliable for the present purpose which is to explore the interpretation of this quantity in combination with the sedimentation constant. The work of Professors Butler[13] and Schachman[16] and their colleagues indicates that there is a rather broad distribution of sedimentation constants in DNA and that this broadens further upon thermal denaturation. On sample SB-11 the value determined at 10 mg./dl. (20.0 S) upon correction for concentration dependence becomes 21 S. Taken at face value, these measurements are in apparent contradiction with the viscosity and light scattering results found in this research. The constant value of the sedimentation constant would imply that two molecules with the same mass but which differ by a factor of three in radius of gyration (a factor of 27 in molecular volume) sediment at the same

rate. Since the chemical composition remains unchanged, the interactions of the individual monomers with the solvent should be of the same order of magnitude in both cases, and if we allow the denatured molecule to have a frictional coefficient more in accord with that characteristic of the single polynucleotide chain, the net resistance to flow per monomer must decrease. Even if the frictional coefficient per monomer were to remain the same, the large decrease in molecular volume at constant molecular weight would of necessity be accompanied by an increase in sedimentation rate. We can invent no mechanism which would enable a constant sedimentation constant to be coupled with a constant molecular weight and a greatly diminished molecular volume. The use of the sedimentation data of Professors Butler and Schachman with our molecular weights and viscosities also stand in contradiction with the empirically well established Flory–Mandelkern relation[17]

$$s_0 = 2.6 \times 10^6 \frac{M^{2/3}}{[\eta]^{1/3}} \frac{(1 - \bar{v}\rho)}{\eta_0 N}$$

In order to be compatible with the observed molecular weight of 8.2×10^6, the observed value of the sedimentation constant would have to be increased by a factor of 2.3.[18]

The problem posed by this large discrepancy is a serious one. The result obtained from sedimentation and viscosity is subject to several criticisms. First, so little is known about the molecular form of the denatured state that the application of the foregoing equations based upon simple models may not be justified. Secondly, the distribution of sedimentation constants, particularly in the denatured material, appears to be so broad that the weight average sedimentation constant, which is the one required in the above relations, may not have been properly determined. Thirdly, as we have pointed out previously,[6] the free draining coil model does permit a contraction of a chain-like molecule with only a small change in sedimentation constant but large decrease in viscosity. The relationship between s, $\overline{r^2}$, and $[\eta]$ is, in this model

$$s_0 = \frac{(1 - \bar{V}\rho)\overline{r^2}}{3600\eta_0[\eta]}$$

which predicts a value for s_0 of 20, in substantial agreement with experiment. However, this model does not fit the sedimentation data for native DNA as well, and the native molecule would be expected to be even more "free draining." Moreover, its applicability to non-homologous molecules may not be justified. Admittedly, the applicability of this model has been very limited but it may possibly be relevant in this case. On the other hand, the light scattering results are not dependent upon a model for their interpretation. With regard to the light scattering experiments it appears that aside from gross experimental errors the only complication that could account for the difference indicated here would be the existence of some aggregates having the same spacial distribution and radius of gyration as the individual denatured DNA molecules. These aggregates would have to have such large sedimentation constants, however, that they would for the most part be removed by the usual centrifuging employed in clarifying light scattering solutions. Such effects were not observed.

In our opinion, then, the light scattering results should be accepted but this dilemma cannot be considered satisfactorily settled until the sedimentation and viscosity data are rigorously interpreted.

Other Characteristics of the Denatured State.—In Fig. 8 the titration curves of undenatured and denatured (15 min. at 100°) DNA with dilute HCl (0.00494 N) are shown. The change produced upon thermal denaturation is similar to that found for exposure to acid[19] and in thermal denaturation studies being currently reported by Cox and Peacocke.[3] This agreement supports the view that essentially the entire hydrogen-bonded structure is destroyed by the thermal denaturation at 100°.

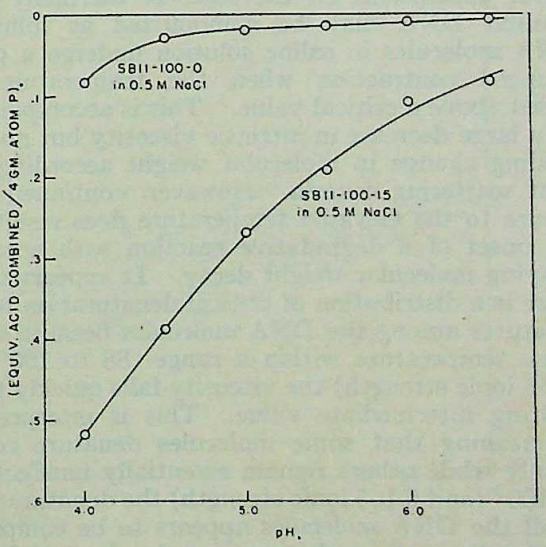

Fig. 8.—Potentiometric titration curve of samples SB-11 in 0.5 M NaCl before and after heating at 100° for 15 min.

If the hydrogen-bonded structure is essentially eliminated by the denaturation, it would be expected that the resulting molecule would be quite flexible in contrast to undenatured DNA. It is well known that typical polyelectrolyte molecules expand when the ionic strength is reduced and that this results in an increase in the reduced specific viscosity. That denatured DNA behaves in this manner while undenatured DNA does not is shown in Fig. 9 where the reduced specific viscosity is shown for solutions of each. In this experiment a portion of a DNA solution in saline–citrate (ionic strength = 0.165) was thermally denatured and then each solution was diluted stepwise with water producing thereby a continuous diminution in ionic strength. The rise in reduced specific viscosity in the case of the denatured DNA shows that its flexibility is comparable to that of ordinary flexible polyelectrolytes. The constancy shown

(17) L. Mandelkern and P. J. Flory, *J. Chem. Phys.*, **20**, 212 (1952).

(18) The use of a value of 2.6×10^6 in the foregoing equation has been shown to imply a very narrow molecular weight distribution [M. L. Hunt, S. Newman, H. A. Scheraga and P. J. Flory, *J. Phys. Chem.*, **60**, 1278 (1956)]. However, if the distribution were as broad as the most probable distribution ($M_z:M_w:M_n$::3:2:1) the calculated value of s_0 would still be 2.1 times that observed.

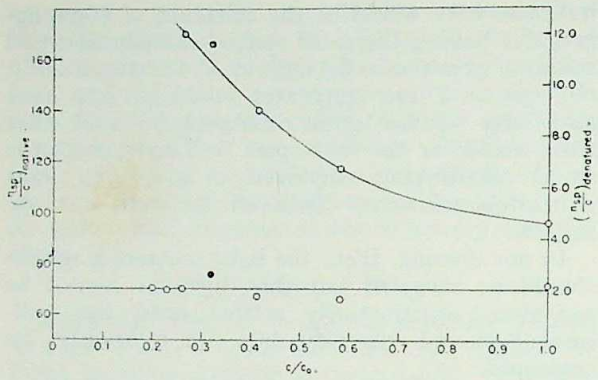

Fig. 9.—The expansion of denatured (15 minutes at 100°) DNA as a function of decreasing ionic strength as shown by η_{sp}/c.

by undenatured DNA reflects its rigidity. The experiment was conducted in the region of salt concentrations where intermolecular interactions are suppressed. At still lower ionic strengths these intermolecular interactions dominate and would mask any polyelectrolyte expansion.

Our conclusions on the state of thermally denatured DNA may be summarized as follows. DNA molecules in saline solution undergo a pronounced contraction when the temperature is raised above a critical value. This is accompanied by a large decrease in intrinsic viscosity but no attending change in molecular weight according to light scattering criteria. However, continued exposure to the elevated temperature does result in the onset of a degradative reaction with accompanying molecular weight decay. It appears that there is a distribution of critical denaturation temperatures among the DNA molecules because at a given temperature within a range (88 to 100° at 0.165 ionic strength) the viscosity falls quickly to a limiting intermediate value. This is interpreted as meaning that some molecules denature completely while others remain essentially unaffected. At 100° (and 0.165 ionic strength) the denaturation of all the DNA molecules appears to be complete in 15 min. and no change in molecular weight is evident. This condition is referred to as the completely denatured state. The extinction coefficient at the 259 mμ peak is 15% greater than before denaturation. The intrinsic viscosity is reduced by a factor of about 15 and the radius of gyration by a factor of 3. The sedimentation constant is apparently not greatly changed although this point in particular deserves further study. When the denaturation is carried out at higher concentrations than those employed here, reaggregation is apparent. This indicates a potential associating tendency of the denatured molecules that may only be operative intramolecularly at the higher dilution used in this work.

The Denaturation Process.—The course of the transition from the native to the denatured state has been followed principally by viscosity studies as illustrated in Figs. 1 and 2. If it is assumed that the intrinsic viscosity is a direct measure of the extent of the denaturation reaction and that the measurements made upon cooling to room temperature do represent the state of affairs existing at the temperature prior to cooling, two deductions are possible.

One of these recognizes that the viscosity has fallen to an equilibrium value within the time of one hour heating and that an apparent equilibrium constant can then be evaluated by interpreting the fractional lowering of the intrinsic viscosity in terms of fractional conversion of the native to the denatured state. (This interpretation of the data of Fig. 1 in terms of an equilibrium constant replaces the kinetic treatment mentioned previously.) When this is done for sample SB-11 a plot of the logarithm of the apparent equilibrium constant against the reciprocal of absolute temperature is found to be linear with the exception of the 100° point where it is known that substantial degradation has occurred. From the slope of this plot a heat of reaction of 110 kcal. and an entropy of reaction of 300 e.u. is derived. The data obtained in the presence of denaturing agents (Fig. 3) is fitted with the same heat of reaction and slightly higher entropy values (308 to 319 e.u.). Similar results are found for sample SC-1; for samples SB-1 and V-1 the values obtained are only one-third of those for the other two samples. These values emphasize that the denaturation reaction involves very large heat and entropy changes without chemical bond scission and in addition these two quantities offer a means of formally characterizing the course of the denaturation when it is carried through a series of temperatures with equilibration permitted at each temperature.

The other possible deduction relates to the kinetics rather than the equilibrium aspect of the reaction. If again the viscosity is assumed to represent quantitatively the progress of the reaction, the initial slope of the viscosity–time plots such as those in Fig. 2 can be subjected to the orthodox treatment of rate constants. When this is done for sample SC-1, the results are found to be linear in an Arrhenius plot (log of rate constant against reciprocal of absolute temperature) and from this an energy of activation of 145 kcal. and an entropy of activation of 325 e.u. is found.

Even if the assumptions on which these numerical results have been obtained are accepted their interpretation remains unclear because it is not known whether they refer to a mole of DNA molecules or to a mole of "segments" or intramolecular regions of DNA molecules. In other words the unit step by which the denaturation process proceeds is not known. The failure of sedimentation studies to settle this point is indeed unfortunate. However, by comparison with other hydrogen bonded systems it appears that the energy of activation and the heat of reaction per base pair should fall within the range of 1 to 10 kcal. Since there are of the order of 10,000 base pairs in a DNA molecule this would imply that values of 10,000 to 100,000 kcal. would be expected if the entire molecule passed from the native state through the transition state into the completely denatured state in one coördinate step. Hence it appears that the unit process cannot involve the entire molecule but only a segment of it composed of 10 to 100 base pairs.

The arguments that can be raised against this

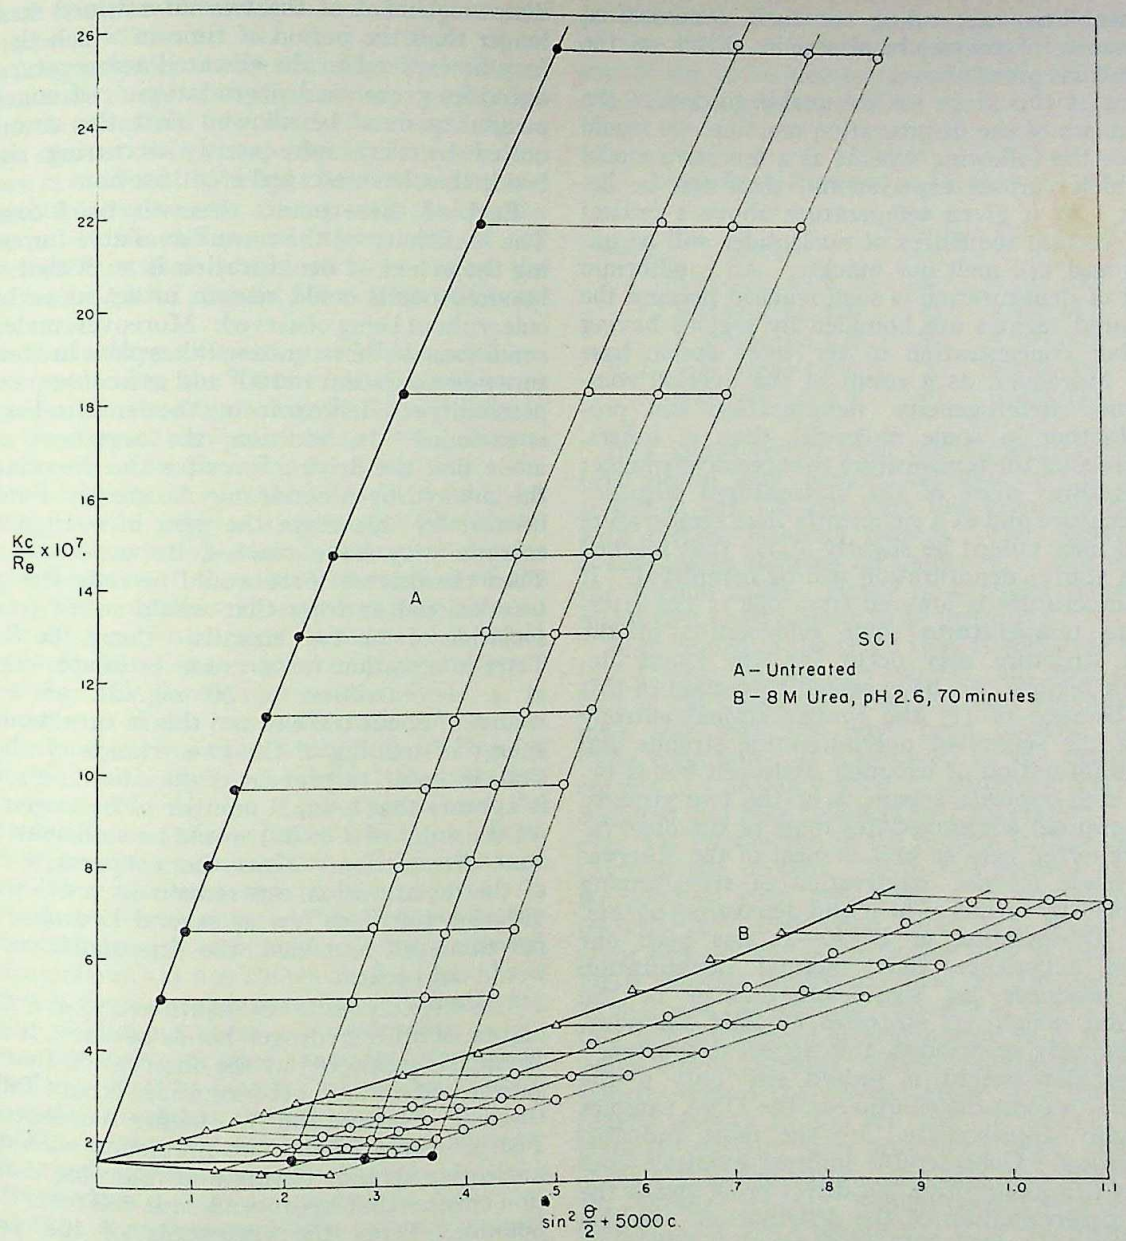

Fig. 10.—Angular distribution of scattered light of sample SC-1 before and after treatment with 8 *M* urea at *p*H 2.6.

interpretation are, however, very serious indeed. Two illustrations will suffice. If the denaturation proceeds by the melting out of one sequence of base pairs after another, the viscosity would be expected to fall sharply when the first few sequences melt out and then respond more gradually. Thus it would not represent a quantitative measure of the extent of the denaturation reaction as assumed in the above calculations. In addition, the previously mentioned difficulties in interpreting the intrinsic viscosity of the denatured state must also extend to the partially denatured state.[20] A more serious difficulty lies in the assumption that equilibrium is achieved at a given temperature and that the distribution so produced is preserved upon cooling. Obviously, much work will have to be done at the temperature of interest in order to assay directly the extent of denaturation and to prove or disprove this assumption.

Thus far no mention has been made of the possible effect of chemical heterogeneity, and indeed the present observations do not require its consideration. Since there are two types of base pairs and since these probably have a difference in stability, the compositional variations revealed by recent fractionation studies[21] would imply variations in the stability of different molecules and it may be expected that this variation would be exhibited among the sequences of segments which may be the unit of the denaturation process. If different regions of the DNA molecules had different ther-

(20) Another indication of the difficulty in interpreting the partially denatured state is shown by comparing the intrinsic viscosity and radius of gyration of material denatured at 94° (Figs. 1 and 4). In this case the radius of gyration has fallen to within 25% of the value for completely denatured DNA while the viscosity has only decreased half-way. Since the radius of gyration depends upon a higher average than the intrinsic viscosity this behavior is obviously incompatible with any simple model of the denaturation process based upon analogies with ordinary polymer molecules.

(21) See, for example, E. Chargaff and J. N. Davidson, "The Nucleic Acids," Vol. I, Academic Press, New York, N. Y., 1955, p. 358.

Digitized by Arya Samaj Foundation Chennai and eGangotri

mal stabilities depending on their composition, this would, of course, have serious effects on the calculations given above.

Since at this stage we are unable to deduce the mechanism of the denaturation reaction, we would propose the following scheme as a tentative model for which various experimental tests can be designed. At a given temperature above a critical value, certain sequences of nucleotides will be unstable and will melt out quickly. An equilibrium extent of denaturation is soon reached because the denatured regions are bounded by regions having a higher concentration of the more stable base pair. Moreover, as a result of the over-all compositional heterogeneity, denaturation will proceed further in some molecules than in others. Upon raising the temperature to successively higher temperatures more of the undenatured sequence will denature and at a sufficiently high temperature (which may indeed be slightly above that reached in this study) denaturation will be completed. If the temperature is lowered from one of the intermediate temperatures some reformation of the native structure may occur but the longer denatured regions can be expected to remain in this state because of (1) the configurational entropy gain of the separated polynucleotide strands and (2) the formation of irregular hydrogen bonds between non-opposite segments of the two strands. This proposal accommodates most of the observations reported here as well as most of the observations made on the inactivation of transforming principle[22] by means of heat and denaturing agents.

The Dissociation of DNA.—It has been our uniform experience that thermal denaturation alone produces no significant change in the molecular weight *as measured by light scattering*. As previously mentioned, this apparent constancy in molecular weight is indeed real only if the molecular weight distribution in the DNA samples is roughly approximated by the most probable distribution. Considerable indirect evidence does support this assumption but direct proof awaits the actual determination of the distribution. In this discussion this assumption is made.

At the ionic strength employed in this work an exposure of about 15 min. at 100° represents the most severe thermal treatment possible without inducing a gradual and continuous decay in molecular weight. In terms of light scattering, viscosity, titratability of basic groups[3] and the change in optical density at 259 mμ[2] the denaturation reaction has reached completion during this treatment. If this conclusion is strictly true, it would be expected that the two polynucleotide strands making up the DNA molecule according to the Watson–Crick structure would separate and the molecular weight would be reduced by half. Upon finding that this does not occur, we are led to conclude (1) that indeed not every hydrogen bond has been dissociated by this condition, (2) that the potential hydrogen bonding capacity of the polynucleotide chains is such that some hydrogen bonds form again between the two previously mated chains or (3) that the time required for the disentanglement of the two intertwined strands is longer than the period of time in which the DNA may be exposed to the elevated temperature without risking chemical degradation. Of course, the possibility must be allowed that the strands are united by very infrequently occurring chemical bonds that have escaped identification.

Each of these points deserves brief comment. The sensitivity of the means available for estimating the extent of denaturation is such that several hundred bonds could remain intact in each molecule without being observed. Moreover, under these conditions the denaturation takes place in a temperature range adjacent to 100° and as a consequence the possibility of safely exceeding the denaturation range is excluded. In addition, the argument can be made that the driving force for the dissociation of the last hydrogen bonds may be greatly diminished because by this stage the gain in configurational entropy may have reached its maximum value. Then the driving force would be only the gain in translational entropy that would result from dissociation of the two strands. Using the Sackur–Tetrode equation for a crude estimate, one finds at a concentration of 50 mg./dl. an entropy change of about 100 e.u. and this in turn requires an energy of binding of the two strands of about 30 kcal. in order to prevent dissociation. From this it appears that a small number of hydrogen bonds (of the order of 3 to 30) would be sufficient to prevent dissociation. Thus the coöperative nature of the denaturation can remain as previously envisioned, but if as few as several hydrogen bonds per thousand remained, the dissociation of DNA would not occur.

The second possibility mentioned above, the formation of other hydrogen bonds between denatured strands, is supported by the observation that aggregation and indeed gel-formation occurs following thermal denaturation at higher concentrations. The proximity of the two previously mated polynucleotide strands during and following denaturation ensures that hydrogen bonds will form if this is possible. From the arguments of the previous paragraph, only a few would be needed to keep the two strands together. At this point, it is relevant to emphasize that fairly extensive hydrogen bonding between the previously mated chains could develop when the temperature is lowered without contradicting any of the previously mentioned evidence. That is, if the newly formed bonds did not unite the previously matched base pairs but rather only led to a disorganized and incomplete pairing, the titratability of the groups involved would remain normal. Moreover, the observed 15% rise in optical density (measured at room temperature following thermal denaturation) is far short of the maximum possible, that is, the 55% attained in complete hydrolysis.[2] Consequently, the possibility of substantial hydrogen bonding of a disorganized type in the denatured material at room temperature appears possible. A structure of this kind would resemble a highly swollen gel particle and may offer a means of explaining the curious hydrodynamic behavior exhibited by denatured DNA.

The final possibility, the requirement of a long

(22) See, for example, S. Zamenhof in "Progress in Biophysics and Biophysical Chemistry," Vol. 6, Pergamon Press, London, 1956, p. 85.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

period of time for disentanglement, has a picturesque appeal. However, the time scale in which equally long polymer chains of rubber-like material explore a wide range of configurations, as exhibited in the fast retraction of stretched rubber, argues strongly against this view. Again, however, the existence of transient hydrogen bonds, forming and dissociating in such a way as to greatly prolong the time required for diffusional movements of the polynucleotide strands, could perhaps extend the time scale enough to account for a delay of the order of minutes.

With these three different possibilities, each capable of explaining the absence of dissociation in DNA under the conditions described, the failure to observe the dissociation is not unexpected. Nevertheless, it would be desirable to bring about the complete dissociation if possible. It would, for example, provide polydesoxyribonucleotide material for experimentation, permit through molecular weight measurement the direct assessment of the number of interruptions, if any, that may occur in the individual polynucleotide strands and it would add belatedly additional evidence for the existence of the Watson–Crick model in solution.

With this in mind, we have made several attempts to bring about the dissociation of DNA by carrying out both acid and thermal denaturation in the presence of 8 *M* urea. In a typical case, the DNA solution in saline–citrate which had been made 8 *M* in urea was brought to *p*H 2.6 for about 1 hour. Then the urea was removed by dialysis against saline–citrate solvent. The light scattering results on this sample compared with the untreated DNA (sample SC-1) are shown in Fig. 10. It is clear that there is no change in the light scattering molecular weight but there is a contraction to the much smaller molecular size; the radius of gyration changes from 2600 to 950 Å.; the value characteristic of the completely denatured state.

Repetition of this and some related experiments, some of which are summarized in Table II, have failed to produce a drop to one-half in molecular weight unless degrading conditions were maintained for the right length of time (see *p*H 2.4 entry in table). However, there are so many possibilities to explore that eventual success in obtaining dissociation without degradation is by no means unlikely. However, it appears appropriate to note here our doubts concerning the claim of Alexander and Stacey[23,24] to have achieved this dissociation. They have reported that a fall to one-half of the original molecular weight could be brought about by (1) exposure to *p*H 2.2 followed by neutralization and (2) exposure to 4 *M* urea at room temperature. In the latter case, a previous treatment of the DNA with ethylenediamine tetraacetate was found to be necessary for thymus DNA but not for herring sperm DNA.

TABLE II

SUMMARY OF ATTEMPTS TO DISSOCIATE DNA

Sample	Condition	Time of exposure, min.	After removal of urea M_w	ρg, Å.
V-1	8 *M* urea, *p*H 2.7	150	8,100,000	1200
	8 *M* urea, *p*H 2.6	45	8,400,000	1120
	8 *M* urea, *p*H 2.4	30	4,100,000	1060
SC-1	8 *M* urea, *p*H 2.6	70	6,700,000	950
	8 *M* urea, *p*H 2.6	70	6,700,000	950

In a recent report from this Laboratory[4] it has been shown that chemical degradation can be detected at *p*H 2.6 and that this increases rapidly with further lowering thereof. The degradation is continuous showing no tendency to stop at half the original value. Hence we consider the above-mentioned observations to be fortuitous.

With regard to the claim that dissociation occurs in 4 *M* urea we can only suggest that during some part of the operation of adding and removing the urea, salt may not have been present. Under these conditions, as mentioned in the earlier discussion of Conway's work, denaturation may have occurred and been followed by dissociation. However, the implication in the reports is that salt was continuously present. With salt present at room temperature even denaturation, a necessary prerequisite to dissociation, does not occur. This point was checked in particular with herring sperm DNA samples kindly provided by Dr. Alexander. In this case, the intrinsic viscosity of the DNA solution was unchanged after exposure to 4 *M* urea in saline–citrate solvent. Moreover, the urea treated sample showed the characteristic 15% increase in optical density at 259 mμ and the 12-fold fall in intrinsic viscosity after heating to 100°. This also showed that the native structure was intact after the exposure to urea. Similar results were obtained with thymus DNA before and after treatment with ethylenediamine tetraacetate. It is on this basis that the present evidence for the dissociation of DNA seems unconvincing.

Acknowledgments.—This work was supported by Public Health Service Grant (C2170(C5)). One of us (S.A.R.) is pleased to acknowledge the award of a Union Carbide and Carbon Fellowship (1953–54) and a Charles A. Coffin Fellowship (1954–55). We are indebted to Dr. N. S. Simmons for two of the DNA samples used in this work and for many helpful discussions.

Polypeptides. XV.[1] Infrared Spectroscopy and the Kinetics of the Synthesis of Polypeptides: Primary Amine Initiated Reactions

BY M. IDELSON AND E. R. BLOUT[2]

RECEIVED MARCH 21, 1957

An infrared spectroscopic method for determining the kinetics of polymerizing systems has been developed. This method has been applied to the determination of the kinetics of the primary amine initiated polymerization of γ-benzyl-L-glutamate-N-carboxyanhydride. Through the infrared kinetic studies it has been shown that the two successive polymerization rate constants k_{2a}(slower) and k_{2b}(faster), are correlated with the formation of low molecular weight (β_L)-polypeptide and high molecular weight (α) polypeptide, respectively. When the polymerization is carried out in dioxane solution the β_L-polypeptide has a degree of polymerization between 3 and 6. Through the use of deuterium labeled hexylamine it has been shown that the β_L-polypeptide is the precursor of the α-polypeptide. This fact and the DP data on the β_L-fractions indicate that the α-helical configuration manifests itself at DP's not much above 6. Measurements on pure α-fractions of primary amine initiated poly-γ-benzyl-L-glutamate show that the DP_w/DP_n is approximately 2 which is indicative of the moderate polydispersity expected for the most probable molecular weight distribution. The infrared kinetic method has the advantage of directly measuring simultaneously both the disappearance of reactant (monomer) and the appearance of product (polypeptide). When different products with different infrared spectra are formed, either simultaneously or consecutively (β_L- and α-polypeptides), their production may be correlated with the reaction rate.

Introduction

Amine initiation has been used for the polymerization of various α-amino acid N-carboxyanhydrides (NCAs) to polypeptides,[3] and the kinetics of the reaction has been treated theoretically[4] as well as investigated experimentally by gasometric methods,[5,6] through which Doty and Lundberg have found that the polymerization exhibits two successive propagation rates. In this paper we describe an infrared spectroscopic technique used to measure the rates of polymerization and present the results of an investigation of amine initiated polymerizations of such anhydrides.[7] Through this infrared method it is shown (1) that there are at least three products of the polymerization reaction, and (2) that the two main products are low molecular weight (β_L) polypeptides which are formed at a slow rate, and higher molecular weight (α) polypeptides, which are formed at a many times faster rate. Finally it is shown that the β_L-polypeptides are precursors of, and are converted into α polypeptides.

We henceforth designate low molecular weight "β" polypeptides as β_L-polymers to differentiate from extended configurations of high molecular weight polypeptides which have also been called β-polypeptides. These latter materials can assume helical configurations under certain conditions and therefore they should be differentiated from the β_L-polymers which cannot assume a helical configuration. We designate the β-forms of high molecular weight polypeptides as β_h-polymers. It is recognized that there may be a molecular weight range of polypeptides having properties overlapping those shown by pure β_L- and β_h-polypeptides.

The method used for determining the kinetics of the polymerization reaction by means of infrared spectroscopy involves determining the consumption of NCA in a polymerizing system. The decrease in the absorbance of the characteristic NCA C=O stretching vibrations at 1860 and 1790 cm.$^{-1}$ is measured as a function of time. Typical spectral data from which such measurements are made are shown in Fig. 1. The solid line (curve A) shows the spectrum of the NCA at the start of the reaction. In addition to the two carbonyl bands due to the NCA moiety, there is an additional C=O absorption frequency at 1735 cm.$^{-1}$ due to the benzyl ester carbonyl group. This band remains unchanged during the reaction and serves as a convenient "internal standard" for the reaction. The dotted line shows the spectrum obtained when approximately 50% of the NCA has been consumed. Of course no change is found in the intensity of the 1735 cm.$^{-1}$ band, but the 1860 cm.$^{-1}$ band has decreased to about 50% of its initial value. In addition, two new bands have appeared, one at 1655 cm.$^{-1}$ and one at 1550 cm.$^{-1}$, which are due to the secondary amide (peptide) groups formed during polymerization. These polymer absorption bands are due, respectively, to C=O stretch (amide I) and NH deformation coupled with C=N stretch (amide II).[8] At the end of the reaction there is no absorption due to the carbonyl bands of the NCA; a typical spectrum for this case is shown by curve C, the dashed line in Fig. 1.

Experimental

Equipment.—All infrared measurements were performed on a Perkin–Elmer Model 21 Double-Beam Spectrometer using a sodium chloride prism. The sample and reference cells were matched pairs with rock salt windows; most experiments were carried out in 0.2 mm. cells at an initial anhydride concentration of 4%. A few experiments were performed in 1 mm. cells with an initial anhydride concentration of 1%. Measurements were made in an air-conditioned room whose temperature was held to ±1°.

The temperature of the polymerizing solution was experimentally determined by means of a thermocouple placed in the cell during a polymerization reaction. The tempera-

ture was 34 ± 1°. The ambient temperature around the absorption cells was maintained at 31 ± 1°.

Because of the effects of small amounts of impurities, especially hydroxide,[9] all glassware was cleaned in chromic acid cleaning solution and rinsed in distilled water until the water was neutral to brom cresol purple indicator.

For the gasometric method the apparatus used for measuring the evolution of carbon dioxide was essentially that described by Doty and Lundberg.[6] The method uses the change in conductivity of a 0.01 *M* barium hydroxide solution as the carbon dioxide is absorbed with the formation of barium carbonate.

Methods.—The Infrared Kinetic Method.—The γ-benzyl-L-glutamate-N-carboxyanhydride,[9] which is stored at −30°, was weighed at −30° into an erlenmeyer flask which was placed in a desiccator and allowed to warm to room temperature. The NCA was then dissolved in a portion of dioxane (or other solvent) and the initiator was thoroughly mixed in a separate flask with the remainder of the dioxane. The anhydride solution was poured into the initiator solution with vigorous swirling. A portion of this solution was transferred to the infrared absorption cell and measurements were begun. Spectra of the polymerizing solution were taken at convenient time intervals through the wave length range 1500 to 1900 cm.$^{-1}$ until the reaction was complete. Pure dioxane was used in the reference cell. The plot of log of absorbancy (or optical density) at 1860 and/or 1790 cm.$^{-1}$ gave the rate curve directly (*cf.*, Fig. 2).

The rate constants derived from anhydride consumption k_{2a} and k_{2b}, were calculated from eq. 1–5.

$$A + I \longrightarrow P + CO_2 \quad (1)$$

$$P + nA \longrightarrow P_{n+1} + nCO_2 \quad (2)$$

$$[P] + \Sigma[P_{n+1}] = [I] \quad (3)$$

$$-\frac{d[A]}{dt} = k[A][I] \quad (4)$$

Equation 1 represents the initiation step which is much faster than the subsequent polymerization reactions indicated by eq. 2. If it is assumed that, during a polymerization which requires a few hours for completion, termination reactions are negligible, eq. 3 is valid; that is the concentration of all the growing chains is constant and the same as the original initiator concentration, [I]. Under these circumstances the rate eq. 4 expresses the change in concentration of NCA, [A], at any time, *t*. The integrated form of this rate equation gives 5, the equation for a pseudo-first-order reaction, where OD represents the optical density of the anhydride absorption bands at 1860 or 1790 cm.$^{-1}$ and is directly proportional to [A]

$$k = \frac{\ln (OD_1/OD_2)}{(t_2 - t_1)[I]} \quad (5)$$

For a comparison of this idealized reaction scheme see the Discussion section and footnote 13.

While polymerization was going on in the sample cell used for the rate measurements it was proceeding also in the remaining large portion of the solution at room temperature. The polymer in this portion of the reaction mixture was isolated the following morning by precipitation into diisopropyl ether. To separate the "α"- and "β"-polymer fractions the following procedure was used. The "β"-polypeptide fraction is the lower molecular weight, more soluble portion of the product. It is soluble in hot ethanol and was separated from the total precipitate by extraction. After removal of the solvent from the ethanol-soluble fraction and drying, its infrared spectrum was determined and found to be that of essentially pure "β_L" material; the ethanol insoluble fraction gave an infrared spectrum characteristic of higher molecular weight "α" polymer.[10,11] The viscosity of the ethanol-insoluble α fraction in dichloroacetic acid was used to determine its molecular weight.[9]

Carbon Dioxide Evolution Kinetic Method.—The anhydride sample was weighed into a reaction vessel at −30° and warmed to room temperature in a desiccator. The dioxane and initiator were added, the vessel was attached

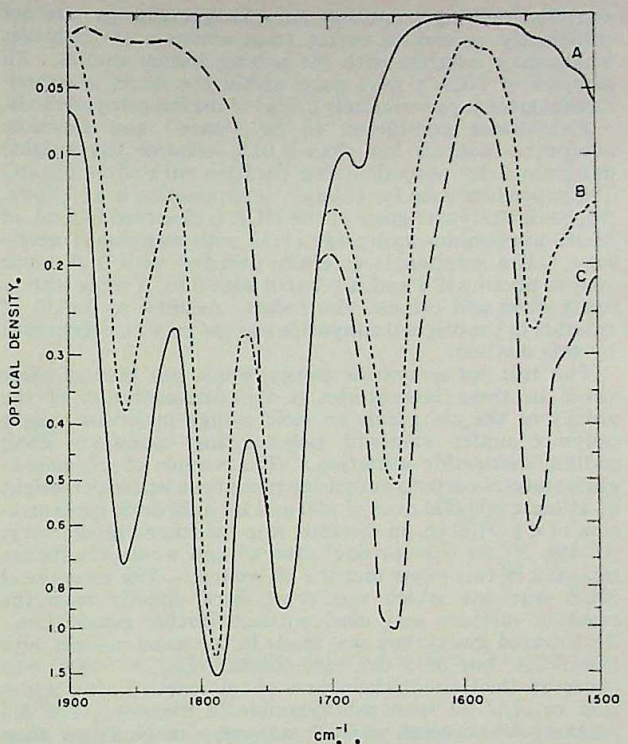

Fig. 1.—Infrared spectra of 4% (by weight) solutions of γ-benzyl-L-glutamate-N-carboxyanhydride in dioxane measured during the polymerization; A/I = 20; initiator, *n*-hexylamine: A———, spectrum at start of reaction; B - - - - -, spectrum at time 50% of NCA consumed; C — — —, spectrum at end of reaction.

to the rest of the apparatus in a thermostated water-bath at 25 ± 0.02° and a stream of purified dry nitrogen saturated at 25° with dioxane was bubbled through the polymerization mixture. The evolved carbon dioxide was carried into and absorbed by a 0.0100 *M* $Ba(OH)_2$ solution in the conductivity cell. The addition of a few drops of *n*-butanol to the $Ba(OH)_2$ solution was essential to disperse the gas for efficient absorption of the carbon dioxide.

The extent of the reaction was calculated from eq. 6 and 7

$$\alpha = WM\left(\frac{R - R_0}{R}\right) \quad (6)$$

$$A = A_0 - \alpha \quad (7)$$

where α was the number of moles of CO_2 evolved; *W* was the weight in grams of $Ba(OH)_2$ solution of molality *M*; R_0 was the initial resistance of the $Ba(OH)_2$ solution and *R* the resistance at time *t*; A_0 was the initial quantity of anhydride in moles and *A* the quantity of anhydride remaining at time *t*. The plot of log A_0/A *vs.* *t* gave the rate curve, and eq. 8 gives the rate constant.

$$k = \frac{\ln \frac{A_0}{A_2} - \ln \frac{A_0}{A_1}}{(t_2 - t_1)[I]} \quad (8)$$

The polymer was isolated as described under the infrared method.

Materials. Anhydrides.—Although most of the work reported in this paper was performed using a single preparation of γ-benzyl-L-glutamate-N-carboxyanhydride (No. MI-I-62C), a number of other anhydride samples, prepared by the same method,[9] also were investigated. At A/I's of 20 and below all anhydrides gave the same values for k_{2a} and k_{2b}. Above A/I 20, however, the polymerization rate k_{2b} was not identical for all preparations, although the k_{2a} was essentially constant from preparation to preparation. Some of the values are shown in Table I. Our experience has been that it is very difficult to prepare two samples of anhydride which behave identically in *all* respects. The usual tests for purity of organic materials, *e.g.*, elementary

analysis, melting point and infrared spectroscopy, are not sufficiently precise to detect trace amounts of impurities which may interfere with the polymerization studies. All samples of NCA's were pure within the limits of experimental error (approximately 0.3%) of the foregoing methods.

Anhydrides considered to be "pure" and therefore acceptable contain less than 0.01% chloride (by weight) determined by potentiometric titration with silver nitrate. The procedure used for chloride determination is as follows. Approximately one gram of the NCA is dissolved in 5 ml. of dilute ammonium hydroxide (1:1) with warming if necessary. The solution is carefully acidified with 6 *N* nitric acid to about *p*H 4 and is titrated with 0.01 *N* silver nitrate using silver and calomel electrodes. As little as 0.01% of chloride in the original anhydride sample may be determined by this method.

The test for anhydride purity which has been of some value in these laboratories is the demonstration of the ability of the anhydride to yield a high molecular weight polymer under standard polymerizing conditions using sodium methoxide initiation.[9] If a sample of γ-benzyl-L-glutamate-N-carboxyanhydride produces a molecular weight of at least 360,000 at *A*/*I* 200 and an anhydride concentration of 4 g./100 cc. in dioxane, it is considered satisfactory. All the NCAs (except one) studied and whose results are reported in this paper met the above test. The exceptional NCA was one which was crystallized directly from the reaction mixture and used without further purification. An infrared kinetic run was made in the usual manner with this NCA, but only one rate constant (k_{2a} = 0.006) was observed throughout the course of the reaction after initiation to *A*/*I* 20 with *n*-hexylamine in dioxane. The β_L-portion of the total product was very much larger than usually observed at this *A*/*I*.[11] With this impure anhydride the β_L-fraction was about 45% of the total product whereas usually it is less than 20% of the product. It was determined subsequently that the NCA used in this experiment had 0.13% by weight (1 mole %) of chloride ion, which was far greater than the amount found (less than 0.01%) in acceptable NCAs.[9]

Initiators.—The *n*-hexylamine was fractionally distilled from calcium hydride; b.p. 131°. It was diluted 1:9 with dioxane and dispensed by means of a Gilmont ultramicroburet (Emil Greiner Co.).

Solvents.—The solvents were purified as previously described.[9] Half of the freshly distilled dioxane froze over a range of 0.25°.

Preparation of Polypeptides from Deuterium Labeled Amine. (a) ***n*-Hexylamine-1d_2.**—5.76 g. of *n*-capronitrile (0.0595 mole) in 10 ml. of anhydrous ether was added dropwise to a solution of 2.50 g. of lithium aluminum deuteride (0.0595 mole) in 50 ml. of ether in a 250-ml. 3-necked flask equipped with a Hershberg stirrer, a dropping funnel with pressure equalizer, and a condenser protected by a soda lime tube. The addition required about ½ hr. and the mixture was stirred for an additional ten minutes. It was then hydrolyzed very carefully with the minimum amount of water to destroy excess deuteride and the complex; a few grams of anhydrous magnesium sulfate was added to dry the mixture which was filtered with suction; the solids were thoroughly washed several times with anhydrous ether. The combined ether solutions were carefully distilled through a 10-cm. Vigreux column; the *n*-hexylamine-1-d_2 fraction boiling at 130–131° was collected and weighed 3.36 g. (55%); $n^{25}D$ 1.4210; for 100% 1-d_2 % D calcd., 13.3; % D found, 11.8.

(b) **Deuterium Labeled Polypeptides.**—10.2 g. of γ-benzyl-L-glutamate-N-carboxyanhydride was dissolved in 250 ml. of dioxane and 1.0 g. of *n*-hexylamine-1-d_2 (*A*/*I* = 4) was added. When the polymerization was complete, the dioxane was removed by freeze drying. Extraction of the product in a Soxhlet with ethyl ether gave β_L-polymer which was not soluble in cold ethyl ether and "γ"-polymer which remained in solution at 0°. The β_L-polymer was filtered and washed with ethyl ether, redissolved in dioxane, and freeze dried (1.0 g.). The infrared spectrum of this material (product A) showed it to be pure β_L-polymer.

The fraction of the original polymer which was insoluble in ethyl ether was dried at room temperature and then extracted with ethanol. The cooled ethanol solution yielded an additional β_L-fraction which was contaminated with some α-polymer, while the ethanol insoluble portion was shown to be pure α-polymer (product B).

End group (free amino) titration of the γ-polymer and ether extracted β_L-polymer (product A) indicated a degree of polymerization (DP) of 4 and 5.9, respectively. These values are equal to or higher than the actual DP, since any cyclization to substituted α-pyrrolidone[12] would increase the DP measured by titration as compared to the actual DP. The molecular weights of these materials were measured by the Archibald method[10,13]; γ-fraction, mol. wt. = 400, DP (subtracting 1 molecule hexylamine) = 1.4; β_L-fraction, mol.wt. = 800, DP_w = 3.2 (product A).

(c) **Initiation with D-Labeled β_L-Polymer.**—0.265 g. of above β_L-polymer (A) was dissolved in 25 ml. of dioxane and 1.00 g. of anhydride was added (*A*/*I* = 20, or theoretical DP = 26). After completion of the reaction the dioxane was lyophilized, and the product was extracted with ethanol. The ethanol extract contained 0.261 g. of β_L-polymer (product C) while the residue was α polymer contaminated with some β_L-polymer. The remaining β_L-polymer in the α-polymer was removed by formic acid extraction[11] and weighed 0.149 g. (product C′). This polymer (product C′) is insoluble in hot ethanol and is higher molecular weight than product C; it therefore contains less deuterium than product C. The formic acid insoluble portion was pure α polymer and weighed 0.688 g. (product D). The results of these experiments are given in Table III.

Determination of Free Amino Groups in Polymers.—The terminal amino groups were titrated with perchloric acid in glacial acetic acid using crystal violet as indicator. 0.0583 g. of product A (β_L-polymer) was dissolved in 5 ml. of glacial acetic acid containing a drop of crystal violet indicator solution (0.1% in glacial acetic acid). Using a Gilmont ultramicroburet, this titration required 0.5055 ml. of 0.081 *N* perchloric acid to reach the green end-point of the indicator. The indicator blank was negligible. Found free amino groups in polymer product *A* = 7.16 $\times 10^{-4}$ meq./mg.

Molecular Weight Determinations.—The reduced specific viscosities of poly-γ-benzyl-L-glutamates in dichloroacetic acid solution were used to obtain the molecular weights in a manner previously described.[9,16] This method of obtaining molecular weights is sufficiently accurate (±10%) for molecular weights above 20,000, *i.e.*, degree of polymerization (DP) >90. It was therefore used for the total reaction products or for the α-polypeptide fraction. The α-polypeptide fractions of *n*-hexylamine initiated polymerizations of γ-benzyl-L-glutamate-N-carboxyanhydride at *A*/*I*'s of 10, 20, 40 and 80 were separated from the β_L-fraction as described above. In each case the α fraction had a weight average DP between 100 and 300 which appeared to be essentially independent of *A*/*I* over the range *A*/*I* 10 to 80. However, as the *A*/*I* was increased, the amount of α fraction increased (*cf.*, ref. 9).

Results

It has been shown previously[10,11] that initiation of γ-benzyl-L-glutamate anhydride with primary amine yields two products, the first a low molecular weight peptide, which is soluble in formic acid and designated β_L-polymer; the second a higher molecular weight polypeptide which is insoluble in formic acid and has been designated α-polymer. The α-material shows a strong C=O amide I absorption at 1655 cm.$^{-1}$, both in solution and in the solid state, whereas the β_L-material shows an amide I frequency at 1630 cm.$^{-1}$ in the solid state and around 1675 cm.$^{-1}$ in dilute dioxane solution. It is this background information that is used in the interpretation of the following results.

Infrared Data.—In the present investigation *n*-hexylamine initiated polymerizations of γ-benzyl-L-glutamate anhydride were performed in dioxane solution of *A*/*I*'s of 4, 10, 20 and 40. Plots

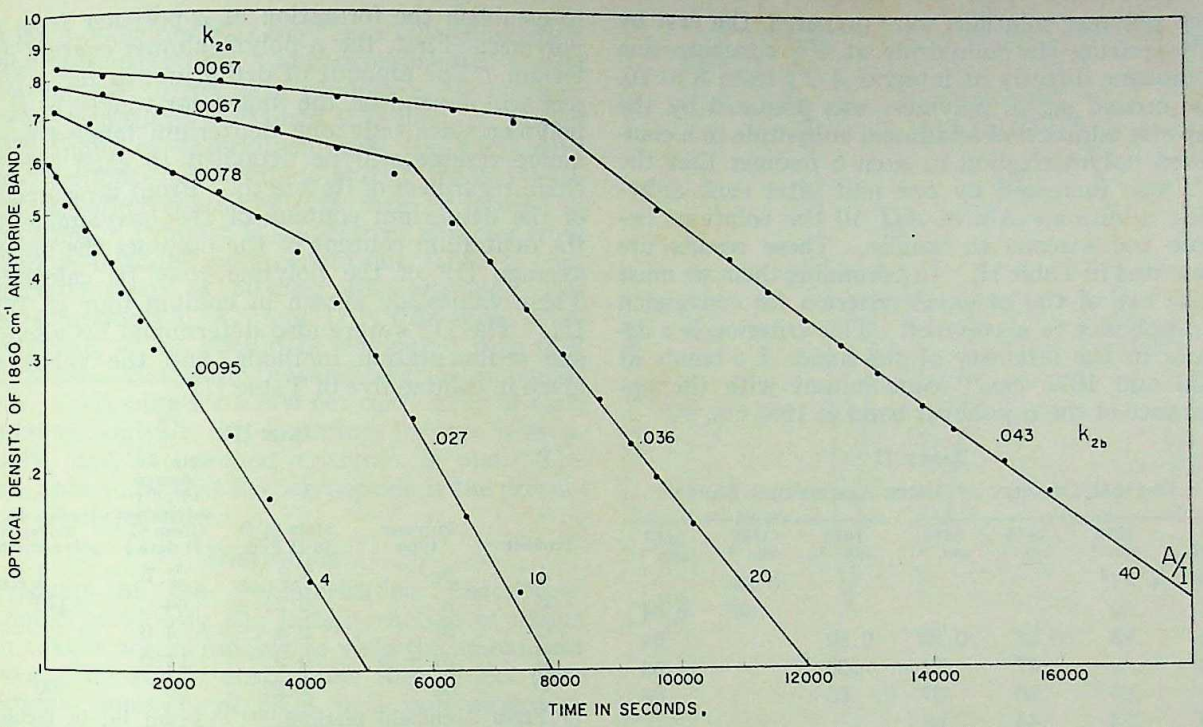

Fig. 2.—Plots of optical density of 1860 cm.$^{-1}$ NCA C=O band measured as a function of time during *n*-hexylamine initiated polymerizations of γ-benzyl-L-glutamate-N-carboxyanhydride at A/I 4, 10, 20 and 40. The initial rate constants, k_{2a}, are shown below the symbol. The final rates, k_{2b}, are shown in a horizontal line with the symbol.

of the rate of disappearance of anhydride as a function of time for these A/I's are shown in Fig. 2.

The reaction rate may be determined by following either the monomer (NCA) concentration or the peptide (polymer) concentration. If the rate is calculated from the appearance of polymer, the optical density must be measured at the end of the reaction, and this value appears in the calculation of every point on the rate curve. This measurement, therefore, requires the greatest accuracy in precisely the region where optical density measurements are least accurate—the region of high densities. However, by following the monomer (NCA) concentration, there is no single measurement upon which all the calculations depend. Further, the measurement of OD_∞ (the zero line) is not necessary for the monomer band method because its value disappears in the calculation of the rate equation. From these data rate constants have been calculated[15] as shown in Table I.

Table I

[a] Measurements using infrared method were at 34 ± 1°. [b] Measurements using CO_2 method were at 25 ± 0.02°.

Katchalski, *et al.*,[4] have discussed theoretically the successive stages in the polymerization of NCA's—initiation (k_1), polymerization (k_2), and termination (k_3 and k_4). The *n*-hexylamine first reacts very rapidly with the anhydride at a rate designated k_1. This reaction was not measured, but it is about one order of magnitude faster than the polymerization reactions. For this reason we may assume that the reaction of anhydride with hexylamine is instantaneous and therefore denote the k_{2a} reaction as the first reaction. At A/I 4 the anhydride disappears at a constant rate, whereas at A/I's of 10 and above the rate of disappearance of anhydride is slow at the beginning (k_{2a}) but later increases several-fold (k_{2b}). Thus successive reactions proceeding at two different rates occur during the course of this polymerization as first demonstrated by Doty and Lundberg by using a gasometric method.[6] If, however, one examines the spectral data from which the plots in Fig. 2 were obtained, it is observed that when the anhydride is being consumed at a low rate (at A/I 4, or k_{2a} in A/I's 10, 20 and 40), the polymer that is formed shows amide I absorption at 1675 cm.$^{-1}$. The 1630 cm.$^{-1}$ band is not seen at A/I's of 10 and above since the concentration of β_L-polymer in the solution is too low.[11] On the other hand, when the reaction proceeds at the faster rate, k_{2b}, α-polymer is formed, as shown by the appearance and increasing intensity of the 1655 cm.$^{-1}$ (amide I) and 1550 cm.$^{-1}$ (amide II) absorption bands. It is now logical to inquire whether the low molecular weight β_L-material is the precursor of the high molecular weight α-polymer.

An attempt was made to answer this question by noting whether, in a series of polymerizations at A/I's from 3 to 10, the total amount of β_L-polymer, as indicated by infrared spectra of the solutions, decreased with increasing A/I. Two sets of

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

such polymer solutions were prepared, the first by polymerizing the anhydride at 4% concentration in dioxane directly at integral A/I's from 3 to 10. The second set of polymers was prepared by the stepwise addition of additional anhydride to a completed polymerization in such a manner that the A/I was increased by one unit after each anhydride addition. Above A/I 10 the solutions became too viscous to handle. These results are presented in Table II. In examining them we must make use of the assumed criterion for conversion of β-polymer to α-polymer. This criterion is a *decrease* in the intensity of the amide I β-bands at 1630 and 1675 cm.$^{-1}$ concomitant with the appearance of the α-polymer band at 1655 cm.$^{-1}$.

[a] A/I by successive integral additions of NCA. [b] A/I by direct initiation of NCA. [c] Shoulder. [d] All optical density values are adjusted to a constant benzyl ester band at 1735 cm.$^{-1}$ of 0.60 optical density.

The data in Table II show that the absorption of the 1630 cm.$^{-1}$ band reaches a maximum at A/I 7 and does not thereafter decrease within experimental error. The 1675 cm.$^{-1}$ band, however, shows a uniform decrease in its intensity as the A/I is increased. It has been shown previously that dilute solutions of β_L-polypeptides absorb at 1675 cm.$^{-1}$, while concentrated solutions or solid films absorb at 1630 cm.$^{-1}$.[11] From results reported here it may be seen that at A/I 3 the amide I band is located at 1675 cm.$^{-1}$ and is very intense (Fig. 3). At A/I 4 this absorption is weaker (Table III) and continues to decrease in intensity as the A/I increases. The 1630 cm.$^{-1}$ appears for the first time in solution at A/I 5 and increases to a constant maximum value at A/I 6–7. The 1655 cm.$^{-1}$ (α-amide I band) also appears at A/I 5 and continues to increase with increasing A/I. Because there is no significant decrease in the amount of β_L-polymer, these data, unfortunately, neither demonstrate nor exclude the conversion of β_L-polymer to α-polymer.

Deuterium Labeled Polypeptides.—To establish β_L-polypeptide is the precursor of the α-polymer, β_L-polymer labeled with deuterium in the *n*-hexylamine initiator was prepared (see Experimental section). The pure deuterium labeled β_L-polymer was used to initiate additional anhydride at A/I 20. Two criteria have to be satisfied to establish the formation of α-polymer from β_L-polymer. First, the α-polymer must contain deuterium. The amount of deuterium in the α-polymer will depend on the molecular weight of the α polymer since only one deuterium labeled hexylamine residue will be attached to each polymer chain regardless of its length. From measurement of the deuterium content of the hexylamine and the deuterium content of the polymer the number average DP of the polymer may be calculated. These values are shown in column four of Table III. The DP's were also determined by viscosity and sedimentation methods, and the values are given in column five of Table III.

TABLE III

Product	Polymer type	Mole % D in H Fed.	No. av. degree of polymerization (from % D detn.)	Wt. av. degree of polymerization

D	α	0.22	60	100[b]

[a] From Archibald method.[13,14] [b] From $[\eta]$ in dichloroacetic acid.[15,16]

The weight average DPs are seen to be consistently higher than the number average DPs and the ratio DP_w/DP_n, indicative of the polydispersity of the polymer, is approximately 2 for the pure α-fractions. This is the value expected for the most probable distribution of molecular weights and is the minimum value that could be expected in this situation. It may therefore be concluded that the DP_n, derived from deuterium determination, is not in disagreement with DP_w derived from viscosity measurements; hence the first criterion for the growth of β_L-polymer into α-polymer is established.

The second criterion for the growth of β_L to α-polymers is that there must be a deuterium balance in the experiments. More exactly, the deuterium content of the deuterium labeled β_L-polymer used for the initiator should equal the sum of the deuterium contents in the newly formed α-polymer

(14) We are indebted to Dr. P. Doty and Mr. J. C. Mitchell for these measurements.

(15) The equation for the calculation of k_{2b} is not strictly correct. At least three reactions must be proceeding simultaneously during this portion of the reaction. Since it has been shown the β_L-polypeptide is the precursor of α polymer (*vide infra*), and since the β_L-concentration appears to reach a constant maximum, an equilibrium must exist between production of new (or longer) β_L-polymer and the loss of β_L-polymer in forming α polymer chains.

Further, the rate of conversion of β_L-chains to rapidly polymerizing α-chains must be in equilibrium with some chain termination process (or processes).[4] During the faster portion of the reaction there are occurring simultaneously (a) slow production of β_L-polymers, (b) rapid growth of α-polymer, and (c) termination processes. β_L-polymerization and termination are neglected, both of which consume NCA; it is not the initiator (*n*-hexylamine) concentration, but rather the *growing* α-chain concentration which must appear in the calculation of k_2b (eq. 1 and 4). Although the final concentration of α-chains may be determined from molecular weight measurement after the reaction is completed, this does not reveal what the actual concentration of growing chains is at any instant during the polymerization. The values of k_{2b} in Table I are, therefore, less than the minimum possible value of the actual rate constant.

and the β_L-polymer that remains at the completion of the polymerization. The experimental results are as follows: 0.265 g. of product A (β_L-polymer used for initiation) contained 0.38 meq. of labeled *n*-hexylamine as determined from the 3.8% deuterium content. Products C and C′ totaled 0.410 g. and together contained 0.29 meq. of labeled *n*-hexylamine. Product D (α-polymer obtained from labeled β_L-initiated polymerization), 0.688 g. contains 0.05 meq. of labeled *n*-hexylamine. The sum of products C, C′ and D is 0.34 meq. of *n*-hexylamine, which should be compared with 0.38 meq. of *n*-hexylamine in the initiating polymer product A. Allowing for a few per cent. error in each deuterium analysis, the deuterium balance is satisfactory, and the second criterion is met. The above data show that β_L-polypeptide is the precursor of α-polypeptide.

Discussion

Products of the Polymerization Reaction.—As noted previously the initial reaction of amine with a NCA occurs quickly to yield the amino acid amide. The amino acid amide then reacts with additional amounts of NCA in a polymerization reaction, and it is the products and rates of this reaction that have been investigated.

γ-Peptides.—This material has not been isolated as a pure compound but from molecular weight, spectroscopic, solubility and kinetic data, and from the method of its preparation it is apparent that γ-peptide has the properties of a DP 1 to 3 polymer. The titrations have been described in the Experimental section. The Archibald method for the determination of the molecular weight gave a value of approximately 400 for γ-peptide from *n*-hexylamine and γ-benzyl-L-glutamate NCA. The spectroscopic evidence includes: (a) only 1675 cm.$^{-1}$ amide I absorption is observed in solution; (b) the amide I absorption in the solid phase lies at a different frequency (1640 cm.$^{-1}$) from that observed with β-peptide (1630 cm.$^{-1}$); (c) the 1675 cm.$^{-1}$ band decreases with increasing A/I indicating conversion of the γ-peptide to another product. When isolated γ-peptide is used to initiate further polymerization, both the β-rate (k_{2a}) and the α rate (k_{2b}) are observed. Finally, γ-polymer is over 90% of the product of A/I 3 polymerizations. All these observations lead to the conclusion that the γ-peptide is a precursor of the α- and β-peptides, and is thus consistent with the γ-peptide being a DP 1 to 3 polymer.

β_L-Peptides.—β_L-Polypeptides have a DP between 3 and 6. The evidence for this is as follows: (1) The infrared spectroscopic properties of β_L-peptides of poly-γ-benzyl-L-glutamate have been described,[11] and are consistent with a low molecular weight non-intramolecularly hydrogen bonded amide. From the present work there is no spectroscopic evidence of β_L-polymer being formed at A/I's less than 3. The product from the A/I 3 reaction shows no 1630 cm.$^{-1}$ (β-amide I) band in solid state measurements. However, from A/I's 4 through 20 β_L-polypeptide is formed as indicated by the presence of the 1630 cm.$^{-1}$ band in solid state measurements. (2) The end group titrations of isolated β_L-polypeptide fractions, from which

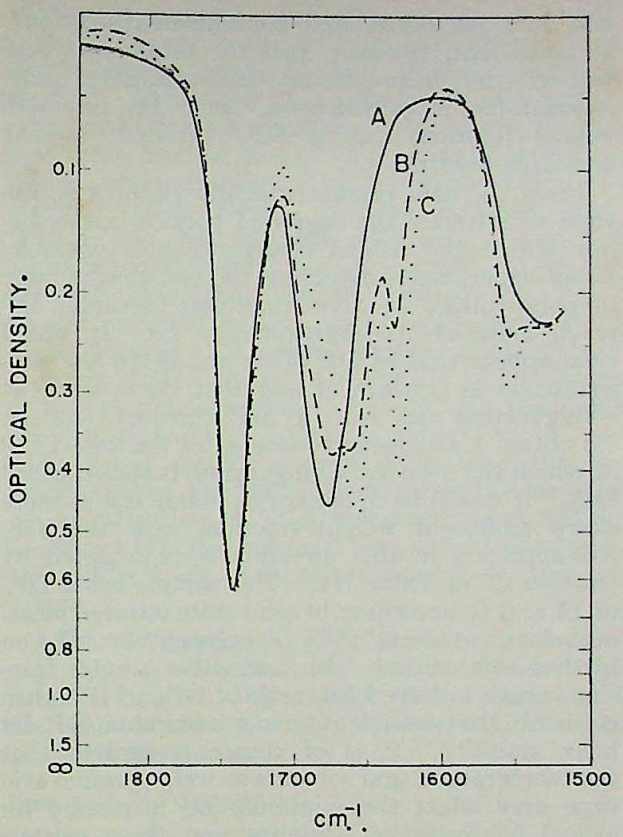

Fig. 3.—Infrared spectra of dioxane solutions at the end of polymerizations of 4% (by weight) of γ-benzyl-L-glutamate-N-carboxyanhydride initiated by *n*-hexylamine: A ———, A/I 3; B — — —, A/I 5 (obtained by addition of NCA to A/I 3 solution); C - - - -, A/I 8 (obtained by addition of NCA to A/I 5 solution). (Note: 1675 cm.$^{-1}$ (γ- and β_L-solution) band in curves A and B. The concentrated solution β_L band at 1630 cm.$^{-1}$ is seen in curves B and C as well as the α band at 1655 cm.$^{-1}$.)

both γ- and α-polymers have been removed, indicated that the DP is not higher than 6. (3) The deuterium experiments indicate the isolated β_L-product has a DP between 3 and 5. (4) Elementary analyses of the isolated β_L product indicate that its DP lies in the range 4 to 6. (5) A measurement of the molecular weight of β_L-polymer by the Archibald method[13] gave a value of 800 or a DP between 3 and 4.[14] (6) Finally, β_L-polymer shows lower solubility in organic solvents than does γ-polymer but greater solubility than α-polymer. When the above facts are considered, it is clear that there is strong evidence for β_L polymer having a DP between 3 and 6.

α-Peptides.—This material is the high molecular weight, least soluble fraction of primary amine initiated polymerizations at A/I's > 4. It is also the exclusive product of strong base initiated polymerizations[9] and has been shown to exist as the α-helix of Pauling and Corey[17] in both the solid state and in most solvents. All samples of unfractionated α-polypeptide isolated from amine initiated polymerizations in dioxane had weight average DP's between 100 and 300 and have the characteristic α-amide I band in the solid state

and in both dilute and concentrated solution.[11] It is evident, however, that the total α-polypeptide fraction from primary amine initiated polymerizations is polydisperse, since (as discussed below) fractions having DP_n's around 15 have been isolated from it.

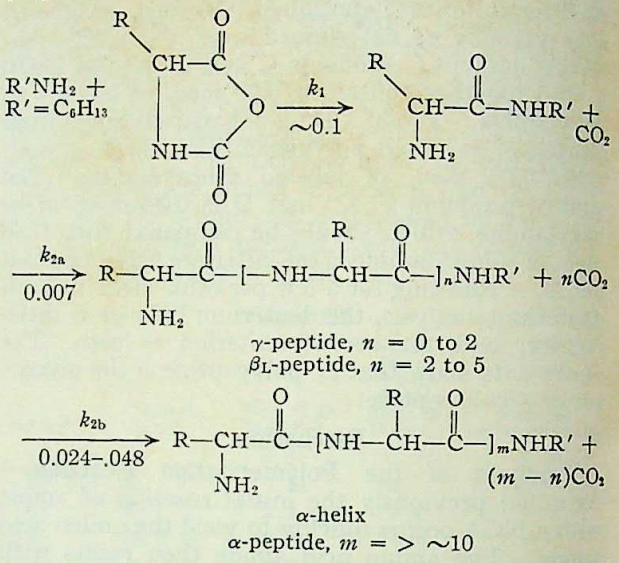
From the data presented in this paper it is possible to estimate the degree of polymerization below which the helical configuration is unstable. From experiments involving the isolation of pure β_L-polypeptides we have found that maximum DP of β_L-materials is approximately six. It would thus appear that at DP of six and below the configuration is non-helical and that the helical (α) configuration may exist at DP's greater than six. To obtain a satisfactory measure of the lowest DP at which the α-helical configuration is stable, called DP_c,[10] it would be necessary to isolate one or more sharp molecular weight fractions near this DP. An approach in this direction is represented by fraction C′ in Table III. This sample has a DP_n of 14 and is, according to solid state infrared measurements, at least 90% α-polypeptide. If, on further examination, this and other similar fractions prove to have a low ratio of DP_w to DP_n then it should be possible to fix a minimum DP for helix stability. It is of course recognized that the temperature, and solvents as well as amino acid type may affect the minimum *DP* necessary for helical configuration stability and these matters are being investigated. At present, however, it is clear that a DP of more than 6 is necessary to produce a helical configuration in poly-γ-benzyl-L-glutamate.

Polymerization Rates and the Reaction Sequence.—It has been shown previously[6] and in this study that the primary amine initiated polymerization of NCA's in dioxane solution show two successive rates of polymerization, the second rate, k_{2b}, being at least several times the primary polymerization rate, k_{2a}. Through the infrared kinetic studies reported here, it has been shown that k_{2a} is associated with production of low DP polymer (γ and β_L), and the k_{2b} rate occurs when higher DP polymer, (α) is being formed. Since γ-polymer yields both β- and α-polymer, it is apparent that γ-polymer is the precursor of β- and α-polymer.

As may be seen from Table I, the results obtained from the two kinetic methods are essentially in complete agreement. The difference observed in k_{2a} is due to the temperature at which the two series of experiments were performed, 25° for the carbon dioxide evolution experiments and 34° for the infrared experiments.

Although there is apparent agreement between the values of k_{2b} determined at different temperatures by both methods, this agreement may be fortuitous; the rates of the initiation, propagation and termination reactions may vary with temperature in such a manner that the observed over-all rate of reaction is coincidentally the same at both 25 and 34°, or the activation energy may be small.

The question whether β-polypeptide is the precursor of α-polypeptide, and is thus converted to α-polypeptide, was answered affirmatively by the experiments using deuterium labeled amine (*vide supra*). Thus it is clear that the reaction sequence from the *n*-hexylamine initiated polymerization of NCA's may be formulated as



The infrared kinetic studies show that α-polypeptide is formed at a rate (k_{2b}) several times that observed for β_L-peptide formation. This fact permits two conclusions: Either (1) the rate of addition of anhydride to a growing α-helix is greater because the growing chain end is relatively accessible to additional anhydride as compared with the β_L (non-helical) form or (2) the α-helix configuration is more sterically favorable for further anhydride addition. In any case, the rate of anhydride addition and polymer growth is very much greater when the growing chain has a helical configuration as compared to a non-helical configuration. Although other factors may influence the absolute rate of anhydride addition, there can be no doubt of the effect of the configuration of the growing chain.

Advantages and Limitations of the Infrared Method.—The infrared technique for determining the rates of polymerization reactions as described above has proved valuable but has certain restrictions which may limit its general applicability. First, the monomer should have at least one strong absorption band in a region free of solvent and product absorption. Secondly, the solvent must dissolve both monomer and polymer in reasonable concentration—*i.e.*, approximately 1% or greater. This latter condition is true for most kinetic work, but is especially important in the infrared method because low solubility entails long solvent path lengths with resultant decrease in the precision of measurement of absorption. Thirdly, a practical consideration is that the polymeric reaction products are often difficult to remove completely from the thin infrared cells. This necessitates repolishing the inner faces of the cell at frequent intervals. If the cell is not thoroughly clean, any residual polymer may influence the rate of a reaction performed in the cell. Finally, for accurate kinetic work, better temperature control, possibly by thermostated cells,[18] should be used. It is re-

(18) N. R. Trenner, R. Arison and R. W. Walker, *Applied Spect.*, **7**, 166 (1953).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

markable, considering the temperature was only controlled to ±1° in the present work, that the results are satisfactorily reproducible.

Despite its limitations, the infrared technique gives information which is not available from any other kinetic method. The first advantage of the infrared method is that it allows the simultaneous determination of the monomer and polymer concentrations throughout the reaction, and thus the determination of *both* the rate of disappearance of monomer and the rate of appearance of polymer. By following the disappearance of monomer, it is not necessary to carry the reaction to completion in order to determine the rate as is necessary in the polymer determination of rate. In the particular type of polymerization discussed in this paper, involving N-carboxyanhydrides, the monomers have two carbonyl absorption bands of different intensities. At the monomer concentrations and cell thicknesses used, the disappearance of the less intense band at 1860 cm.$^{-1}$ was followed for the first 80% of the reaction, while the more intense band at 1790 cm.$^{-1}$ was followed for the last 20% of the reaction. This fortunate circumstance allows the accurate determination of the rate of monomer disappearance up to at least 90% anhydride consumption.

The most important advantage of the infrared method is that during the polymerization it is possible to distinguish qualitatively, quantitatively and simultaneously two or more reaction products (if the various products have different infrared spectra). This allows the correlation of reaction rates with reaction products. For example, the gasometric method showed that primary amine initiated polymerizations of NCA's involved two different reaction rates; previous infrared work showed that two different polymers (α and β_L) could be isolated from such reactions. Using the presently described infrared method for determining reaction rates, correlations have been made between the initial slower reaction rate (k_{2a}) and the formation of the low DP (β_L) polymer as well as the later faster reaction rate (k_{2b}) and the formation of high DP (α) polymer.

Finally, it should be noted that, since this infrared method has been applied advantageously to the investigation of NCA polymerizations, within the above specified scope, it also should have general utility in the study of the kinetics of other reactions.

Acknowledgment.—We are pleased to acknowledge the support of this work by the Office of the Surgeon General, Department of the Army, and the valuable assistance of Miss Evelyn DesRoches in the kinetic studies.

Polypeptides. XVI. The Polydispersity and Configuration of Low Molecular Weight Poly-γ-benzyl-L-glutamates[1]

BY J. C. MITCHELL, A. E. WOODWARD AND PAUL DOTY

RECEIVED MARCH 21, 1957

Titrations of amine and carboxyl groups in samples of poly-γ-benzyl-L-glutamate prepared by primary amine initiation show that (1) amine groups are nearly preserved throughout the polymerization but are easily lost during polymer isolation and storage, presumably by end group cyclization with the elimination of benzyl alcohol and (2) carboxyl groups are present to the extent of about one per three hundred residues regardless of the molecular weight of the sample. From this value it can be concluded that the Sela and Berger termination step will have a negligible broadening effect on the molecular weight distributions of these low molecular weight polypeptides. In order to estimate the molecular weight distributions the weight average molecular weights of a number of samples in the range of 1000 to 20,000 molecular weight were determined in the ultracentrifuge by means of the Archibald approach-to-equilibrium method. The results show pronounced deviations from the intrinsic viscosity–molecular weight relation established for higher molecular weight samples. The ratios of the weight to number average degrees of polymerization are found to be extraordinarily large[3-11] and suggest striking anomalies in polymerization. It is not surprising, therefore, to find that the samples can be separated into two fractions of widely different molecular weights and having different configurations (α and β) by a variety of means: solvent extraction, paper chromatography and dialysis. The minimum degree of polymerization required for stability of the α-helical configuration in dioxane and dimethylformamide solution is found to be approximately 10.

Early in 1955 end group determinations and intrinsic viscosity measurements on numerous low molecular weight samples of poly-γ-benzyl-L-glutamates clearly suggested that the molecular weight distributions in samples prepared by hexylamine initiation were extremely broad in contrast to the very narrow Poisson distribution generally expected. A rigorous and quantitative proof of this result required, however, the correlation of intrinsic viscosity measurements with weight average molecular weights in the region below 20,000. Since this correlation has only now been achieved, by use of the Archibald approach-to-equilibrium technique in ultracentrifugation, the publication of these results has been delayed. In the interim, however, knowledge of these results and corresponding infrared investigations[2] have motivated kinetic studies of the polymerization in a search for the origin of the observed polydispersity. A preliminary report of the findings has been made[3] and the full reports[4] are being published concurrently with this one.

Another reason for pursuing the absolute es-

tablishment of molecular weights in this relatively low molecular weight region lies in the desire to determine the critical length of the polypeptide chain required for the α-helical configuration to become the stable configuration. Of course this critical degree of polymerization will depend on the nature of the polypeptide residues and on the solvent. The results presented here identify fairly well this critical chain length in two solvents and, in conjunction with infrared spectra,[2,4b] in the solid state as well.

Following a presentation of experimental details this report takes up the titration of amine and carboxyl groups of poly-γ-benzyl-L-glutamates and the relation these bear to number average molecular weights. The calibration of intrinsic viscosity in dichloroacetic acid solutions against weight average molecular weight is considered next. This then permits an assessment of the magnitude of the polydispersity in the samples. In the final section the problem of helix stability and molecular weight is examined.

Experimental Details

Reagents.—Dimethylformamide and dichloroacetic acid were purified as described elsewhere.[4a] Phenol (Analytical Reagent Grade) was purified according to the method of Waltz and Taylor.[5] Phenol solutions were prepared by dissolving 83 g. of purified phenol in 17 g. of absolute ethanol and stored in the dark.

Sodium methoxide solution was prepared by dissolving 1.0 g. in 1800 ml. of methanol (Reagent Grade) and also stored in the dark. Standardization was made against potassium acid phthalate.

Perchloric acid solutions were made by mixing 2 ml. of 70% perchloric acid (Analytical Reagent Grade) with two liters of methanol. Standardization was carried out conductometrically, as described below, against standard sodium methoxide solution in a mixture of 45 ml. of phenol, 8 ml. of absolute ethanol and 8 ml. of distilled water.

Polypeptides.—Titration studies were made on a number of poly-γ-benzyl-L-glutamate samples prepared by Blout and Karlson[1,6] but only three of these are reported on in detail here. These three samples (no. 862, 834 and 863) were made in dioxane solution by hexylamine initiation using anhydride–initiator mole ratios ([A]/[I]) of 4.0, 8.0 and 20.0, respectively. After the polymerization was 99% complete the product was precipitated by pouring into 20 volumes of diisopropyl ether and dried at 50° *in vacuo*. More recently, three other polypeptides made in dioxane solution in this [A]/[I] range became available for viscosity and molecular weight measurements. Two of these (no. 428 L of [A]/[I] = 4.0 and RL-V202 of [A]/[I] = 20.0) were prepared by R. D. Lundberg and the other (no. 384-10 at [A]/[I] = 10) by M. Idelson and E. R. Blout.[4b]

The samples used in the viscosity–molecular weight study had to be of relatively narrow molecular weight distribution. Consequently fractions and samples prepared in dimethylformamide solution were employed. Details concerning these will be given later.

Titration.—In order to estimate all the groups present, both acid and base titrations were performed. The sample weight was chosen so as to require from 1 to 5 ml. of titrant: this was delivered from 5-ml. micro-burets.

Titrations with 0.01 *N* perchloric acid were carried out conductometrically in the solvent system phenol–ethanol–water[5] with sodium chloride being added, when necessary, to increase the starting conductivity to a measurable value. A dipping type conductivity cell with a constant, *K*, of 1.00 was used. Two conductivity bridges (Industrial Instruments) were employed; one was a Model RC with a maximum reading of 2.5×10^5 ohms, the other a Model RC 16 B with a maximum of 2.5×10^6 ohms.

The polymer samples were dissolved in a given amount of phenol solution in ethanol and then equivalent volumes of ethanol and water were added. The amount of each solvent used depended on how much ethanol and water the polymer would tolerate prior to precipitation while the total volume was kept within about 70 ml.

To check the method, known amounts of *n*-hexylamine and glycylglycine were titrated in 35 ml. of phenol solution, 15 ml. of ethanol and 15 ml. of water. The agreement was found to lie within ±4%. Duplicate titrations of poly-γ-benzyl-L-glutamates were found to agree within ±3% for a polymer of $\overline{DP}_n$ equal to 19 and ± 8% for one with a $\overline{DP}_n$ of 226.

Titrations with 0.01 *N* sodium methoxide were carried out in 25 ml. of chloroform and 10 ml. of absolute ethanol with 0.1% phenolphthalein in ethanol as indicator: the titer of the solvent alone was subtracted from the sample titer. To compare the method with an aqueous titration, an acetic acid solution was titrated in both the chloroform–ethanol system and distilled water; the values obtained agree within 1%. As a further check a low molecular weight polypeptide was titrated in (1) chloroform–ethanol, (2) potentiometrically in 20% water–80% dioxane (volume/volume), (3) in dioxane–water–formaldehyde solution and (4) in benzyl alcohol with phenolphthalein as indicator. The average value of these titrations varied from ±2% for a low molecular weight polymer to ±5% for one of $\overline{DP}_n = 550$.

Viscosity Measurements.—All viscosity measurements were made at 25° with a modified Ubbelohde type capillary viscometer using dichloroacetic acid as the solvent. The solutions were clarified by passing them through a medium sintered glass filter.

Ultracentrifuge Measurements.—Weight average molecular weights were determined by the Archibald[7] approach-to-sedimentation-equilibrium method following the procedure given by Klainer and Kegeles.[8,9] The essential feature of this method is that the vanishing of the flux of solute across the two cell boundaries, meniscus and bottom, allows the application at these planes of the equation for sedimentation equilibrium

$$(\bar{M}_w)_{app} = \frac{RT}{(1 - \bar{v}\rho)\omega^2}\left[\frac{dc/dx}{xc}\right]_m$$

in which $(\bar{M}_w)_{app}$. is the apparent weight average molecular weight (differing from the true weight average molecular weight by a correction for the non-ideality of the solution), R the gas constant, T the absolute temperature, $\bar{v}$ the partial specific volume of the solute, ρ the density of the solution, ω the angular velocity, c the solute concentration and x the radial distance from the center of rotation. The subscript "m" on the square bracket indicates that the enclosed ratio is evaluated at the air-liquid meniscus.

The measurements were made with a Spinco model E ultracentrifuge equipped with a phase-contrast schlieren diaphragm. A 2-degree centerpiece modified to form synthetic boundaries between solvent and solution according to the suggestion of Kegeles[10] was used in the determination of the concentration at the meniscus.

The angle of the schlieren diaphragm was maintained at 80° in all measurements. Photographs of the schlieren patterns were made on Kodak type II-O and III-O spectroscopic plates through a Wratten #34 A filter and were read using a modified toolmaker's microscope equipped with a projection head[11] as a two-dimensional microcomparator.

The vertical comparator readings were corrected for solvent gradient in the following manner. It was observed that at several speeds the solvent gave only a horizontal schlieren line except for a slight downward curvature, possibly due to diffraction effects, within 0.03 mm. of the meniscus. Thus the average comparator reading of the horizontal (plateau) region in a solution photograph was subtracted from the readings in the curved region, with an appropriate correction for the solvent curvature in the immediate vicinity of the meniscus.

The partial specific volume of poly-γ-benzyl-L-glutamate in dimethylformamide was found to be 0.791 ± 0.006.

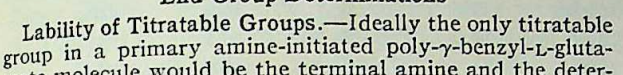
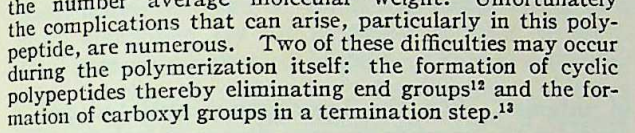
The measurement was made at 25° in a special pycnometer consisting of a volumetric flask with its neck replaced by part of a 0.1-ml. capillary-bore volumetric pipet.

End Group Determinations

Lability of Titratable Groups.—Ideally the only titratable group in a primary amine-initiated poly-γ-benzyl-L-glutamate molecule would be the terminal amine and the determination of amine groups would therefore lead directly to the number average molecular weight. Unfortunately the complications that can arise, particularly in this polypeptide, are numerous. Two of these difficulties may occur during the polymerization itself: the formation of cyclic polypeptides thereby eliminating end groups[12] and the formation of carboxyl groups in a termination step.[13]



After the polypeptide has been formed, two other reactions may occur that would alter the number of titratable groups. These are (1) the loss of amine groups by end group cyclization to form substituted pyrrolidone rings[14] as shown



and (2) the production of carboxyl groups by debenzylation.

Titration of amine groups in reaction mixtures showed at once that the number present was essentially equal to the number added as initiator: consequently significant amounts of cyclic polypeptide formation (and condensation) could be ruled out under the polymerization conditions (25°). However, it soon became apparent that the ordinary procedures of isolation, drying and storage at room temperature as either solid or solution were accompanied by a continuous loss of amine groups. The isolation procedure used for the three samples of the 800 series involving drying at 50° leads to losses of 50 to 70% of the amine groups present in the reaction mixture (Table I). Moreover, 80% loss of amine groups was produced by exposure to a steam-bath for 5 hours. Thus lyophilization of the reaction product (dioxane solution) appeared to be the best way of preserving most of the amine groups. When this was carried out on an [A]/[I] = 4 sample (no. 428 L) over a period of 48 hours the amine content was 85% of that added as initiator. No significant loss of amine groups occurs during storage at −30° over a period of several months. It is of interest to note that no change in intrinsic viscosity was observed during these alterations of amine group concentrations. As a consequence condensation was ruled out here as well and the end group cyclization reaction was accepted as the explanation of the depletion of amine groups.

The carboxyl group concentration of numerous samples was found to be in the same range as for the three polymers listed in Table I. The number of carboxyl groups was essentially unaltered by ordinary isolation procedures and as a consequence it seemed likely that those initially present might arise from the termination reaction of Sela and Berger.[13] However, the carboxyl group concentration could be increased by more drastic treatment. For example it would double upon five hours exposure to 100° presumably due to hydrolysis of the benzyl ester groups.

Discussion

The conservation of amine groups during the polymerization is indicative of the absence of the formation of cyclic polypeptides and condensation reactions, and it clearly indicates that the number average DP of the product is essentially that given by the anhydride–initiator ratio. This conclusion makes use of the observation from kinetic studies[2-4] that all the hexylamine initiator reacts rapidly to produce polymer.

The lability of the amine group due to end group cyclization prevents its assay from being useful as an accurate measure of number average molecular weight. However, it is clear that by lyophilization and cold storage the amine groups can be largely conserved. The loss of amine groups through this reaction is not serious in polymerizations lasting a few hours at room temperature. But polymerization carried out at higher temperatures or for longer times would be expected to show a decay in rate due to this reaction.

The constant carboxyl group concentration found here can be interpreted as arising from a termination reaction. The amount found, about 15 $\times 10^{-6}$ equivalent per gram, upon multiplication by the residue molecular weight gives 0.0033 which, in view of the unknown extent of the debenzylation reaction, would be interpreted as an upper limit for the probability of chain termination occurring each time a monomer adds to the polypeptide chain. More recent work of Lundberg and Doty,[4a] however indicates that this value is considerably too high and that the situation is complicated by the end group cyclization reaction acting as an additional termination step. Nevertheless it can be concluded from these findings that termination steps play a small role in these polymerizations and cannot be held responsible for the unusually wide molecular weight distributions mentioned above.[15]

The Molecular Weight Dependence of Intrinsic Viscosity for Short Polypeptide Chains

In an earlier study[16] of this polypeptide the intrinsic viscosity was related to weight average molecular weights determined by light scattering for degrees of polymerization ranging from 100 to 2000 in two solvent systems, one in which the chain configuration was randomly coiled (dichloroacetic acid) and one in which it was helical (chloroform saturated with formamide). For the purposes of this paper it was necessary to extend this intrinsic viscosity–molecular weight relation down to degrees of polymerization in the neighborhood of 5. The Archibald approach to equilibrium method was used for this purpose. The measurements were made on dimethylformamide solutions of a number of samples prepared either by fractionating the products of polymerizations in dioxane[1,6] or by polymerization in dimethylformamide, a polymerization medium in which it has been discovered that the molecular weight distribution produced is very narrow.[3,4a]

The weight average molecular weights were determined as described briefly in the Experimental Section. In each case the concentration depend-

ence of the apparent molecular weight as expressed in the second virial coefficient was employed to obtain the actual molecular weight at infinite dilution. The virial coefficient was found to increase substantially with decreasing molecular weight. The magnitude of this effect is surprising and is being investigated further.

The molecular weights thus determined are plotted against the intrinsic viscosity in dichloroacetic acid on a double logarithmic scale in Fig. 1 as open circles. The earlier results for the higher molecular weight range are shown as filled circles. It is seen that deviations from the linearity of the higher molecular region set in at a DP of about 100 and become quite marked below a DP of 50. In this connection it is of interest to note that in the case of polystyrene a somewhat similar study[17] has shown that the deviations set in at a molecular weight of about 5000. Such a molecule of polystyrene has a chain length equivalent to poly-γ-benzyl-L-glutamate of DP 86. Hence the onset of deviation from the Mark–Houwink behavior occurs at roughly the same chain length in these two cases.

Polydispersity and Fractionation of Polypeptides Prepared in Dioxane

The results of the two foregoing sections now permit a quantitative assessment of the polydispersity of the poly-γ-benzyl-L-glutamate samples of interest. For the hexylamine initiated polypeptides the number average degree of polymerization, DP_n, can be taken as equal to the anhydride–initiator ratio. The weight average value, DP_w, can be assessed from the intrinsic viscosity determinations with the use of Fig. 1. The ratio, DP_w/DP_n, is a direct measure of the polydispersity. For the Poisson distribution it should approach 1 (that is, it should equal $1 + 1/DP_n$) and for the most probable distribution, expected for many polycondensations, it should be equal to 2.

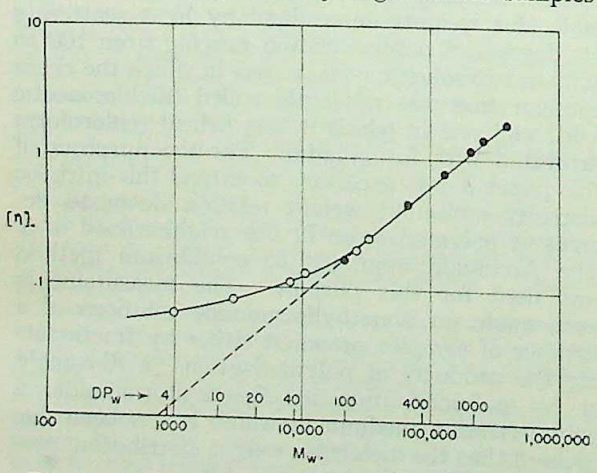

Fig. 1.—Double logarithmic plot of intrinsic viscosity measured in dichloroacetic acid against weight average molecular weight of poly-γ-benzyl-L-glutamate: ●, molecular weights determined by light scattering measurements; O, molecular weights determined by the Archibald ultracentrifugal method.

The results on six polypeptides produced in dioxane are assembled in Table I. The polydispersity is seen to be very great indeed. Actually it is so large that the values of DP_w obtained from Fig. 1 are probably somewhat too low because the intrinsic viscosity corresponds to an average slightly lower than the weight average. Measurements on samples with [A]/[I] values greater than 20 show a continual decrease of the polydispersity with molecular weight.[3,6] These results are of course incompatible with the growth of polypeptide chains by the addition of monomer units through a single rate process following rapid initiation. The origin of this broadening of the molecular weight distribution has been found[3] and is described in detail in the accompanying papers.[4]

Fractionation.—With this evidence of very wide molecular weight distributions it was expected that a sample could be fractionated easily into two parts having quite different molecular weights. This has been done in three different ways. The first was fractional extraction with formic acid[2] or hot ethanol.[4b] These liquids appear to dissolve almost exclusively those polypeptide chains that are too short to form stable helical configurations. Consequently, polypeptides such as those listed in Table I were divided in a single step into two parts having intrinsic viscosities in dichloroacetic acid of the order of 0.06 and 0.20. Even if only the earlier viscosity–molecular weight relation were employed this would indicate a difference in molecular weight of a factor of about 5. With the use of Fig. 1 it is seen that this indeed corresponds to differences of about 25-fold in molecular weight.

As a particular example, the two fractions of sample 384–10 prepared by ethanol extraction by Idelson and Blout were examined by both the Archibald method and intrinsic viscosity. The lower fraction (entirely of the β-configuration in the solid state according to the infrared spectrum) had a DP_w of 4 while the higher fraction (entirely of the α-configuration) was of a DP_w of 150. For the unfractionated material the DP_w by the Archibald method was 104. Thus the very great polydispersity is confirmed.

A similarly striking separation into two parts was found in paper chromatograms. Chloroform solutions were applied to strips of Whatman No. 4 filter paper. When dry, the strips were developed in a closed chamber by the descending method using the *n*-butanol–acetic acid–water system. After drying and spraying with ninhydrin two purple spots developed, one at the origin and another at a point described by an R_f value of 0.92 ± 0.02. The chromatograms of fractions showed only one spot: at the origin ($R_f = 0$) for the high fractions and $R_f = 0.92$ for low fractions. Thus it is clear that the short chains not in the helical configuration move in this system while those in the helical configuration remain at the point of application.

The third method of fractionation employed was simple dialysis. A bag made of cellophane tubing and conditioned stepwise to a dioxane–water mixture (25:1) was filled with a 3.4 g./dl. solution in dioxane of a polypeptide with a DP_w of 37. Within a week (two changes of solvent of volume twice that of the bag) the loss from the bag had stopped. The material that had remained inside had a DP_w of 120 and that collected on the outside had DP_w of 4. The two fractions showed only single spots on paper chromatograms. Thus this type of separation has produced results very similar to the other two.

Molecular Weight Dependence of Helix Stability

The onset of helix stability with increasing chain length will be expected to occur rather abruptly[18] and the critical chain length, DP_c, at which it occurs will depend on a number of factors: the composition of the polypeptide, the environment of the polypeptide chain (solid state or solvent) and the temperature. The determination of DP_c for a given set of these factors would be simple if samples of uniform chain length were available. When the actual samples have a distribution of molecular weights the assignment of the value of DP_c is subject to an error proportional to the breadth of the distribution. Thus the accuracy with which DP_c can be specified increases as the molecular weight distribution is narrowed.

For example, sample number 834 was found to be half in the β-configuration (β_L form in Blout's terminology[4b]) and half in the α-configuration as a result of infrared studies on the solid material.[2] Yet it would be misleading indeed to conclude that DP_c was equal to the DP_w of this polypeptide. Since fractionation of this sample[2] produced two parts, one nearly pure β_L and one pure α having DP_w values of 2 and 100, respectively, it is clear that the proportion of α and β configuration shown in the original polypeptide was only a reflection of the amounts of material present having chain lengths below and above DP_c. Thus the value of DP_c must be located within the range of chain lengths present in the sample but it cannot be more definitely fixed.

The fractions produced by formic acid extraction by Blout and Asadourian[2] have somewhat narrower molecular weight distributions and a comparison of their configuration as deduced from infrared spectra with the DP_w values that can now be assigned to them by the use of Fig. 1 permits an approximate estimation of DP_c in the solid state. Their results and our own may be summarized by the statement that peptides containing at least 90% β_L configuration have not been observed with $[\eta]$ greater than 0.075. This intrinsic viscosity corresponds to DP_w to 10. However, the uncertainty in the intrinsic viscosity measurements (± 0.005) and in the possible lack of detection of small amounts of material in the samples place an uncertainty of ± 3 on this estimate. Moreover, since the DP_n of these fractions was not well known the polydispersity of the samples can only be estimated. It is for this reason that the value assigned to DP_c is only an estimate.

In order to obtain a more accurate value of DP_c, particularly in solutions, use was made of the observation that poly-γ-benzyl-L-glutamate samples prepared in dimethylformamide solution were of much narrower molecular weight distribution than those made in dioxane.[4a,19] Two such samples prepared at [A]/[I] of 4 and 10 have been used for the present study. These samples were found to have DP_w values of 5 and 14, respectively. Taking DP_n as equal to [A]/[I] it is seen that the chain length distributions in these samples are very narrow.

The fraction of residues in the helical configuration for dioxane and dimethylformamide solutions of these polypeptides was determined by rotatory dispersion measurements.[20] The results, along with those for a high molecular weight, completely helical sample, are plotted in accordance with Moffitt's equation in Fig. 2. The helical content is deduced from the value of b_0 (obtained from the slopes of the plots). Since the high molecular weight sample was found to have $b_0 = -682°$ in dioxane and −620 in dimethylformamide, the per cent. helical configuration in solution is taken as $100b_0/-682$ and $100b_0/-620$, respectively.

The results are summarized in Table II where it is seen that the [A]/[I] = 4 sample shows no helical content, whereas the [A]/[I] = 10 sample is nearly half helical.[21]

These results permit the assessment of an upper and lower limit to the critical chain length for helix stability, DP_c, in these solvents. If the [A]/[I] = 10 sample were of uniform chain length of 14 and exhibited 50% helical content DP_c would equal 14. However, since some spread in molecular weight distribution exists this can only be taken as an upper limit. It is likely to be several units lower. The lower limit can be found by taking into account the molecular weight distribution

(19) Current work by J.C.M. is demonstrating that samples prepared in this manner do indeed approach the expected Poisson distribution.

(20) J. T. Yang and P. Doty, THIS JOURNAL, **79**, 761 (1957).

(21) The coefficient of the normal dispersive term, a_0, was found to be quite concentration dependent as the two values in Table II illustrate. This is similar to the behavior already witnessed in chloroform solution[20] and appears to be due to an intermolecularly hydrogen bonded form that breaks up upon dilution to give the solvated β_L chains as first observed by Blout and Asadourian.[3] The use of the high molecular weight value of b_0 to calibrate the scale of helical content may possibly involve some uncertainty in this application since the effect per residue may be somewhat different due to end effects in short chains.

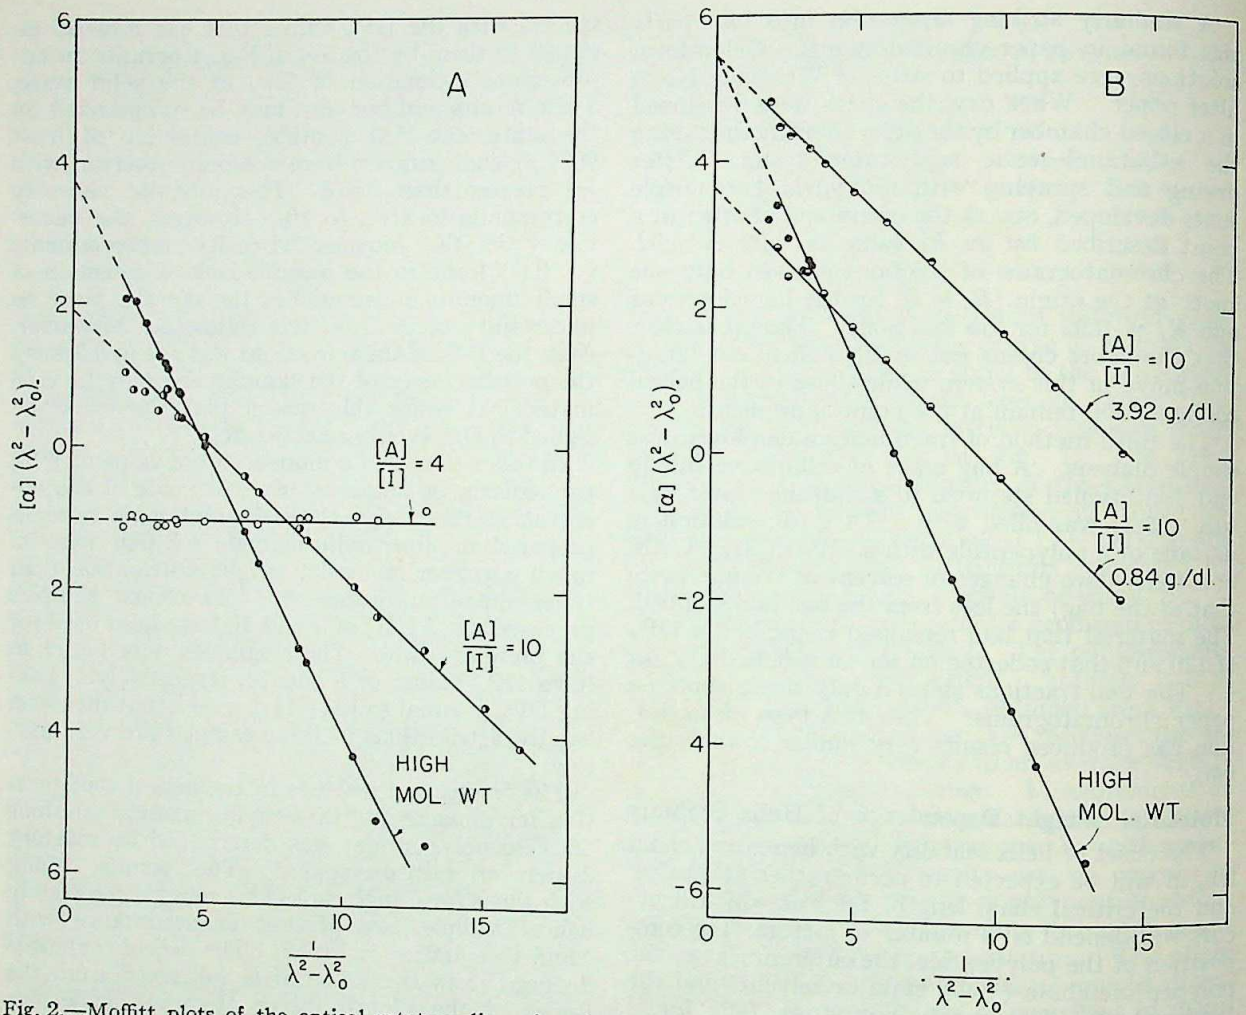

Fig. 2.—Moffitt plots of the optical rotatory dispersion of poly-γ-benzyl-L-glutamate in (A) dimethylformamide and (B) dioxane: λ is in microns; λ_0 is taken as 0.212 μ.

of the [A]/[I] = 4 sample. Since the DP_w is equal to that expected for a Poisson distribution, this distribution can be assumed. In this distribution about 10% of the sample by weight has a DP in excess of 7. If this were helical it could clearly be detected by the rotatory dispersion method. Consequently this forms the lower limit of DP_c. Thus these preliminary studies locate DP_c for these polypeptide–solvent systems between 7 and 14. The average of this range, that is DP of 10, appears as a reasonable estimate of DP_c but further investigation of fractionated samples of polypeptides produced in dimethylformamide will be required to reach the most accurate and precise value of this constant.

Polypeptides. XVII. A Study of the Kinetics of the Primary Amine-initiated Polymerization of N-Carboxy-anhydrides with Special Reference to Configurational and Stereochemical Effects

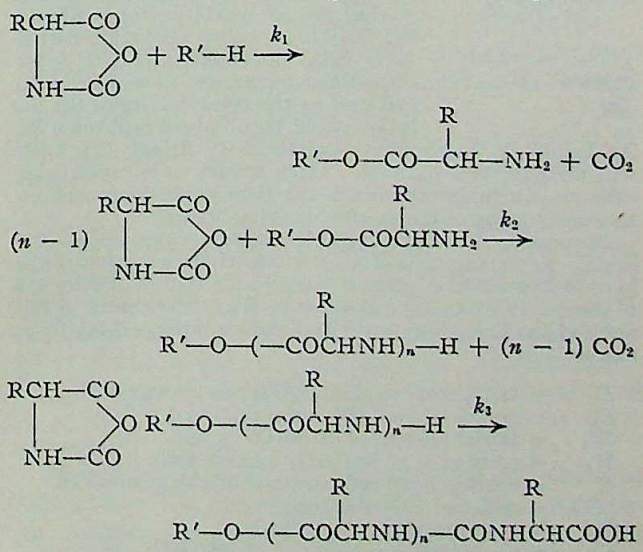
BY R. D. LUNDBERG[1] AND PAUL DOTY

RECEIVED MARCH 26, 1957

The primary amine-initiated polymerization of N-carboxy-anhydride of γ-benzyl-L-glutamate in a number of solvents is shown to proceed at two successive rates following a relatively rapid initiation. The rate constant for the second propagation step is at least five times larger than that for the first and as a consequence those growing chains that first achieve the condition for the faster propagation then grow rapidly and, by lowering the anhydride concentration, reduce the rate of growth of the chains that have not attained the condition for fast growth. This is the origin of the very broad molecular weight distributions previously observed. In dioxane the transition from the slow to the fast propagation rate occurs when the average chain length has reached approximately 8 residues. Since this chain length lies in the range (7 to 13) which has been assigned to the critical length for stabilization of the α-helical configuration in this solvent it appears that the cause of the change in propagation constants is the configurational transition. It is shown that very minor HCl contamination of the N-carboxy-anhydride can substantially lower the second propagation constant and in the limit prevent its appearance altogether. Two alternative termination steps are identified and their combined effect limits the average degree of polymerization to about 500. In dimethylformamide only a single rate constant is observed and the molecular weight distribution of the resulting polypeptides is greatly reduced over that of the dioxane case. Thus the preparation of low molecular weight polypeptides having the narrow Poisson distribution of molecular weights appears possible. Investigation of the rate of polymerization of racemic and D,L-mixtures of N-carboxy-anhydride shows a pronounced lowering of the propagation rate relative to that of the pure L-anhydride. While the growing chain is non-helical the lowering is less than a factor of two and is thereby accounted for in terms of a preference of the chain to add the isomer corresponding to its terminal residue. Later, when the growing chain has reached the helical configuration, the lowering of the rate is greater than a factor of two and this indicates a preference exerted by residues lying behind the terminal one. When optical rotation as well as CO_2 evolution is used to follow polymerizations of L-, DL- and D-N-carboxy-anhydrides with preformed L-polypeptide (helical configuration) it is found that the screw sense of the initiating helix tends to be continued. In the D-anhydride case, the reversal of the helix sense occurs after about four residues have added; in the DL-anhydride case, reversal occurs later presumably as a result of the occasional addition of four D-residues in sequence.

The polymerization of N-carboxy-α-amino acid anhydrides has been generally thought to proceed by a repetitive, stepwise addition of the peptide units with the simultaneous expulsion of carbon dioxide.[2-7] If initiation is not slow relative to propagation and side reactions do not occur, chain growth should proceed at a nearly uniform rate producing a Poisson distribution of molecular weights. Recently a termination step has been suggested[8a] and the broadening of the molecular weight distribution which this would bring about has been analyzed.[8b] Thus the polymerization is presumed to occur by the mechanism shown.

The purpose of this investigation has been to determine to what extent the formation of poly-γ-benzyl-L-glutamate from its N-carboxy-anhydride follows this kinetic scheme. This particular amino acid residue was chosen because it is one of the few precursors of naturally occurring amino acids whose anhydride and polypeptide are both soluble in liquids suitable for polymerization. Earlier investigations in this series[9,10] had raised questions concerning the adequacy of the foregoing scheme even when primary amines were used as initiators. The most obvious difficulty arose from finding that the molecular weight distribution of the resulting polymer was extraordinarily broad, that is, far broader than that which could be accounted for by any adjustment of the above mechanism. Consequently, we wished to search for the kinetic origin of this abnormally broad molecular weight distribution and eliminate it if possible. Finally, there



was obvious interest in seeing if optical isomers had an effect in the kinetics and if particular preference was exhibited in the polymerization. This last point gained interest as evidence accumulated that the helical configuration had only one screw sense (probably right handed)[11,12] and when it was

found that the helical configuration was substantially less stable when the polypeptide contained both D- and L-residues.[13] It is these questions as well as those which arise in a conventional kinetic study that must be answered before this type of polymerization can be employed in making polypeptides that approach the specifications which are required of protein analogs.

Experimental Details

Measurement of CO_2 Evolution.—The rate of carbon dioxide evolution provides a convenient method for measuring the progress of this reaction. Since previous investigators[14] have shown that the manometric techniques may lead to difficulties when the carbon dioxide pressure increases, a method similar to that of Breitenbach and Allinger[6] was used. The gas was swept out by a stream of prepurified nitrogen and absorbed in a previously standardized solution of barium hydroxide. Although any strong base may be employed, barium hydroxide was used here because of the relatively large change in resistance resulting from precipitation. By measuring the decrease of conductivity of this solution with time, the amount of carbon dioxide evolved is measured and from this the amount of anhydride consumed is determined.

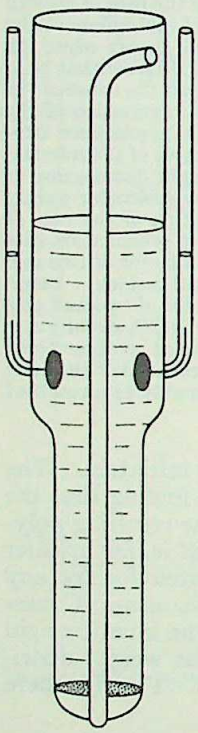

Fig. 1.—Carbon dioxide absorption cell.

For convenience the $Ba(OH)_2$ solution was prepared in 20 liter volumes. Several solutions of different strength (0.005 *M*, 0.01 *M*, 0.02 *M*) were made up and used according to the amount of carbon dioxide to be measured. It was necessary to add 0.5% of *n*-butanol in order to obtain complete absorption of the gas. The solutions were standardized with known amounts of carbon dioxide evolved from the permanganate–oxalic acid reaction.

An absorption cell was constructed so that the gas would be dispersed into the $Ba(OH)_2$ solution through a fritted glass disk. As shown in Fig. 1, a set of platinum electrodes were sealed into this cell so the conductivity of the solution could be obtained continuously. An Industrial Instruments Conductivity Bridge (RC 16B) was used for this purpose. With a number of absorption cells an equivalent number of reactions could be run simultaneously using only one conductivity bridge.

In practice the amounts of gas measured were about 10^{-3} mole. In the interests of greater sensitivity a volume of the barium hydroxide solution was used such that W_t at the end of the reaction would be about $5 \times W_0$. The theory of this method has been described[15] and can be expressed briefly as follows. If

C_0 = initial concn. of $Ba(OH)_2$ soln. in equiv./l.
C_t = concn. of $Ba(OH)_2$ soln. at time t
W_0 = initial resistance of $Ba(OH)_2$ soln.
W_t = resistance of $Ba(OH)_2$ soln. at time t
K = conductivity cell constant of absorption cell
$[CO_2]$ = moles of CO_2 absorbed.
V = vol. of $Ba(OH)_2$ soln. in l.
Λ = equivalent conductance of $Ba(OH)_2$

Then

$$2[CO_2] = V(C_0 - C_t) = V\left[\frac{1000K}{\Lambda W_0} - \frac{1000K}{\Lambda W_t}\right]$$

$$[CO_2] = \frac{1000VK}{2\Lambda}\left[\frac{1}{W_0} - \frac{1}{W_t}\right]$$

$$= \frac{VC_0}{2}\left[1 - \frac{W_0}{W_t}\right]$$

$$C_0 = \frac{1000K}{W_0}$$

$$C_t = \frac{1000K}{W_t}$$

The presence of precipitated $BaCO_3$ had almost no effect on C_0 in this range.

Anhydride Preparation.—All the anhydrides used in this work were prepared by Drs. E. R. Blout, M. Idelson and G. Fasman and R. H. Karlson according to the procedure they have described.[9] It is important to note that all possible steps in the preparation and purification of these anhydrides were done at −30° to preclude the reaction of water with anhydride. These anhydrides were recrystallized until the chloride content was less than 0.01 weight %. However, it was shown eventually that HCl even at this low level had a detectable effect on the reaction.

These anhydrides were then stored at either −30° or at Dry Ice temperatures. Under these conditions reproducible runs were obtained even after months of storage.

The technique for handling the anhydride was as follows. The anhydride was transferred to small tared capped vials at −30°. These were stored at −30° or Dry Ice temperatures until used. A vial was then brought to room temperature in a desiccator and weighed. After the desired amount of initiator was added to the solvent by means of a Burroughs–Wellcome micrometer syringe, the vial containing the anhydride was uncapped and added to initiate the polymerization. Solution of the anhydride was complete in about 1–2 minutes. As a precaution against the presence of water, solvents were fractionally distilled immediately before using. All transfers of anhydride were conducted at −30° with the exception of the final one which took only about two seconds.

The carbon dioxide was driven out of the reaction vessel by a flow of prepurified nitrogen which was saturated with the reaction solvent. This was then absorbed in the $Ba(OH)_2$ solution. Resistance measurements were made at intervals until the reaction was 90% complete. However, as a check, the reaction was allowed to proceed until 98–100% of the theoretical amount of CO_2 was evolved.

Polymer Isolation.—After the reactions were at least 99% complete the polymers were isolated by lyophilization or precipitation into reagent grade isopropyl ether. The former technique was necessary for the low A/I material.

Solvents.—Dioxane was purified according to Fieser's method and then fractionally distilled from sodium before using. Alternatively, dioxane was purified by refluxing with sodium for 24 hours, fractionally distilling, storing over sodium and redistilling immediately before use. The dioxane prepared by these methods was identical in its behavior. The latter method was more generally used.

Nitrobenzene was treated with anhydrous P_2O_5, decanted and then fractionally distilled before use. Ethylene dichloride was fractionally distilled. Dimethylformamide was treated with $NaHCO_3$, decanted and fractionally distilled from phthalic acid at reduced pressure (40 mm., T = 75°).

Dichloroacetic acid was fractionally distilled at reduced pressure.

Molecular Weight Determinations.—Intrinsic viscosities were measured in dichloroacetic acid using a modified Ubbelohde viscometer. Weight average molecular weights were obtained from these results by means of previously established relations.[10]

Titrations.—The method used in analyzing for amine groups was a conductimetric one.[10] The polymer was dissolved in a phenol–ethanol medium and the change in conductivity was followed as 0.0100 *M* $HClO_4$ was added. The intersection of two straight lines gives the end-point.

The titration of N-carboxy-anhydride with sodium methoxide has been described.[16] The titrations were conducted in dioxane solvent after bubbling prepurified nitrogen through the solution to drive out CO_2. The base (0.100 *M*)

was added rapidly to prevent polymerization of the anhydride.[9] The reproducibility of the method was ±2%.

Polymerizations in Dioxane

Initiation and Propagation.—According to the reaction scheme given in the Introduction the consumption of anhydride can be represented as follows using [A], [I] and [P] for the molar concentrations of anhydride, initiator and polymer, respectively.

$$-\frac{d[A]}{dt} = k_1[A][I] + k_2[A][P] + k_3[A][P]$$

However, if $k_1 \geqslant k_2 \gg k_3$ and $[P] = [I] < [A]$ this can be represented adequately by a pseudo first-order rate equation

$$-\frac{d[A]}{dt} = k_2[A][P] = k'[A]$$

Consequently the conventional first-order plot of log ($[A_0]/[A]$) against time can be expected to be applicable. Our data are presented in this manner but the rate constants given are always bimolecular in units of liter mole^{-1} sec.$^{-1}$.

Some typical results are shown in Fig. 2. These correspond to four polymerizations at different anhydride–initiator mole ratios: 4, 10, 20 and 40. The intercepts of the plots, extended back to zero time, are equivalent to the reaction of equimolar amounts of anhydride and initiator. This shows that the initiation by hexylamine is fast relative to the propagation step. From a study of the early part of the reaction the initiation rate constant can be estimated as 0.2 ± 0.1 liter mole^{-1} sec.$^{-1}$

For the case where [A]/[I] is 4 the reaction is seen to proceed in a completely linear fashion throughout. However, for the other three cases two successive linear regions are found. At first encounter this behavior may be thought to be simple autocatalysis. But the repeated and never failing display of two linear regions for all the purified anhydrides available prevents the acceptance of this interpretation. Consequently, we conclude that two successive propagation reactions do occur and that two propagation constants, k_{2a} and k_{2b}, can be used to describe the kinetics of the reaction. Values of these constants derived from the slopes of the two linear regions are listed in Table I for a number of

experiments. It is seen that k_{2a} is about 0.006 and k_{2b} is about 0.033 liter mole^{-1} sec.$^{-1}$. The somewhat higher values k_{2b} are associated with anhydrides of exceptional purity. In general the reproducibility of k_{2a} for a given anhydride was within ±20%; that for k_{2b} was within ±5%.

The other conclusion worth drawing from Fig. 2 concerns the location of the transition between the two linear regions of the kinetic plot. It is seen that in terms of fraction of anhydride consumption it occurs earlier in the reaction as the ratio [A]/[I] increases. The other polymerizations listed in Table I showed similar behavior. An eventual explanation of the two successive propagation steps must therefore also elucidate dependence of the transition on the [A]/[I] ratio and its absence at very low values of this ratio.

Initiation by Preformed Polymer.—It is of interest to determine whether the second propagation rate is continued in the presence of more anhydride. Therefore a preformed polymer was prepared in dioxane by initiating to [A]/[I] of 20 and followed kinetically to 98% completion (k_{2a} = 0.0063, k_{2b} = 0.035). Sufficient anhydride was added to give an additional [A]/[I] = 12, and more solvent added to maintain a concentration of 4%. The rate curve obtained (Fig. 3) is linear except for the very early stages of the reaction. In this region one must allow for complete solution of the anhydride in the viscous medium. However, some of the curvature may be real, caused by generation of more of the faster reacting species. The rate constant obtained for the linear portion of the curve is k_2 = 0.038 liter mole^{-1} sec.$^{-1}$, which is in good agreement with k_{2b}.

Molecular Weights of Polypeptides Prepared in Dioxane.—The number and weight average molecular weights of poly-γ-benzyl-L-glutamate samples prepared in dioxane by hexylamine initiation have been investigated by Mitchell, Woodward and Doty.[10] Their relevant results together with supporting observations of our own are summarized here.

The number average degree of polymerization, according to the proposed reaction scheme, should be equal to the [A]/[I] ratio. The proof that this is the case could be obtained by showing that the

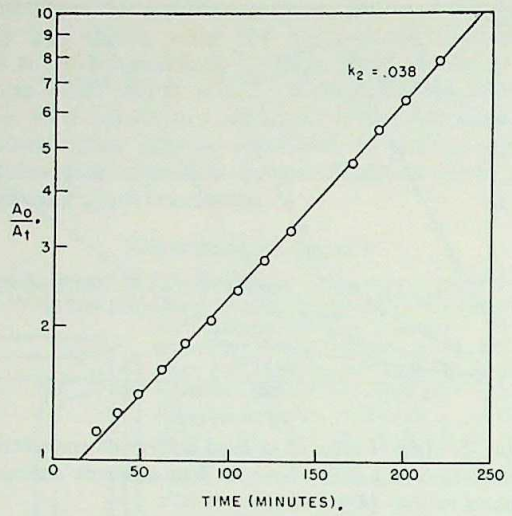

Fig. 3.—Kinetic curve for polymerization initiated by preformed polymer: $[A_0] = 0.063$, $[I] = 0.0046$.

moles of amine groups in the product is the same as the moles of initiator added. The following experiment offers a test of this point. A polymerization at [A]/[I] = 20 was allowed to proceed for 10 hours whereupon it would be expected to have reached 99.8% of completion. It was then lyophilized to remove the dioxane over a period of another 10 hours. When this product was dissolved and titrated it was found to contain 85% of the amine groups added as initiator. This indicates that the number has not substantially altered during this long polymerization. Since the reaction of the initiator was found to be very rapid and since any that might have remained would have been lost during lyophilization, it appears that amine groups are conserved during the ordinary polymerization. Therefore each initiator appears to have given rise to one polypeptide chain and the number average degree of polymerization, DP_n, can be taken as equal to the ratio, [A]/[I].

The weight average degree of polymerization, DP_w, is derivable from intrinsic viscosity measurements in dichloroacetic acid as a result of recent studies.[10] (The average value actually falls slightly below the weight average for samples having a broad molecular weight distribution but this need not concern us here.) Consequently the ratio DP_w/DP_n can be evaluated and used as an indication of the breadth of the molecular weight distribution. Some typical results are shown in Table II where they are compared with the result expected for a Poisson distribution, that is, the distribution expected for the mechanism described earlier provided that the termination reaction is negligible. If the termination reaction is not negligible the value of the ratio, DP_w/DP_n, will be increased toward a limiting value of 2. The observation is, however, that the ratio is much greater than this. Its magnitude exceeds that generally encountered in any kind of polymerization and consequently its explanation should require a very substantial alteration in the mechanism proposed.

It is relevant to note that if trace amounts of water or other possible initiator had interfered in these polymerizations they would have increased the

Table II

number of chains produced and hence have lowered the molecular weight over that expected. Consequently an explanation cannot be expected from this source.

Termination Steps.—Evidence for a termination step of the kind indicated in the Introduction was provided by titration data[10] which showed that carboxyl groups were present. Since the concentration of these groups (about one for each 300 residues) was independent of the [A]/[I] ratio and hence of the time required for the polymerization, and since the production of carboxyl groups by debenzylation was not detectable under polymerization conditions, these results were interpreted as favoring the termination step mentioned. If this were the only termination step involved, a check could be made on this suggestion by carrying out a polymerization at a [A]/[I] ratio that exceeded 300. If the proposed termination step were valid the rate of polymerization should gradually slow and come to a stop before all of the anhydride was consumed.

A polymerization of this kind was carried out and the kinetic plot is shown in Fig. 4. The anhydride concentration was determined in this case directly by titrating with sodium methoxide.[16] The solid circles correspond to a control experiment under identical conditions with no added initiator. The qualitative behavior of the polymerization is clearly of the type anticipated above. A quantitative consideration of this experiment, however, leads to an inquiry into other aspects of the polymerization.

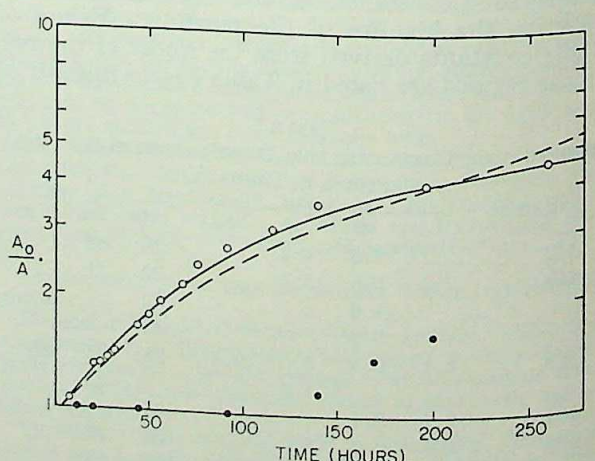

Fig. 4.—Kinetic curve for polymerization initiated by *n*-hexylamine at very high [A]/[I]. The dashed line is the calculated curve for Sela–Berger termination reaction. Solid line is calculated assuming termination through cyclization. The solid points are those for a control with no initiator added.

The calculated curve for $k_{2b} = 0.032$ and $k_3 =$ $k_2/300$ shows very poor agreement with the experi-

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

mental data. Indeed the value of k_{2b} calculated from the initial slope of the data in Fig. 4 is only 0.015. On the basis of a subsequent discussion on the effect of residual HCl in the anhydride it is evident that the most likely explanation of the low apparent value of k_{2b} is that some of the initiator was inactivated by reaction with HCl. The amount of HCl required to remove half of the initiator and therefore restore the value of k_{2b} to that usually found is 1.3×10^{-4} g. per gram of anhydride. Since the residual chloride content is at just this level (0.01%)[9] this explanation seems tenable. If this is accepted, the [A]/[I] in this case was actually about 1000. If the anhydride consumption is recomputed on this basis a fairly satisfactory fit of data can be obtained if $k_3 \sim k_{2b}/1000$ (dashed line in Fig. 4). This result indicates that only one-third as many chains are terminated with carboxyl groups as titration results had indicated.[10] Thus the majority of the carboxyl groups found by titration may have been the result of debenzylation.

Having gone into this matter in so much detail it becomes necessary to pursue the possible effects of another termination step that is peculiar to this particular polypeptide, that is, the loss of amine end groups through a cyclization reaction with the elimination of benzyl alcohol.[9,17] The experiment described in the last section shows this reaction proceeds at a detectable rate (about 0.5–1.0% amine loss per hour).[6] Over the period of time taken for polymerization of [A]/[I] of 40, for example, it produces termination of about 5% of the chains. But during the much longer reaction time of the polymerization for [A]/[I] of 510 (or 1000) this cyclization reaction would have very pronounced effects. Indeed the assumption of 1% loss per hour of amine groups by a unimolecular mechanism can account for nearly all of the decay in rate observed (solid line in Fig. 4 calculated on this basis). It is clear however, that the role of this termination will be negligible in the other polymerization discussed in this paper because they were completed in much shorter times.

The result of these considerations is to show that a termination is readily demonstrated at very high anhydride–initiator ratios, and therefore a ceiling does exist for the molecular weight. The present evidence does not enable us to delineate the relative importance of the two termination steps. However, the effect of these termination reactions is not large enough to be revealed kinetically for [A]/[I] of 40 and less. For example, in a polymerization of [A]/[I] = 20 carried to 95% completion (5 hours) one would estimate that less than 7% of the chains would be terminated.

Helix Formation as the Cause of the Change in the Propagation Constant and the Consequent Broadening of the Molecular Weight Distribution.—The termination steps discussed in the previous section are obviously of minor importance in the kinetics of the polymerization in the anhydride–initiator ratios dealt with in this investigation [A]/[I] 4 to 40. Consequently, no explanation can be found here for the extreme breadth of the molecular weight distribution shown by the molecular weight studies. The origin of this effect would appear to lie in the nature of the kinetics of the polymerization as shown in Fig. 2. This is evident by recognizing that inasmuch as the amine groups are essentially preserved during the reaction, the individual chains can be expected to grow throughout the reaction. Yet the rate constant governing their growth appears to increase sharply at a certain point. Regardless of the cause of this change its effect is clearly the endowment of chains with a much faster rate of growth once some condition has been met. As a consequence, those chains that qualify for this faster growth can be expected to undergo a rapid increase in chain length. Those chains that may, for statistical reasons, be somewhat delayed in attaining the conditions for vast growth will be further delayed by the rapid consumption of anhydride by the fast growing ones. Therefore, many of the chains may never actually reach the condition for rapid growth and as a consequence a very broad molecular weight distribution would result. Thus the extreme broadening of the molecular weight distribution is seen to be the direct result of the phenomenon of two successive propagation constants for chain growth.

The cause of the shift from a slow propagation constant to a fast one is of obvious interest. The mid-point of the transition from one rate to another is seen (Fig. 2) to occur at a point where the anhydride molecules consumed per initiator is in the region of 7 to 12 for an [A]/[I] 20. That is, the transition occurs when a certain chain length is reached and is not obviously related to the anhydride–initiator ratio. Since previous studies[10] have shown that the minimum chain length required for formation of the α-helical configuration is about 10, it appears that this configurational change is the cause of the dramatic shift in propagation rates. Convincing evidence for this conclusion and proof of the transfer of chains from this β to the α configurations through growth has been provided by an infrared spectral study of the reaction by Idelson and Blout.[18] They have shown that the βL-polypeptide (non-helical) is produced in the region corresponding to the lower rate, and simultaneously with the incidence of the higher rate the formation of the α-polypeptide (helical) is observed. Through the use of deuterium labeled initiator, these investigators have shown that the βL-form is indeed the precursor of the α-polypeptide. Since the energy of activation for both rate constants is found to be low (<10 kcal.) the change in rate accompanying the configurational change is apparently due to a lowering of the entropy of activation resulting from an increased accommodation provided for the anhydride molecule at the end of a helix.

We may express the above interpretation through the equations

$$A + I \xrightarrow{k_1} P_1 + CO_2$$

(17) The rate of disappearance of amine groups in the lyophilized solid sample is about 0.5% per hour at 25°. Consequently titrations must be carried out promptly or the material must be stored at −30° or lower. Other experiments[10] also support this conclusion.

$$A + P_1 \xrightarrow{k_{2a}} P_2 + CO_2$$
$$\vdots \qquad \vdots$$
$$A + P_9 \xrightarrow{k_{2a}} P_{10} + CO_2$$
$$A + P_{10} \xrightarrow{k_{2b}} P_{11} + CO_2 \ldots$$

$$-\frac{d[A]}{dt} = k_{2a}[A]\left(\sum_{i=1}^{10}[P_i]\right) + k_{2b}[A]\left(\sum_{10}^{\infty}[P_j]\right)$$

where $[P_i]$ represents the concentration of the polymer chain containing i peptide units.

Thus in the early stages of the polymerization, the anhydride consumption should be first order. This is the situation that is observed at an [A]/[I] of 4, and in the early regions at higher [A]/[I]. However, if additional anhydride is available to increase the chain length sufficiently to form an α-helix, this configuration may react at a new and higher rate (k_{2b}). The flux of polymer chains through the region of critical chain length will result in an autocatalytic reaction since

$$\frac{d\sum_{j=10}^{\infty}[P_j]}{dt} = k_{2a}[A][P_{10}]$$

This conversion is dependent on the concentration of chains just below the critical size and the anhydride concentration. When both have been lowered sufficiently the reaction will again be pseudo first order. This is the effect observed in Fig. 2. Consequently, a relatively large number of the more slowly propagating chains will remain as such because insufficient anhydride is available for them to reach the critical size. Because of this, the rate constant obtained for the second propagation rate will be an underestimate of its true value, perhaps by as much by a factor of 2—see also footnote 13 in reference 18. Ostensibly, at sufficiently high [A]/[I] all of the chains should be able to pass through this critical size region before the anhydride is consumed. A trend of higher rate constants for k_{2b} should therefore be observed with increasing [A]/[I]. This is the observed behavior in Fig. 2 at [A]/[I] of 10 and 20 but not beyond. A subsequent discussion on the role of impurities in this polymerization demonstrates that a small amount of HCl is sufficient to suppress this trend at higher [A]/[I]. However, Idelson and Blout do observe an increase in k_{2b} with [A]/[I] with a highly purified anhydride sample.[18] Thus the kinetic behavior and the molecular weight distribution of the products are compatible with the concept that a configuration change under the conditions of this polymerization has effected a change in reaction rate.

Effect of Impurities.—It has been observed that some samples of γ-benzyl-L-glutamate anhydride gave a rate constant for k_{2b} which differed from each other more than could be explained by probable experimental error. To investigate the origin of these occasional variations, a sample of the N-carboxy anhydride was polymerized directly after its first crystallization. At an [A]/[I] of 20, a linear pseudo first-order behavior was observed throughout the polymerization (case A, Fig. 5) in marked contrast to the two successive growth stages previously observed. However, after one recrystallization of this anhydride from methylene dichloride, two successive propagation rates became clearly evident (B in Fig. 5). In both cases the initial propagation rates of the polymerization, k_{2a}, were about equal.

In addition to the difference in kinetic behavior, there was a striking difference in the reaction mixtures when the polymerizations neared completion. The solution of impure anhydride was a quite rigid gel, whereas the product of the recrystallized anhydride was a viscous solution. The α-helical content estimated from infrared spectra was about 40% in case A and about 75% for case B. Such marked differences in kinetic behavior and reaction products must therefore be the result of different growth mechanisms.

One of the impurities to be removed by recrystallization of the anhydride is HCl. Analysis of the unpurified anhydride showed the HCl content to be 1.0 mole %. Since this could react with the initiator, *n*-hexylamine, to produce a salt which in turn may affect the course of the polymerization, a series of reactions were carried out on a highly purified anhydride at an A/I of 20 (case C, Fig. 6) to which 5.0, 0.67, and 0.23 mole % of *n*-hexylamine hydrochloride had been added (D, E and F, respectively, in Fig. 6). The results show that this adduct completely eliminates the second propagation rate in cases D and E.

Further evidence that the propagation mechanism has been altered drastically is offered by the molecular weights of the products. The weight average DP was determined in the ultracentrifuge by the Archibald approach-to-equilibrium method for case C and E, and found to be 170 and 46, respectively. The DP_w expected in absence of any complicating factors would be 21. In concordance with the evidence introduced earlier it is seen that the absence of the second propagation step has reduced the weight average DP and therefore narrowed the molecular weight distribution. (It can be argued that since alkali halides[6] do initiate the polymerization, then the presence of this added amine salt could lower the molecular weight. Actually, the amount added corresponds to only 13% of the initiator present on a molar basis. Also, the initial propagation rate is not affected significantly; this indicates that the salt is no more active as an initiator than the amine itself.)

The kinetic behavior in the presence of only 0.23 mole % of amine salt (case F of Fig. 6) deserves further comment. Under these conditions the second propagation rate is just beginning to appear. Taken by itself this behavior might be falsely interpreted as an autocatalytic reaction. However, the behavior observed with the more highly purified anhydride (case C) clearly indicates that this is just the emergence of the second propagation rate. The explanation for the variation in k_{2b} for different anhydride samples is now evident. Since the lower limit of chloride detectability is about 0.08 mole %, it is apparent that amounts of HCl beyond detection can have a large effect on the rate. The difficulty in obtaining exactly reproducible results from one anhydride preparation to another can be ascribed to variations in HCl content all of which

are below the limits of detection. This emphasizes the importance of sufficient recrystallizations to eliminate this impurity. We are indebted to Dr. E. R. Blout for suggesting the examination of the anhydride after its first crystallization and of the role of hexylamine hydrochloride.

The Occurrence and Elimination of the Two-stage Propagation in Other N-Carboxy-anhydride–Solvent Systems

L-Leucine N-Carboxy-anhydride.—The kinetic behavior of γ-benzyl-L-glutamate anhydride has been correlated with the molecular weight distribution of the products, and the origin of the behavior traced to the coil-helix transition during chain growth. However, since this anhydride cannot be purified through sublimation, the possibility remains that some impurity not removable through recrystallizations is responsible for the observed behavior. Therefore, a study of the polymerization of the anhydride of L-leucine purified in the same way was carried out. These polymerizations were conducted in nitrobenzene solution at an [A]/[I] of 20 and are shown in Fig. 7. The polymer formed does

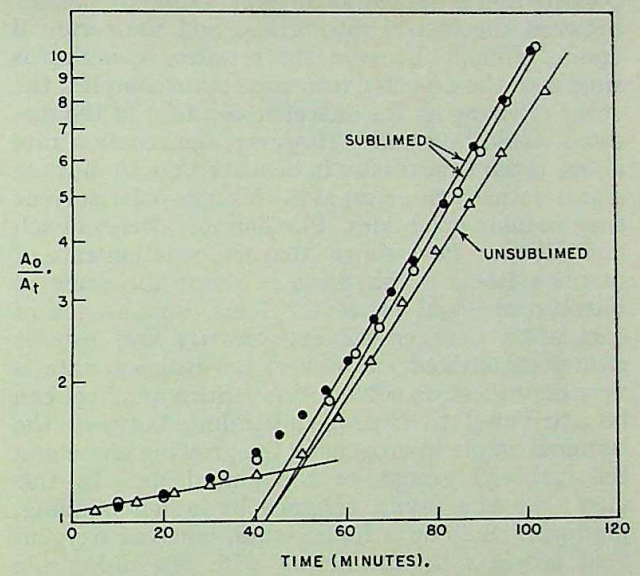

Fig. 7.—Polymerization of L-leucine N-carboxy-anhydride with initiation by *n*-hexylamine; $[A_0]$ = 0.134, [I] = 0.0066; (k_{2a} = 0.013, k_{2b} = 0.090 l. mole^{-1} sec.$^{-1}$).

precipitate under these conditions after the reaction is about 25% complete. As a result the quantitative significance of the rate constant obtained is questionable, but the demonstration of a large increase in rate similar to the γ-benzyl-L-glutamate case is apparent. (Precipitation of the polymer would be expected to decrease the rate so that this does not affect the argument.) When this anhydride was sublimed its polymerization was found to be essentially the same as for the unsublimed case. These observations therefore support the argument that the analogous behavior exhibited by γ-benzyl-L-glutamate is not due to the method of anhydride purification and indicate that two-stage propagation may be a general feature in the formation of polypeptides by this reaction. Similar behavior has also been found with L-phenylalanine anhydride.

Polymerization of γ-Benzyl-L-glutamate Anhydride in Other Solvents.—The phenomenon of two apparent rate constants in the polymerization of γ-benzyl-L-glutamate in dioxane has been observed in a number of solvents. The rate constants obtained are listed in Table III.

TABLE III
PROPAGATION RATE CONSTANTS IN VARIOUS SOLVENTS
T = 25°, [A]/[I] = 20

Solvent	Dielectric constant	k_{2a}	k_{2b}
Nitrobenzene	36	0.021	0.11
Ethylene chloride	10.3	.015	.14
Chloroform	5.1	.045	.30
Benzene	2.3	.062	.31
Dioxane	2.3	.006	.032

There is seen to be a surprising lack of correlation of rate with dielectric constant of the solvent.

Bamford,[7] *et al.*, have noted that the propagation rate of the polymerization of several racemic anhydrides is very dependent on solvent polarity. They have observed that the polymerization of γ-benzyl-L-glutamate is less sensitive to the solvent polarity and proposed as an explanation a complex between the benzyl ester group and the terminal amine group.[7] Because the resulting complex is similar to the expected transition state complex, the effect of changing the dielectric constant of the medium would be small. However, the reaction rate above is ten times faster in benzene than in dioxane and is actually more rapid in this non-polar solvent than in more polar ones. Furthermore, Breitenbach and Allinger[6] have shown that the reaction rate of DL-phenylalanine anhydride is about the same in nitrobenzene and benzene. Thus, an absence of correlation between solvent *polarity* and rate is clearly manifested; however, the reaction rate is very dependent on solvent type. Such an effect can be attributed to hydrogen bonding between the terminal amine hydrogens in the growing chain and the carbonyl groups of the anhydride. In this view, benzene would enhance hydrogen bonding, producing thereby a higher rate, whereas oxygenated solvents by competing with the anhydride molecules for the growing chain would suppress the rate. Thus the solvation of the end of the growing chain would be greatly dependent on the solvent type.

The Absence of Two-stage Propagation in Dimethylformamide.—To elucidate further the effect of solvent upon the course of the polymerization, a medium was desired which was strongly solvating and yet inert in its behavior toward the anhydride. Dimethylformamide has been shown to prevent intermolecular association of polypeptides and would appear to satisfy these requirements.

When polymerizations were conducted in this medium it was found that the kinetic behavior contrasted strikingly with dioxane and other solvents. Only linear rate curves for the disappearance of anhydride were obtained at [A]/[I] of 20, 40 and 80 ($k_2 = 0.057 \pm 0.004$). The viscosities of the polymers were much less than those obtained from polymerizations conducted at the same [A]/[I] in dioxane. This indicated a considerably lower DP_w and assuming [A]/[I] = DP_n, a narrower distribution.[10] Because of the insensitivity of intrinsic viscosities in this low DP region, the weight average molecular weights were measured directly on several polymers; the results on two are given in Table IV.

TABLE IV

THE POLYDISPERSITY OF TYPICAL POLYMERS PREPARED IN DIMETHYLFORMAMIDE

[A]/[I]	[η]	DP_w	DP_w/DP_n Poisson	DP_w/DP_n expt.
10	0.081	14	1.1	1.4
40	.13	48	1.03	1.2

Since lyophilization of dimethylformamide is not practical those products had to be isolated through precipitation, and therefore fractionation was a serious problem for the lower [A]/[I] samples. Consequently, the [A]/[I] ratio is not strictly equal to DP_n for [A]/[I] of 10, and by making this assumption the distribution appears more broad than it actually is. Therefore, the experimental ratios above represent a maximum for the [A]/[I] 10 case. At an [A]/[I] of 40, however, the isolation of the polymer was nearly quantitative. The molar weight distribution is seen to be quite narrow and closely approximates the Poisson distribution at the higher [A]/[I] where fractionation is negligible. The pronounced difference between these polymers and those obtained in dioxane solution (Table II) confirms the kinetic observations in each case. In the absence of any complicating factors and with only a single propagation rate, the Poisson distribution should be observed. When those requirements are achieved, as in dimethylformamide the molecular weight distribution at least approaches this theoretical limit. Therefore, a means has been found of preparing low molecular weight synthetic polypeptides with a very narrow molecular weight distribution.

Reactions were conducted at several temperatures in dimethylformamide and the rate constants obtained are given in Table V.

TABLE V

TEMPERATURE DEPENDENCE OF PROPAGATION CONSTANTS IN DIMETHYLFORMAMIDE

T, °C.	0	25	40
$k_2 \times 10^3$	19	56	87

At higher temperatures the observed rate decreased with time, evidently because the cyclization reaction was taking place more rapidly. A rather low activation energy of 6.6 kcal. is obtained from the constants in Table V. Apparently a higher activation energy is characteristic of the cyclization reaction. As a consequence, there will be a larger rate of termination at high temperatures ($T > 50°$) and polymers with broader molecular weight distributions will result.

The Role of Optical Isomers in the Polymerization

The Polymerization of Racemic N-Carboxy-anhydride in Dioxane.—N-Carboxyanhydrides of γ-benzyl-DL-glutamate were prepared in the same way as the L-isomer. Upon initiation with *n*-hexylamine at [A]/[I] equal to 20 the kinetic data were found to exhibit the same general features as the L-isomer, but quantitatively there were two differences. The propagation constants were substantially lower, $k_{2a} = 0.004$ and $k_{2b} = 0.013$ liter mole^{-1} sec.$^{-1}$, and more anhydride was consumed before the transition in rates took place.

In order to ensure that these differences were not due to residual impurities in the racemic anhydride, further experiments were carried out with N-carboxy-anhydrides of the pure L- and pure D-isomers and then with the equimolar (racemic) mixture of the two (D + L). The results in dioxane at the usual concentration (4 g. anhydride/100 cc.) and for two [A]/[I] values are summarized in Table VI.

The lower rate of propagation for the racemic mixture is clearly evident: k_{2a} is reduced to about two-third and k_{2b} to about one-half of the values for the pure isomeric forms.

		4.2	17
		4.4	16

The observation that the onset of the faster propagation constant occurs at a longer chain length in the case of the racemic N-carboxy-anhydrides indicates that a longer chain length is required for the helical configuration to be assumed. This is to be expected, if a copolymer of L- and D-residues has formed, due to the demonstration that helix stability does decrease upon the introduction of increasing amounts of the opposite optical isomer into the polypeptide chain.[13]

Standing in contrast to this correlation, however, is the intriguing possibility of interpreting the lowering of k_{2b} by a factor of two in the following manner. If chain growth in the helical form at least did permit only the addition of pure isomers to themselves so as to produce chains of pure D- and pure L-residues at the usual rate, it would be expected that the observed rate would be only half of the usual one because the concentration of anhydride molecules that could add to any one chain would be only half the total concentration. In order to explore this matter further some investigations were made in dimethylformamide where greater accuracy could be obtained.

The Polymerization of Mixed D- and L-N-Carboxy-anhydrides in Dimethylformamide.—Kinetic measurements were made on polymerizing mixtures of various proportions of D- and L-anhydrides in dimethylformamide. The results were first order in each case; the propagation constants are listed in Table VII.

TABLE VII

DEPENDENCE OF PROPAGATION CONSTANTS ON ANHYDRIDE COMPOSITION IN DIMETHYLFORMAMIDE

% L-isomer	100	92.5	85.5	74.7	50	0
$k_2 \times 10^3$	56	46	39	30	22	58
					22	
					21	

The effect of the opposite optical isomer on the rate of the polymerization is seen to be quite large and about the same as exhibited for k_{2b} in dioxane. Such an effect can be explained only if the propagation step is quite selective with respect to the optical isomers. This can be demonstrated more clearly by analyzing the reaction on the assumption that selectivity is determined only by the terminal residue with which the anhydride reacts. Thus in dimethylformamide solution we have

$$\text{Rate} = -\frac{d[A]}{dt} = k_2[A][I]$$

Since we wish to consider the effect on the rate of varying amounts of L- and D-anhydride ($[A_L]$ and $[A_D]$) but keeping their sum constant, we shall use mole fractions, denoted by primes. Thus

$$[A_L'] = [I_L']$$
$$[A_D'] = [I_D']$$
$$[A_D'] + [A_L'] = 1$$
$$[I_D'] + [I_L'] = 1$$
$$\text{Rate} = k'([I_D']^2 + [I_L']^2) + 2k''([I_D'][I_L'])$$

Where

$[I_D']$ = Mole fraction of polymer ending in D-residues
k' = Propagation constant for reaction between D-anhydride and polymer molecule ending in D-residue
k'' = Propagation constant for reaction between D-anhydride and polymer ending in L-residue

The dependence of the rate (and therefore the observed rate constant) on the composition of optical isomer is quadratic. Introduction of a new variable z such that $[I_L'] = z + 0.5$ leads to the simpler form

$$\text{Rate} = z^2(2k' - 2k'') + 0.5(k' + k'')$$

This expression is shown in Fig. 8 as the solid line for $k'' = 0$ (or the case where no cross-reaction exists). The values in Table VII are also plotted. It is rather surprising to find that the experimental points fall consistently below the line, whereas for any positive value of k'' they should fall above this calculated line.

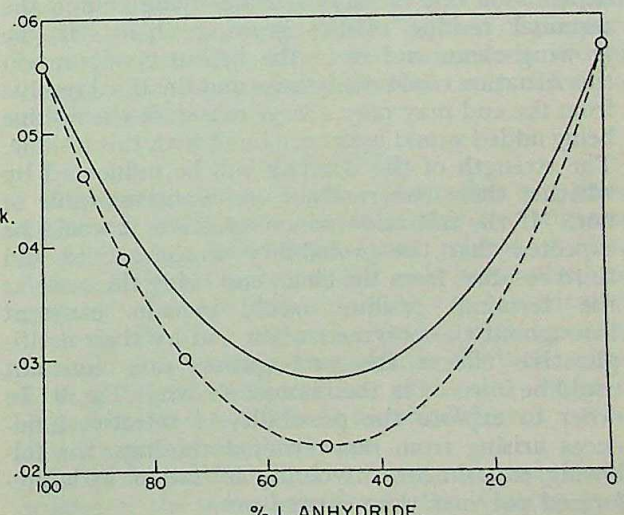

Fig. 8.—Propagation constants obtained in dimethylformamide at [A]/[I] = 20 as a function of varying D- and L-anhydride compositions. The solid line is calculated assuming L-anhydride does not react with polymer ending in D-residues (absolute preference).

The data may be treated more quantitatively by taking the log of the above expression together with the experimental points as shown in Fig. 9. The experimental points are seen to fall on a straight line within probable experimental error and this line is below the theoretical one for complete selectivity.

It is apparent therefore, that the rate constants obtained do agree with the interpretation that this polymerization is preferential with respect to the optical isomers. A complication is presented, however, in that the rate constants are lower than the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

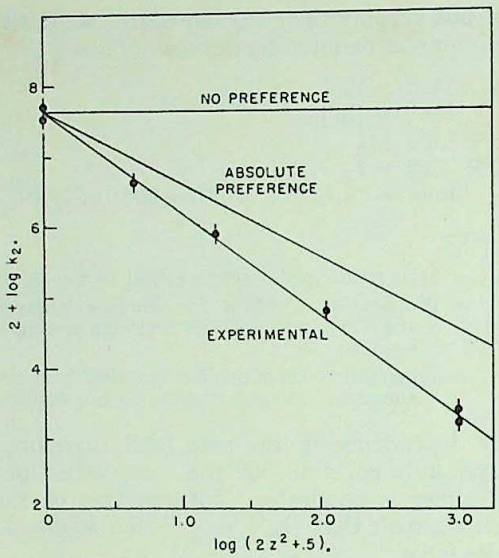

Fig. 9.—Quantitative treatment of data in Table VII according to equations in text.

minimum possible for a preferential reaction of the type assumed. Consequently, the assumption that the selectivity of this reaction is due only to interaction between the anhydride and the last residue in the chain is seen to be an invalid one. The most reasonable alternative seems to be that selectivity depends on one or more residues lying behind the terminal residue of the growing chain. If the growing chain end is in the helical configuration this situation could easily arise and the third residue from the end may play a large role since the residue being added would hydrogen bond with this residue. The strength of the bonding will be influenced by whether these two residues are enantiomorphic or not. If the initiation is non-selective, it would be expected that the probability of the second and third residues from the chain end being the same as the terminal residue would remain constant throughout the polymerization and by their multiplicative effects the propagation rate constant could be lowered in the manner shown in Fig. 9. In order to explore the possibility of selective influences arising from non-terminal residues, the following experiments involving initiation with preformed polymer were carried out.

The Polymerization of Racemic and Enantiomorphic N-Carboxy-anhydride by Preformed Polypeptide.—The polypeptide used for initiation was that made in dimethylformamide at [A]/[I] equal to 20 from L-anhydride. Consequently, it had a narrow molecular weight distribution and was predominantly in the helical configuration[10] when employed as initiator in dimethylformamide solution. Equal aliquots of this initiating polymer were added to solutions of L-, D- and DL-anhydride in such proportion that an average of 12 residues would be expected to add to each initiating chain. The results are shown in Fig. 10. It is seen that the L-anhydride continues to react at about the same rate as the initiating L-polymer. In the DL-anhydride case the reaction initially has a rate somewhat slower than in the L-anhydride case and then the rate decreases before half of the anhydride has been consumed. This is the behavior which would be anticipated from the earlier observations on the amine initiated case. That is, initially the L-anhydride present would be consumed more rapidly than the D-anhydride and as it is depleted, the rate, calcu-

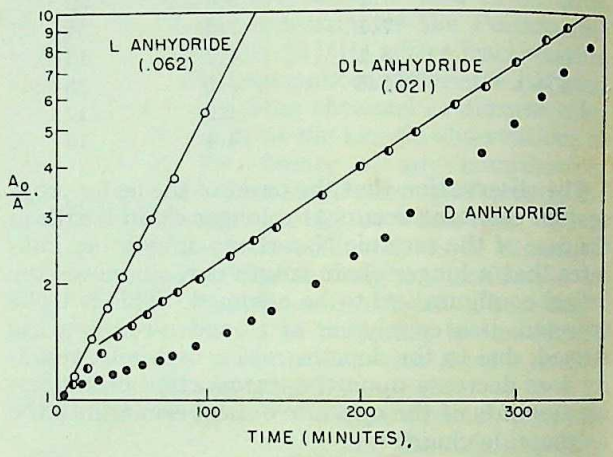

Fig. 10.—Initiation by aliquots of preformed polymer (DP = 20 of polybenzyl-L-glutamate on L (○), DL (◐), and D (●), carboxy-anhydrides of γ-benzyl-glutamate in dimethylformamide; $[A_0] = 0.058$; $[I] = 0.0048$.

lated on the basis of total anhydride concentrations, would be expected to fall. Meanwhile, one would expect the D-anhydride to be gradually added to the growing chains. The result would be an autocatalytic one according to the equation

$$-\frac{d[A_D]}{dt} = k''[A_D][I_L] + k'[A_D][I_D]$$

Since $k'' < k'$, the rate should increase as the more reactive species I_D is produced. The observed behavior is qualitatively similar to this expectation. However, the initial portion of the curve is nearly linear and has a rate constant of *ca.* 0.011 or about $^1/_5$ of that for the reaction of the pure isomer. The apparent linearity over this region is interpreted as meaning that several D-residues must add to the L-polymer before the period of autocatalysis begins.

A possible explanation for this behavior can be obtained from following the same polymerization by optical rotation. Such a study conducted in dioxane solution is shown in Fig. 11. Here equal amounts of L-, DL- and D-anhydride have been initiated by L-polymer.

The addition of L-anhydride ($[\alpha]^{25}D$ −16°) to L-polymer ($[\alpha]^{25}D$ +10) causes the optical rotation to increase continuously throughout the reaction.

The addition of DL-anhydride produces a large increase in the optical rotation because the DL-helix thus formed has a preferred screw sense in the same direction as the initiating polymer and this contributes a large positive rotation.[13]

In the case of the addition of D-anhydride, the first residues to add do so in the same helix sense as that of the initiating L-polymer. Measurement of the number of moles of CO_2 given off at the time of the maximum in the curve indicate that an average of about 4 peptide units have added to each L-polymer chain at this point. The optical rotation of a racemic helix directed in one screw sense at this wave length has been measured and found to be large and

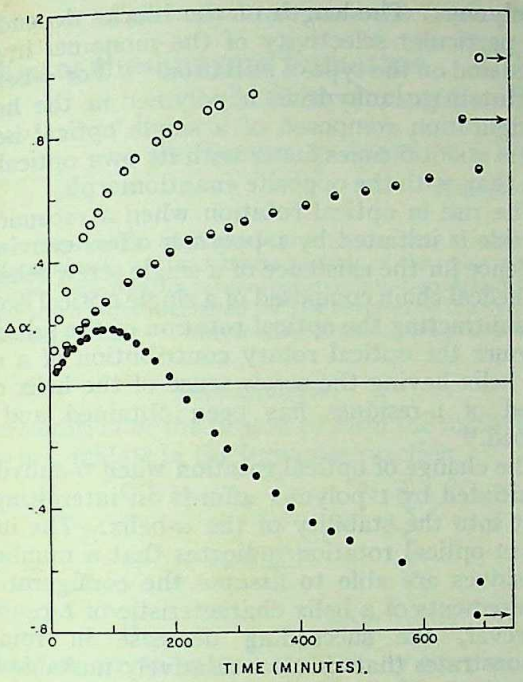

Fig. 11.—The change in optical rotation of L(○), DL (◐), and D (●), carboxy-anhydride of γ-benzyl-glutamate during polymerization initiated by aliquots of an L-polymer; $[A_0] = 0.076$; $[I] = 0.0034$; polarimeter tube length 20 cm.

positive.[13,19] The intrinsic residue rotation of D-peptide units is also large and positive.[19] The additive nature of these two effects is evidently what makes it possible to observe the increase in rotation at all. The fall in rotation after the maximum has been reached indicates that after sufficient D units have added the helix sense is inverted and the helix characteristic of D-peptides is formed, the mirror image of the L-peptide helix. This same behavior has been observed in dimethylformamide solution.

These results are consistent with the hypothesis that D-anhydride reacts more rapidly with a polymer chain characteristic of D-peptide residues. It is apparent that a number of these must exist in a sequence (at least 4) before this configuration can be realized, and the rate of the pure isomer obtained.

To summarize, the effect of the opposite enantiomorph on the reaction rate is seen to be greater than can be expected if it is assumed that only the last residue of a growing chain exerts selectivity. The most probable explanation is based on the steric influences of residues further removed, and these would be relatively large if the polymer configuration were helical.[13] The existence of this configuration under the reaction conditions has been amply demonstrated above, and elsewhere.[10,18]

In dimethylformamide a single propagation rate is observed for the L-isomer of γ-benzyl-glutamate anhydride (Fig. 12). On the basis of the above hypothesis there should be a perceptible difference in rate for the racemic anhydride corresponding to whether the growing chain is helical or not. Because of the additional interference of peptide residues further removed from the last one in a growing chain, it would be predicted that the rate should be less in the region where the helix exists as the stable configuration. Therefore at an [A]/[I] of 20 two rates should be perceptible for the racemic anhydride. Such an effect is detectable in Fig. 12, where a rate corresponding to $^3/_5$ that of the pure isomer obtains for the first 25–30% of the reaction, and then a lower rate prevails ($^2/_5$) that of the pure isomer). However, the small magnitude of the change between the rates precludes any definitive test of the hypothesis.

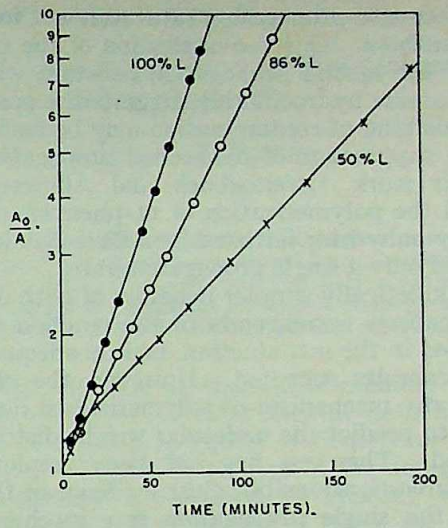

Fig. 12.—Initiation by *n*-hexylamine in dimethylformamide on N-carboxyanhydrides of γ-benzyl-glutamate with various percentages of D- and L-isomers present: 100% L (●), 86% L (○), 50% L (X); $[A_0] = 0.152\ M$; $[I] = 0.0076$.

Discussion

Relation to Other Work.—The rather surprising nature of the kinetic results of this investigation invites comparison with other related studies. Actually there appear to be only two other examinations of the kinetics of this polymerization that are relevant: others have dealt with sarcosine N-carboxy-anhydride, the polymer of which cannot form a helical configuration, and other types of initiation which give rise to a quite different mechanism than that explored here.

Ballard and Bamford[7,14] have reported kinetic studies of the polymerization of the N-carboxy-anhydride of γ-benzyl-L-glutamate in dioxane ($k_2 = 0.022$) and in nitrobenzene ($k_2 = 0.070$) and of DL-leucine in nitrobenzene ($k_2 = 0.042$). In all these cases they have found a behavior that is essentially that of a single propagation constant with occasional mild increases in rate toward the end of the reaction which they attribute to autocatalysis. The rate constants they find are intermediate between the k_{2a} and k_{2b} values we have reported above. These authors place great emphasis on the need of eliminating moisture but it seems unlikely that this can play any role in our results because of the absence of polymerization in blank experiments and the finding of a higher DP than expected, not a lower one that would result from introducing more initiating centers. Thus we find agreement in the magnitude of our rate constants with those of Ballard and Bamford but sharp difference in that

two successive propagation rates were not found by these authors. Our demonstration of the elimination of the second propagation constant with sufficient amine hydrochloride suggests the possibility that this kind of contamination may be responsible for the suppression of the second propagation rate in their work. Breitenbach and Allinger[5] have studied the polymerization of DL-phenylalanine N-carboxy-anhydride initiated by a diethylamide, and reported only a single propagation rate.

The kinetically simpler behavior of both of these investigations corresponds to the reaction scheme described in the introduction, and its adequacy has been generally accepted. However, the ultimate test of any mechanism of polymerization lies in its ability to predict the molecular weight distribution obtained. This test has not been employed in earlier investigations but clear evidence of the failure of the single propagation rate mechanism is contained in the work of Blout and Karlson[9] who found that the DP_w did not vary in the predicted manner with the anhydride–initiator ratio. The demonstration of the existence of a broad molecular weight distribution[10] then became the basis of the starting point of this investigation.

Whether the contrast between the experimental findings of this work and that of other investigators is a function of the particular amino acid used, its non-racemic nature, the purity of the anhydride, or other undetermined factors, is not clear. *However, the consistent reproduction of the results reported herein, the abnormally broad molecular weight distribution, the suppression of this anomaly by careful selection of solvent, or by deliberate addition of an impurity, and the infrared spectral studies on both the rate and products*[18] *provide clear and consistent support for the contention that two successive propagation rates do exist for this polymerization.*

The dependence of these propagation rates on the anhydride–initiator ratio leads to the presumption that the two propagation rates are a development of the configurational change occurring in solution. Independent infrared spectral evidence has been presented[18] to support this postulate.

Role of Optical Isomers in the Polymerization.—The effect of the enantiomorph on the rate of the polymerization has been investigated very little. The evidence presented above demonstrates the presence of a rather large selectivity in the reaction. Therefore the product of the polymerization of racemic N-carboxy-anhydrides is not a polymer composed of randomly mixed D- and L-peptide residues, but approaches very closely that of a block copolymer. The length of the blocks depends on the particular selectivity of the monomer investigated and on the type of initiation.[20] For γ-benzyl-DL-glutamate anhydride a polymer in the helical configuration composed of a single optical isomer reacts about 5 times faster with its own optical isomer than with the opposite enantiomorph.

The rise in optical rotation when a racemic anhydride is initiated by L-polymer offers convincing evidence for the existence of a single screw sense for the helical chain composed of a single optical isomer. By subtracting the optical rotation of the initiating polymer the optical rotary contribution of a racemic helix having the screw sense of the helix composed of L-residues has been obtained and described.[19]

The change of optical rotation when D-anhydride is initiated by L-polymer affords an interesting insight into the stability of the α-helix. The initial rise in optical rotation indicates that a number of D-residues are able to assume the configurational requirements of a helix characteristic of L-residues. However, the succeeding decrease in rotation demonstrates that this is a relatively unstable configuration. If the eventual breakup of the helical configuration is assumed to be due to side chain steric repulsion, it can be shown that maximum repulsion is attained when the L-peptide residues are in a right-handed helical sense. In this structure the side chains are directed along the chain such that L- and D-groups would interfere when a block polymer of L and D-residues is prepared. The existence of a left-handed helix for L-residues would result in the side chains being directed in opposite directions for the two residues with a consequent loss of interference. Therefore the helical breakup affords additional indirect evidence that L-peptide residues exist in a helix of right-handed screw sense as first suggested by Perutz.[21]

Acknowledgment.—We are pleased to acknowledge as a gift the N-carboxy-anhydrides used herein from Dr. E. R. Blout and Mr. Roy Karlson. We also would like to acknowledge the help and advice of Dr. J. T. Yang and Mr. J. C. Mitchell, one of whom (J.C.M.) was responsible for many of the molecular weight measurements reported. Studies of the Enzyme Fumarase. VI.[1] Study of the Incorporation of Deuterium into L-Malate during the Reaction in Deuterium Oxide[2,3]

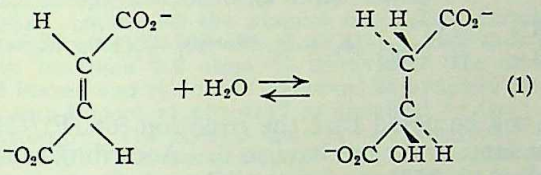
BY ROBERT A. ALBERTY, WILMER G. MILLER AND HARVEY F. FISHER

RECEIVED JANUARY 28, 1957

The incorporation of deuterium into L-malate during the dehydration to fumarate by fumarase in deuterium oxide has been determined. After various periods of time the reaction was stopped and the L-malate analyzed for non-exchangeable deuterium. Deuterium is incorporated into L-malate more slowly than fumarate is produced, and the rate is in quantitative agreement with that expected for the reversal of the over-all reaction. In order to explain the absence of exchange and of a deuterium rate effect it is necessary to introduce a further intermediate into the mechanism of the fumarase reaction.

Introduction

The addition of the proton to form the methylene group in L-malate in the fumarase reaction



(1)

has been shown to be stereospecific by carrying out the reaction in deuterium oxide.[4] The L-malate which is formed by the action of pig heart fumarase contains one atom of deuterium in the methylene group. Since the hydroxyl deuterium exchanges rapidly with an aqueous medium, and is always exchanged out before analysis for deuterium, the product will be referred to as monodeutero-L-malate. By use of nuclear magnetic resonance experiments at low temperatures it has been possible to show that the two protons in the monodeutero-L-malate are in the gauche position in solid L-malic acid.[5] When the monodeutero-L-malate was dehydrated enzymatically in ordinary water it was found that both the maximum initial velocity and the Michaelis constant are the same as for ordinary L-malate. If the breaking of the methylene carbon–hydrogen bond were rate determining, substitution of deuterium for the hydrogen would be expected to produce a decrease in rate of approximately two to sevenfold.[6,7] The absence of deuterium rate effect in the dehydration of monodeutero-L-malate suggests that there might be an exchange of this specific hydrogen atom with hydrogen atoms of the medium proceeding at a rate considerably faster than that of the dehydration reaction. Usually an exchange reaction is studied in the absence of an over-all reaction so that there is only a "virtual" reaction.[8] If in the present case we started with an equilibrium mixture of fumarate and L-malate in D_2O it would be difficult to detect a slow direct exchange of a methylene hydrogen of L-malate with the medium because the amount of exchange would be obtained from the experimental data by subtraction of the incorporation of deuterium due to reaction 1. Greater sensitivity in the detection of direct exchange is obtained by starting with L-malate in D_2O. A correction is made for the incorporation of deuterium into L-malate in the hydration of the fumarate produced by the use of equations recently derived for first-order reactions.[9]

Theory

A considerable simplification in the calculation of the deuterium incorporation into L-malate by the reverse reaction is made possible by carrying out the reaction under conditions where the approach to equilibrium is first order.

$$\mathrm{M} \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \mathrm{F}\ (+\mathrm{H_2O}) \qquad (2)$$

If only L-malate is initially present

$$\ln \frac{(\mathrm{M})_0 - (\mathrm{M})_{eq}}{(\mathrm{M}) - (\mathrm{M})_{eq}} = \ln \frac{(\mathrm{F})_{eq}}{(\mathrm{F})_{eq} - (\mathrm{F})} = (k_1 + k_2)t = 0.693t/t_{1/2} \qquad (3)$$

where $(\mathrm{M})_0$ is the initial concentration of L-malate, $(\mathrm{M})_{eq}$ is the equilibrium concentration and (M) is the concentration at time t. The concentrations used throughout are total molar concentrations without regard to the extent to which the weak acids exist in various ionized forms. The second form of the logarithmic term comes from the fact that $(\mathrm{M})_0 = (\mathrm{M}) + (\mathrm{F}) = (\mathrm{M})_{eq} + (\mathrm{F})_{eq}$. The first-order rate constants k_1 and k_2, which for the enzymatic reaction are directly proportional to the enzyme concentration, may be calculated from a plot of $\log [(\mathrm{F})_{eq} - (\mathrm{F})]$ *versus* t, and the apparent equilibrium constant for reaction 2.

$$K_{app} = \frac{(\mathrm{F})_{eq}}{(\mathrm{M})_{eq}} = \frac{(\mathrm{F})_{eq}}{(\mathrm{M})_0 - (\mathrm{F})_{eq}} = \frac{k_1}{k_2} \qquad (4)$$

It is shown[10] readily that for mechanisms of the type

$$\mathrm{M} + \mathrm{E} \rightleftharpoons \mathrm{X_1} \rightleftharpoons \mathrm{X_2} \rightleftharpoons \cdots \rightleftharpoons \mathrm{F} + \mathrm{E} \qquad (5)$$

where E represents the enzymatic site and X_1, X_2, . . . are intermediates, the over-all reaction will be pseudo first order under conditions where the Michaelis constants for the forward and reverse re-

actions are equal.[11] This statement applies under conditions where $(E)_0 << (M)_0$ and the time required to reach the steady state is negligible. Fortunately, conditions under which the Michaelis constants for the two substrates are equal can be achieved experimentally.[12,13] Carrying out the reaction under first-order conditions does not lead, of course, to any actual simplification of the mechanism but just to a simpler calculation of the fraction of L-malate present at any time that has been formed by the reverse reaction. The integrated rate equation[14] for mechanism 5 shows that the pseudo first-order rate constants k_1 and k_2 in equation 3 are proportional to enzyme concentration and are functions of the initial concentration of L-malate.

When the over-all reaction is carried out under pseudo first-order conditions in D_2O, the incorporation of deuterium through the reversal of the forward reaction may be represented by

$$\mathrm{M} \underset{k_2(\mathrm{T})}{\overset{k_1}{\rightleftharpoons}} \mathrm{F} \underset{k_1}{\overset{k_2(\mathrm{T}^*)}{\rightleftharpoons}} \mathrm{M}^* \qquad (6)$$

where M* is L-malate with deuterium in the specific methylene position, and (T) and (T*) are the mole fractions of the two isotopically different forms of the solvent. Thus (T) + (T*) = 1. The use of k_1 for the specific rate constant for the dehydration of both M and M* is justified by the absence of any isotope rate effect.[4] Since (T*) >> (T) in the experiments to be considered, the fact that F may react with H_2O and D_2O at somewhat different rates in the same solution would not introduce an appreciable error in these calculations.

The integrated rate equations for reaction 6 for the boundary condition (M) = $(M)_0$, (F) = 0, and (M*) = 0[15] at $t = 0$ are[9]

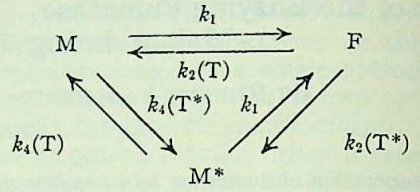
$$\frac{(M)}{(M)_0} = \frac{(T)}{(k_1 + k_2)} [k_2 + k_1 e^{-(k_1+k_2)t}] + (T^*)e^{-k_1 t} \qquad (7)$$

$$\frac{(F)}{(M)_0} = \frac{k_1}{(k_1 + k_2)} [1 - e^{-(k_1+k_2)t}] \qquad (8)$$

$$\frac{(M^*)}{(M)_0} = \frac{(T^*)}{(k_1 + k_2)} [k_2 + k_1 e^{-(k_1+k_2)t}] - (T^*)e^{-k_1 t} \qquad (9)$$

Once the values of k_1 and k_2 have been obtained from studies of the over-all reaction, the concentration of deutero-L-malate, M*, expected from mechanism 6 may be calculated for any time. There is an induction period in the formation of M* which arises initially as a function of t^2.

If deuterium is incorporated into the specific methylene position of L-malate by an additional process, for example by a rapid exchange of an intermediate with the medium, the first-order rate constant of this additional process is represented by the value of k_4 in



(10)

The integrated rate equations for this mechanism are[9]

$$\frac{(M)}{(M)_0} = \frac{(T)}{(k_1 + k_2)} [k_2 + k_1 e^{-(k_1+k_2)t}] + (T^*)e^{-(k_1+k_4)t} \qquad (11)$$

$$\frac{(F)}{(M)_0} = \frac{k_1}{(k_1 + k_2)} [1 - e^{-(k_1+k_2)t}] \qquad (12)$$

$$\frac{(M^*)}{(M)_0} = \frac{(T^*)}{(k_1 + k_2)} [k_2 + k_1 e^{-(k_1+k_2)t}] - (T^*)e^{-(k_1+k_4)t} \qquad (13)$$

It will be noted that the equation for $(F)/(M)_0$ is the same as for mechanism 6. According to mechanism 10, M* appears initially as a linear function of time.

Procedure

The reactions were carried out in deuterium oxide[16] solutions containing potassium succinate which acted as a buffer and provided a convenient dilution of the D_2O obtained by burning the dry sample. The potassium succinate, prepared from Merck succinic acid (m.p. 185–187°), contained less than 0.01 mole % fumarate as determined spectrophotometrically by treatment with fumarase. Succinate acts as a competitive inhibitor of fumarase and so it does combine with the enzymatic site, but investigation showed that fumarase does not catalyze the exchange of the hydrogen atoms of succinate with the medium under the conditions of the present experiments. The L-malic acid was obtained from the Pfanstiehl Chemical Company and was recrystallized from ethyl acetate.[17] Absorbancy measurements at 250 mμ showed that the L-malate preparation contained less than 0.03 mole % fumarate. If malic acid absorbs at all at this wave length, the percentage of fumarate impurity is less than 0.03%.

In view of the importance of the observation[4] that deutero-L-malate is dehydrated enzymatically at the same rate as ordinary L-malate when a rather large effect might be expected,[6,7] this rate experiment was repeated. Monodeutero-L-malate prepared enzymatically was purified by partition chromatography,[18] using a 35% butanol–65% chloroform mixture as the flowing phase and 0.5 *N* sulfuric acid supported on Hyflo Super-Cel as the stationary phase. The Michaelis constants in ordinary water obtained using 0.05 *M* phosphate buffer of *p*H 7.3 were 2.2 m*M* for ordinary L-malate and 2.7 m*M* for the deutero-L-malate. The ratio of the maximum initial velocities in H_2O for the normal to the deutero compound was 0.94, which is equal to unity within the experimental error in conformance with the earlier result.[4]

The solutions for the exchange experiments were prepared by dissolving L-malic acid and potassium succinate in D_2O, titrating to the desired *p*H with potassium hydroxide dissolved in D_2O, and finally diluting to the desired concentration. The *p*H values of the D_2O solutions determined with a Beckman Model G *p*H meter cannot be given to simple interpretation, but it was noted that they are very nearly equal to the *p*H values obtained after reconstituting the dried reaction mixtures in ordinary water at 25°.

(11) W. E. Lands and C. Niemann, This Journal, **77**, 6508 (1955), have shown that an enzymatic reaction which goes to completion is pseudo first order if the competitive inhibition constant for the product is equal to the Michaelis constant for the substrate.

Fumarase crystallized from pig heart muscle extract by the method of Frieden, Bock and Alberty[19] was used in these experiments. The reaction was started by the addition of enzyme which had been diluted to the desired concentration in 99.5% D_2O. The reaction mixture was placed in cuvettes in a Beckman DU spectrophotometer, and the absorbancy was recorded at one minute intervals at 300 mμ. The spectrophotometer was equipped with thermospacers held at 25 ± 0.3° by water circulated from a thermostat.

In order to stop the reaction at appropriate times 3-ml. aliquots of the reaction mixture were pipetted into 3 ml. of boiling ethyl alcohol. The samples were evaporated to dryness on a steam-bath and the ionizable deuterium was exchanged out by redissolving the samples three times in 3 ml. of water and each time evaporating to dryness. Finally the samples were dried at 35° in a vacuum oven. Blanks were run to determine the rate of non-enzymatic incorporation of deuterium into L-malate and succinate during the reaction period and during the evaporation on the steam-bath. These blanks were found to contain the normal isotopic abundance of deuterium.

Before combustion the samples containing appreciable deuterium were diluted with malic acid so that they contained less than 0.8 atom % deuterium. The samples were burned and the water converted to hydrogen by use of a zinc furnace at 410–414° as described by Graff and Rittenberg.[20] The H_2–HD samples were analyzed with a Consolidated mass spectrometer.[21] The normal abundance of deuterium in the L-malate used was found to be 0.012 atom per cent.

The fumarase concentration was determined at various times during the reaction by diluting 0.1 ml. of the reaction mixture to 4.1 ml. in ordinary water containing 0.05 M L-malate and 0.05 M phosphate buffer of pH 7.3. The turnover number for the enzyme under these conditions[17] is 10^5 min.$^{-1}$. The initial steady-state rate was determined using a DUR spectrophotometer.[12]

Experimental Data

A plot of the apparent first-order rate constant according to equation 3 is given in Fig. 1 for experiment B over a period of eight half-lives. The fact that the plot has a slope of 5×10^{-4} min.$^{-2}$ M rather than a zero slope, as would be expected for a first-order reaction, indicates that under these conditions the Michaelis constants for the forward and reverse reactions are not quite equal. The deviation from first-order behavior is small enough to be negligible. The rate constants calculated from equations 3 and 4 are $k_1 = 0.107$ min.$^{-1}$ M and $k_2 = 0.024$ min.$^{-1}$ M for this enzyme concentration which is 3.3×10^{-7} M. Therefore, the first-order constants for one molar enzyme are

$$k_1' = (0.024 \text{ min.}^{-1} M)/(3.3 \times 10^{-7} M)(60) = 1.2 \times 10^3 \text{ sec.}^{-1}$$

$$k_2' = (0.107 \text{ min.}^{-1} M)/(3.3 \times 10^{-7} M)(60) = 5.3 \times 10^3 \text{ sec.}^{-1}$$

Under conditions where the Michaelis constants for the forward and reverse reactions are equal, the integral equation[14] for mechanism 5 reduces to

$$\ln \frac{(F)_{eq}}{(F)_{eq} - (F)} = \frac{V_M + V_F}{K_M + (M)_0} t \qquad (14)$$

where V_M and V_F are maximum initial velocities for L-malate and fumarate as substrate and K_M is the Michaelis constant for L-malate. Since in the present experiments $(M)_0 >> K_M$, k_1' above would be interpreted as $V_M/(M)_0$ and k_2' as $V_F/(M)_0$. The experimental values of k_1' and k_2' are slightly smaller than would be expected from the values of V_F and V_M for phosphate and tris-(hydroxymethyl)-aminomethane buffers.

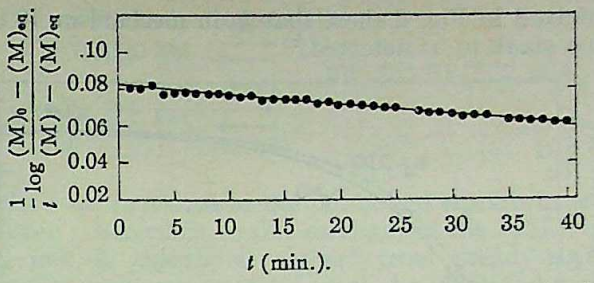

Fig. 1.—Plot of kinetic data for the fumarase reaction in D_2O at 25°. The reaction mixture contained 0.952 M potassium L-malate, 0.952 M potassium succinate and had a pH of 5.8 when reconstituted in H_2O.

The fractions of total substrate deuterated at various times are given for two experiments in Table I. For experiment A the pH of the reaction mixture reconstituted in ordinary water was 6.6 at 25° and for experiment B was 5.8. In experiment A the initial concentrations of potassium L-malate and potassium succinate were each 0.1 M. The enzyme concentration was such that the half time ($t_{1/2}$) for the over-all reaction was 21.8 min., and samples were taken for analysis after 3.7 and 40 min. In experiment B the initial concentrations of potassium L-malate and potassium succinate were each 0.0952 M. The half-time for the over-all reaction was 5.25 min., and the reaction was stopped in samples for analysis 2, 10, 25, 75, 226 and 291 minutes after addition of fumarase. The calculated values of the fractions of the substrate which are expected to be deutero-L-malate were obtained using mechanism 6 and equation 9, letting $k_1 = 1$, $k_2 = 4.55$, (T) = 0.03, and (T*) = 0.97. The time variable in equation 9 is a generalized time τ and is determined by correlation with the half-time of the fumarate to L-malate reaction. The error in measuring the equilibrium constant causes most of the uncertainty in the calculated values, since the values for k_1, k_2 and the relationship between the generalized time τ and the experimental half-times are dependent upon the equilibrium constant. The experimental data

plotted in Fig. 2 show that k_4 in mechanism 10 is too small to be detected.[22]

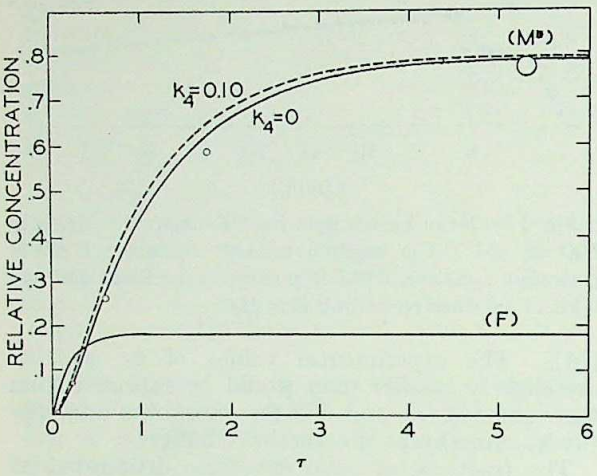

Fig. 2.—Relative concentrations of fumarate and monodeutero-L-malate as a function of generalized time. The lines are calculated using equations 8 and 9 letting $k_1 = 1$, $k_2 = 4.55$, (T) = 0.03 and (T*) = 0.97. The dashed line shows the relative concentration of monodeutero-L-malate expected if k_4 in mechanism 10 is 0.10 (calculated with equation 13).

The concentration of active enzyme is given in Table II as a function of time for experiment B.

TABLE II

CONCENTRATION OF ACTIVE ENZYME AS A FUNCTION OF TIME

Time (min.)	Molar concn. of active enzyme × 10^7	Time (min.)	Molar concn. of active enzyme × 10^7
18	3.7	131	3.3
48	2.9	279	3.3
81	3.3		

Av. = 3.3×10^{-7} M

The concentration of active enzyme as determined by the standard assay remained constant within the experimental accuracy during the entire reaction period.

The apparent equilibrium constant for the fumarase reaction defined by equation 4 has been determined earlier[23] as a function of ionic strength, pH and temperature. Since the values in heavy water are required in this research they have been determined at 99.5% D_2O. At 25°, pH values from 5.8 to 7.5 and ionic strengths up to 0.4, the equilibrium constant is approximately 5% lower than the corresponding values for ordinary water. In this connection it is interesting to note that the equilibrium constant for the hydrolysis of ethyl acetate is the same in D_2O and H_2O.[24]

Table III gives the molar absorbancy indices of dipotassium fumarate in D_2O at 25° and also the ratios of the absorbancy indices determined for D_2O and H_2O solutions.

(22) This conclusion is in contradiction with that reached in preliminary experiments[4] in which only very small extents of reaction were used.

260	805	.95			

Discussion

The observed concentration of monodeutero-L-malate is in good agreement with that calculated for mechanism 6. Actually all that can be done experimentally is to set a maximum value for k_4 in mechanism 10. The dashed line in Fig. 2 for $k_4 = 0.10$ shows that if exchange accompanies the over-all reaction, the value of k_4 must be less than a tenth the value of k_1. Since no exchange has been detected the carbon–hydrogen bond must be formed in a step preceding the rate-determining step, or in the rate-determining step, in the hydration of fumarate. Since there is no isotope rate effect, the carbon–hydrogen bond must be formed in a step preceding the rate-determining step. Earlier kinetic calculations[1] had shown that the dissociation of fumarate from the enzyme is not the rate-determining step in the dehydration of L-malate. If this were not true it would be expected that an appreciable value of k_4 would have been obtained in the present experiments. Englard and Colowick[25] have obtained results showing that deuterium is incorporated into citrate under the action of aconitase *via* the process: citrate → aconitate ⇄ labeled citrate.

The significance of the absence of both a deuterium rate effect and exchange in the fumarase reaction may be discussed with reference to the possibilities indicated in Table IV.[26] These are the general types of simple mechanisms which might be followed by the fumarase reaction. The abbreviations HCCOH, C=C and $^-$CCOH represent the enzyme–substrate complexes and intermediates in the reaction from which the indicated ions, H^+ or OH^-, have been removed. The HCCOH intermediate dissociates to produce free enzyme and L-malate, while the C=C intermediate dissociates to produce free enzyme and fumarate. The fact that no deuterium rate effect and no exchange are observed would appear to eliminate a concerted mechanism[27] and indicates that the reaction follows a mechanism of the first type. Thus in order to account for these observations it has been necessary to introduce a further intermediate into the mechanism for the fumarase reaction. Thus the earlier representation[28] of the intermediates which were required to account for the effect of pH on the forward and reverse reactions may be extended as shown in Fig. 3. According to this mechanism the acid dissociation constants for EM obtained as described in the preceding article in this series would

(3)	slow	fast	Yes	No
(4)	fast	slow	No[a]	Yes
Concerted mechanism				
(5)	$HCOOH \rightleftharpoons H^+ + C{=}C + OH^-$		Yes[b]	No

[a] Isotope effects on equilibria would be expected to be too small to show up in measured rates. [b] A smaller isotope rate effect than the "normal" might be expected.

be those for the enzyme-L-malate complex, but those for EF would be a weighted average of the acid dissociation constants for the two intermediates shown on the left. The movement of the positive charge on RH^+ to the dicarboxylic acid in the new intermediate may be the cause of the acid strengthening of K_{aEF} over K_{aE} which is found experimentally and which stands in contrast with the acid weakening caused by the binding of L-malate.

The data of Table I are further evidence for the absence of even a small effect of the substitution of deuterium for hydrogen on the rate of dehydration of L-malate. If ordinary L-malate were dehydrated faster than the monodeutero-L-malate formed, the concentration of fumarate would go through a maximum which easily could be observed. If the ratio of first-order rate constants for the dehydration of ordinary malate and monodeutero-L-malate was 1.36, a maximum fumarate concentration 10% greater than the equilibrium fumarate concentration would be reached after six half lives for the over-all reaction.

The treatment of the data in terms of mechanisms 6 and 10 is required by the complicated nature of the actual mechanism and the fact that kinetic data can be obtained only in the steady state. The actual mechanism is of the type

$$\left.\begin{array}{l} M + E \underset{}{\overset{}{\rightleftharpoons}} EM \overset{\text{slow}}{\rightleftharpoons} \\ M + E \underset{}{\overset{}{\rightleftharpoons}} EM^* \overset{\text{slow}}{\rightleftharpoons} \end{array}\right\} EX \rightleftharpoons EF \rightleftharpoons E + F \qquad (15)$$

where the reactions in the unmarked equilibria are faster. According to this mechanism the values of k_3 and k_4 calculated earlier[1] from steady-state studies over a range of pH would be identified with the rate constants for EM $\rightleftarrows$ EX rather than EX $\rightleftarrows$ EF. It is necessary to postulate an intermediate EX in order to explain the absence of an isotope rate effect and of exchange. The branch in the mechanism is placed at EX because if EM could exchange with D_2O to give M*, there would be no induction period in the formation of M*. If the branch was placed at EF it would be necessary to introduce a further intermediate to keep the mechanism symmetrical with respect to M and M*. Speyer and Dickman[29] believe that the aconitase reaction follows mechanism 14 and have suggested that EX contains a "bound" carbonium ion.

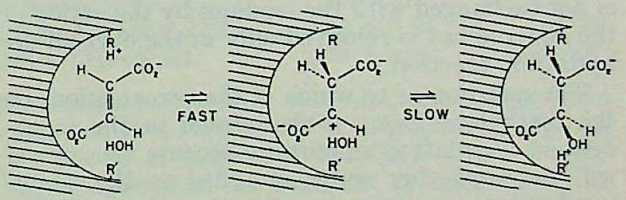

Fig. 3.—Structures of intermediates in the fumarase reaction suggested by the study of the effect of pH on the kinetics and the absence of a deuterium isotope rate effect or exchange.

On the basis of the mechanisms in Table IV it is predicted that L-malate containing O^{18} in the hydroxyl group would not show exchange during dehydration but that there should be an isotope rate effect. This prediction is being tested.

Acknowledgment.—The authors are indebted to Professor E. L. King for helpful discussions and to Drs. Raymond G. Wolfe, Jr., and Nehemia Shavit for preparations of crystalline fumarase.

The Mechanism of the Stereospecific Enzymatic Hydration of Fumarate to L-Malate[1]

BY T. C. FARRAR, H. S. GUTOWSKY, R. A. ALBERTY AND W. G. MILLER

RECEIVED FEBRUARY 7, 1957

It is found that the addition of water to the double bond of fumarate occurs in a *cis* manner when catalyzed by the enzyme fumarase from pig heart muscle. This is shown by the configuration of the monodeutero-L-malate formed when the hydration is carried out with deuterium oxide. The configuration of the monodeutero-L-malate was established by observing the dipolar broadening of the proton magnetic resonance absorption in solid DOOCCH(D)C(OD)HCOOD.

Introduction

When the hydration of fumarate to L-malate is catalyzed in deuterium oxide by the fumarase from pig heart muscle, the L-malate which is formed contains one deuterium atom per molecule which is not readily exchangeable with the medium.[2] Since only monodeutero-L-malate is formed in the over-all reaction and the fumarate does not incorporate deuterium, the addition of the deuterium is stereospecific, as is the addition of the OH or OD group. This observation has been confirmed.[3] Further work has shown that the deuterium atom is not exchanged with the medium by the action of the enzyme but is removed only in the over-all dehydration reaction.[4]

The question as to which of the two positions on the methylene group is deuterated in the monodeutero-L-malate is important because the answer will show whether water is added to the double bond of fumarate in a *cis* or *trans* manner. Whereas it frequently is assumed that substrates are bound on the surface of an enzyme, a *cis* addition by fumarase would prove that the entering groups came from the same side, and presumably from that of the protein since their addition is under stereochemical control. The ability of the enzyme to distinguish unerringly between the two hydrogen positions on the methylene group of L-malate may find practical application in the determination of the structure of partially deuterated compounds which may be transformed to malic acid.

The stereospecificity of the diphosphopyridine dehydrogenases already has been investigated.[5] It has been found that the hydrogen transfer catalyzed by the β-hydroxysteroid dehydrogenase[6] and glucose dehydrogenase[7] occurs at the opposite side of the nicotamide ring from that used by the alcohol, lactic and malic dehydrogenases. Therefore, it is not to be assumed that fumarase from other sources would necessarily cause deuterium to be added in the same position as pig heart fumarase.

The question of whether the fumarase catalyzed hydration occurs in a *cis* or *trans* manner can be answered by establishing the steric relation of the fumarate protons on carbons 2 and 3 in the monodeutero-L-malic acid. This is shown schematically in the right-hand portion of Fig. 1. If the hydration occurs in the *cis* manner as depicted in the figure, the protons are gauche to one another. On the other hand, if the hydration is *trans*, then the protons are *trans*. These particular relations hold only if the carboxyl groups are *trans* in L-malic acid, as shown; if the carboxyl groups are gauche, then the proton–proton relations are the reverse of those just given.

X-Ray diffraction studies of succinic and tartaric acids[8] have shown that in the crystalline solids the carboxyl groups are *trans*, and undoubtedly they are also *trans* in crystalline malic acid. Therefore, the only structural feature to be established is whether the protons are gauche or *trans* in the monodeutero-L-malic acid. This type of structural problem is suitable for proton magnetic resonance solid-state methods. The hydroxyl and acidic protons exchange readily with D_2O to give DOOCH(D)C(OD)HCOOD, in which the protons in question are the most important magnetic nuclei. The dipolar broadening of the proton magnetic resonance in the solid depends very largely on the intramolecular proton–proton distance. The broadening is very sensitive to the interproton distance so it is relatively easy to determine unequivocally whether the configuration is *trans* or gauche, as has been done for solid *sym*-tetrachloro- and tetrabromoethane.[9]

Experimental

Preparation of Deutero-L-malic Acid.—Crystalline fumarase obtained from pig heart extract[10] was added to a solution containing 0.2 *M* potassium fumarate and 0.0083 *M* dipotassium phosphate and 0.0017 *M* monopotassium phosphate in 99.5% D_2O[11] and the reaction was allowed to proceed to equilibrium, as determined spectrophotometrically. The reaction was stopped by heating to 90° for 3 minutes and the solution was then lyophilized.

The deutero-L-malate was separated from the 0.18 mole fraction fumarate present at equilibrium by partition chro-

matography as described by Cleland and Johnson[12] with 0.5 *N* HCl replacing 0.5 *N* H_2SO_4 as the stationary phase. Treatment with $AgNO_3$ showed the deuteromalic acid recovered from the eluent to be free of chloride. Aqueous extractions of fractions collected midway between the fumaric acid and deuteromalic acid peaks showed no evidence of either substrate upon addition of concentrated solutions of fumarase, thus indicating that the separation was quantitative. The deuteromalic acid was redissolved three times in 1.5 ml. of 99.5% D_2O and each time lyophilized to dryness to replace exchangeable hydrogen with deuterium.

The resulting compound, DOOCCH(D)C(OD)HCOOD, had a melting point of 97–99° as compared with 103–104° for normal L-malic acid. The change in melting point upon deuteration is in the direction predicted by Schäfer[13] and compares favorably with the lowering of the melting point of succinic acid upon deuteration.[14] The deuteromalic acid contained 0.97 atom of deuterium per molecule in the specific methylene position and about 2.85 atoms of deuterium per molecule in the carboxyl and hydroxyl positions, as determined by mass spectrometric analysis.

Nuclear Magnetic Resonance Apparatus.—The broad line magnetic resonance spectrometer has been described elsewhere.[15] It consists of a self-detecting oscillator, a 30 c.p.s. phase sensitive amplifier and a strip chart recorder. The magnetic field is modulated at 30 c.p.s. with an amplitude a small fraction of the line width. The magnetic field is also swept linearly in time at an adjustable rate of about 3 gauss/min., while the frequency of the oscillator is constant. The system thus records the derivative of the magnetic resonance absorption as a function of applied magnetic field. A permanent magnet with a field strength of 6300 gauss was used in these experiments. The sample was 0.3 g. and was contained in a small, sealed test-tube. Measurements were made at liquid nitrogen temperature with a special cryostat, to improve signal to noise and also to ensure that motional narrowing[16] was unimportant.

Experimental Results and Discussion

The broadening of the magnetic resonance absorption is expressed quantitatively most conveniently by the second moment of the absorption line, *i.e.*, by the mean square deviation of the absorption intensity from the line center. For a crystal powder in which nuclear motions are unimportant, the second moment, ΔH_2^2, is given theoretically[17] by the equation

$$\Delta H_2^2 = \frac{6}{5}\frac{I(I+1)}{N} g^2\beta^2 \sum_{i>k} r_{ik}^{-6} + \frac{4}{15}\frac{\beta^2}{N}\sum_{i,f} I_f(I_f+1)\, g_f^2 r_{if}^{-6}$$

In this equation g is the g-value of the nuclear species observed, in this case the proton, and g_f is the value for other "foreign" magnetic species in the sample. I and I_f are the nuclear spins; r, the internuclear distances; and N is the number of protons considered in the calculation.

Because of the r^{-6} dependence of the broadening, the most important contributions arise from the dipolar interactions within the CHD–CH group. These intramolecular terms can be calculated quite accurately from the molecular structure.

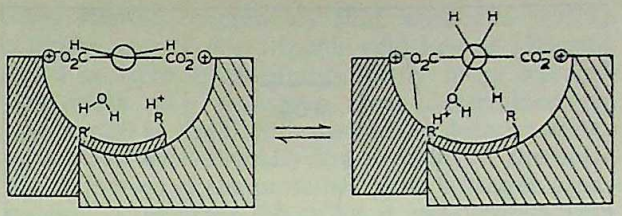

Fig. 1.—Schematic representations of the enzyme–fumarate and enzyme-L-malate complexes for the case of *cis* hydration (*cf.* Fig. 4 of the preceding article[4]).

The results for the *trans* and gauche configurations are summarized in Table I. In the calculations,

TABLE I

VALUES FOR THE SECOND MOMENT OF THE PROTON MAGNETIC RESONANCE CALCULATED FOR THE *trans* AND GAUCHE CONFIGURATIONS OF THE PROTONS IN DOOCCH(D)C(OD)HCOOD

	trans	gauche
CHD–CH: H–H	0.46 gauss^2	1.63 gauss^2
D–H	0.18	0.16
CH_2–CH: H–H	8.90	8.90
Intramolecular	1.02	2.14
Intermolecular	1.4 ± 0.4	1.8 ± 0.5
Effect of CO_2H and OH	−0.16 ± 0.03	−0.3 ± 0.05
Net ΔH_2^2 predicted	2.25 ± 0.5	3.65 ± 0.6

tetrahedral bond angles were assumed and the bond distances used were C–C,[8] 1.50 Å. and C–H, 1.09 Å. The D–H distance in the CHD group is sufficiently short that the resultant broadening of the proton resonance is significant, even though the magnetic moment of deuterium is small. For the same reason, the contribution to the proton second moment from the CH_2 group interactions cannot be neglected even though only 3 mole % of the molecules are CH_2–CH. In calculating this correction, it must be remembered that the relative contributions to ΔH_2^2 of protons in different molecular species depend upon the proton fraction rather than the mole fraction. Thus the contribution of the 3 mole % CH_2–CH is 0.045 × 8.9 gauss.^{2}

An accurate calculation of the other contributions to the broadening requires a knowledge of the crystal structure of malic acid, which does not appear to have been determined. However, an estimate sufficiently good for our purpose can be made by referring to the calculations made[9] for *trans* and gauche $CHCl_2CHCl_2$. The main additional contributions are from the proton–proton interactions between neighboring molecules. Consideration of the crystal structures of succinic and tartaric acids suggests that, as in the *sym*-tetrachloroethane, the intermolecular broadening will be greater for the gauche configuration than for the *trans*, but not by as large a factor. The molar volume of the *sym*-tetrachloroethane is 1.25 that of malic acid, so if all intermolecular distances were reduced proportionally, the intermolecular contribution to the second moment in malic acid would be $(1.25)^2 = 1.5$ times that in the tetrachloroethane. In the latter, the *trans* and gauche intermolecular contributions were calculated to be 0.7 ± 0.2 and 1.4 ± 0.3 gauss.^{2} Using the arguments just outlined, the values for the monodeutero-L-malic acid are estimated to be 1.4 ± 0.4 and 1.8 ± 0.5 gauss.^{2}

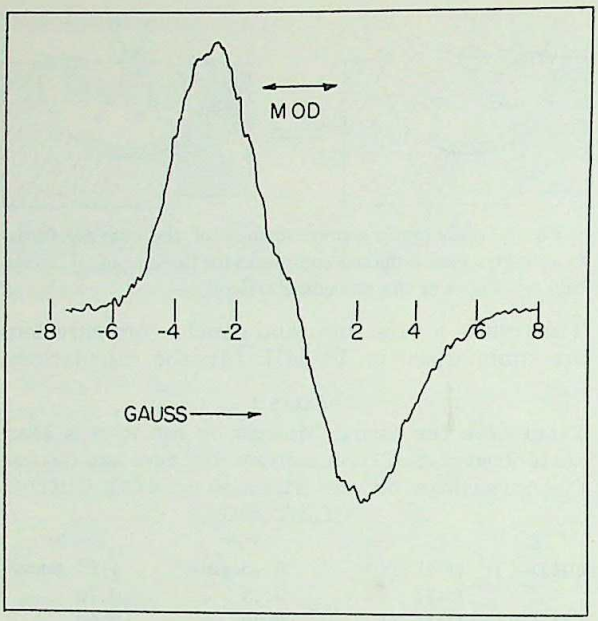

Fig. 2.—The first derivative of the proton magnetic resonance absorption in DOOCCH(D)C(OD)HCOOD at −196°, plotted as a function of applied magnetic field at a fixed frequency of 25.27 Mc. The arrow indicates the amplitude of the 30 c.p.s. modulation of the magnetic field.

The final correction is for the incomplete exchange of protons in the CO_2H and OH groups. These protons have no near magnetic neighbors and thus they have a much smaller second moment than protons in the CHD–CH group. A value of 0.3 ± 0.1 gauss^2 is estimated. About 5% of the protons in the CO_2H and OH groups were not exchanged. This reduces the net second moment by 7.5% of the difference between 0.3 ± 0.1 gauss^2 and the value computed assuming complete exchange. The various terms are summarized in Table I. The net values predicted for ΔH_2^2 are 2.25 ± 0.5 gauss^2 for the *trans* and 3.65 ± 0.6 gauss^2 for the gauche configuration.

A typical recording of the first derivative of the proton absorption in the monodeutero-L-malic acid sample at −196° is reproduced in Fig. 2. Numerical integration of this curve gave a value of 3.43 gauss^2 for one side and 3.63 gauss^2 for the other. A second curve gave values of 3.28 and 3.71 gauss.^{2} The resulting best experimental ΔH_2^2 is 3.5 ± 0.2 gauss.^{2} Line shapes plotted at room temperature had the same widths as those at low temperature so motional narrowing does not appear to be important. Comparison of the experimental value for the second moment with the calculated values shows conclusively that the protons are in the gauche configuration.

In addition, line shapes were plotted at −196° for a sample of $DOOCH_2CH(OD)COOD$. The second moment for this sample was 11.2 ± 0.6 gauss.^{2} A detailed comparison of this value with the intramolecular value of 8.9 gauss^2 computed for CH_2–CH confirms the estimates of the intermolecular contributions to the broadening. The experimental second moments were corrected for the modulation broadening[18] produced by the relatively large modulation used.

In the preceding article,[4] the deuterium labelling experiments and the effect of *p*H on the kinetics of the enzymatic hydration of fumarate indicated that the reaction occurs in the *cis* manner represented by the structures of the enzyme–fumarate and enzyme–L-malate complexes given in Fig. 1. The finding here that the protons in crystalline DOOCCH(D)C(OD)HCOOD are in the gauche configuration proves that the addition is *cis*. In view of this mechanism it is perhaps not surprising that *meso*-tartrate is a much more powerful competitive inhibitor of pig heart fumarase than *d*- or *l*-tartrate.[19]

Heats of Adsorption of Water Vapor on Bovine Serum Albumin[1]

BY C. H. AMBERG[2]

RECEIVED FEBRUARY 21, 1957

Heats of adsorption of water vapor on bovine serum albumin were measured calorimetrically at 20° and are presented together with the isotherms. The heat curves are discussed and critically compared with calculated values from the literature. Possible mechanisms for the adsorption process are considered, with special regard to the high initial heats and the appearance of a maximum in the heat-coverage curve near the B.E.T. value for a complete monolayer.

Introduction

The interaction of proteins and water is a subject of considerable interest to the biochemist and biologist. An extensive amount of data has been accumulated over the past two or three decades, the bulk of the systems studied having been aqueous solutions of various proteins. While this has yielded important information regarding the extent of hydration as well as the size and shape of the hydrated molecules,[3] solution techniques tend to be insensitive to non-uniformity in properties over various regions of the interacting polymer molecule. For this reason, a number of workers

have studied the hydration of quasi-anhydrous proteins from the vapor phase. (A comprehensive review of this work was published by McLaren and Rowen.[4]) From the point of view of those interested in biological systems this method of attack has a disadvantage in that proteins such as the serum albumin discussed in this report occur naturally in solution or in an advanced state of hydration. Moreover, the adsorption of vapors is most conveniently studied in vacuum systems on the purest possible adsorbents whereas, of course, natural systems exist in the presence of both interacting and non-interacting gases and solutes. Nevertheless, there can be no doubt that, from the physicochemical point of view, the simplest systems are desirable provided they can be prepared without introducing permanently irreversible changes in the protein molecule.

Adsorption isotherms of water vapor on a variety of purified proteins were measured by Bull[5] at 25° and at 40°, in the presence of air. His data were discussed by Pauling[6] and an analysis of heat, free energy and entropy changes was undertaken by Dole and McLaren[7] and Davis and McLaren.[8] Although Bull did not measure desorption isotherms for all the systems studied by him, it is evident from his and also later work that many of these systems show marked hysteresis. In view of this the computation of thermodynamic equilibrium functions from either the adsorption or desorption branch of the hysteresis loop is of questionable significance and may actually result in grossly misleading values. This is demonstrated by the work done in this Laboratory which will be discussed later.

Pauling[6] concluded that in most cases the initial water uptake proceeded in such a manner that one water molecule would attach itself to a polar side chain. His view that internal hydrogen bonding of the peptide carbonyl and imido groups would largely preclude adsorption of water molecules by these groups was not substantiated by Mellon, Korn and Hoover.[9] These authors examined a series of polyglycine polymers with from two to six units per molecule and found definite correlation between the increase of water adsorption and increasing number of peptide links. By benzoylating successively higher numbers of free amino groups in casein these authors[10] demonstrated that amino groups are responsible for approximately one quarter of the total water uptake.

As part of their series of investigations on The Surface Areas of Proteins, Benson and his coworkers have given a detailed account of the adsorption of water vapor on a variety of proteins.[11–13] They showed conclusively that while the B.E.T. nitrogen area of egg albumin and bovine albumin could be increased substantially by spray freezing techniques, the analogous areas determined by application of the B.E.T. method to data on water adsorption were virtually independent of the state of subdivision of the protein. With nitrogen areas roughly in the range 1–5 m.²/g. it was obvious from these data that water molecules would have to penetrate into the interstices of the protein structure much more extensively than nitrogen. It was held likely that water adsorption in contrast to nitrogen adsorption is a specific molecular property of the protein.

In view of the uncertainties connected with the calculation of heats of adsorption from isotherms exhibiting hysteresis it was felt that the calorimetric measurement of heats of adsorption of water vapor on a suitable protein would be of value. It seemed particularly interesting to check by direct measurement the anomalous negative "net" heats obtained by Seehof, *et al.*,[11] for the system H_2O–bovine serum albumin between 20 and 25°, which were also discussed by Benson and Richardson[13] in the light of more recent experiments. As a reliable calorimetric method had been developed in this Laboratory in connection with other adsorption problems[14–16] such measurements were carried out using bovine serum albumin, fraction V.

Experimental

Material.—The adsorbent used was a sample of bovine serum albumin, fraction V, milled powder, lot No. N-12302, kindly provided by Dr. J. L. Oncley. Its nitrogen surface area was found to be 1.4 m.²/g. 2.774 g. of the undried material was loaded into the calorimeter. Crystalline egg albumin (Armour, lot No. E-90115) was used for two preliminary runs, but it was abandoned in favor of the bovine albumin which has somewhat greater resistance to heat denaturation and is free from additives. It is not denatured at temperatures up to 70°.[17] The egg albumin had been spray frozen from an approximately 1% aqueous solution and had a nitrogen surface area of 26.4 m.²/g. Poor reproducibility was experienced in the calorimetry with this adsorbent which may have been due to the necessarily low out-gassing temperature (two days at room temperature) or to inherent structural features of the crystallized material. Surface active agents frequeutly used in the crystallization process may also have influenced the behavior of the adsorbent.

Distilled water was used as the adsorbate; it was outgassed by boiling under reduced pressure and by further pumping down while the reservoir was kept in a Dry Ice–acetone bath. This procedure was repeated several times.

Apparatus and Procedure.—The apparatus used was described in detail by Beebe and Amberg.[18] Its essential features are the calorimeter, mercury U-tube manometer and water reservoir, all joined to a vacuum manifold and immersed in a constant temperature bath.

The calorimeter was the same in principle as the one used for previous work in this Laboratory.[14] A glass jacket surrounded the platinum cylinder (7 cm. long, 2 cm. diameter), the spacing between the two being about 1 cm. A copper–constantan thermocouple junction was soldered to the outside of the platinum cylinder and the leads joined to the external measuring system through Kovar-Pyrex seals de-

scribed in a previous publication.[15] The platinum cylinder contained a removable platinum bucket with a set of close-fitted iron fins and a threaded brass cap. Both the fins and cap had been successively nickel and chrome plated and the cap provided with two small holes for vapor admission. A 140 ohm heater wound from enamel covered Advance wire and wrapped in aluminum foil was housed axially in a 3 mm. well in the center of the fins.

Water vapor pressures were read on the mercury manometer by means of a Gaertner travelling microscope. The water reservoir, 30 ml. in volume, was about half filled with water. It was connected to the rest of the system through a two-way stopcock and ground glass joint and could be removed for weighing.

All runs were carried out at 20°. The constant temperature bath was controlled to ±0.01° but effective fluctuations in the calorimeter with the outer jacket evacuated were only ±0.003°.

The methods employed for the measurement of electrical energy input during calibrations and for amplification and recording of the thermal e.m.f. have been described in previous publications from this Laboratory. A Perkin–Elmer d.c. breaker-amplifier was used in conjunction with an Esterline–Angus automatic recorder. The procedure outlined by Beebe and Dell[16] was followed.

Before runs 1–3 the adsorbent was outgassed at room temperature for about 36 hr. and then the temperature was slowly raised to 50° where it remained for about 6 hr. A Dry Ice–acetone trap was used to collect the water removed. Before runs 4 and 5 the temperature was maintained at 100° for two hours each in order to test the possible effects of denaturing the adsorbent.

Helium dead-space calibrations were carried out using a conventional gas buret system. The variation in dead-space in the U-tube manometer with increasing pressure was negligible.

Before each run, a small quantity of helium (of the order of 0.3 mm. pressure) was admitted to the system to facilitate heat conduction inside the calorimeter. It had been found during the initial runs with egg albumin that in the absence of helium heat evolution became too slow to calculate heats of adsorption with any degree of confidence, particularly for the first vapor increment where the calculated heat was as much as 6 kcal./mole below that obtained in the presence of helium. With helium, the "adiabatic" method[16] resulted in constant reconstructed heat values 5–8 min. after vapor admission (±0.2% deviation from total heat of adsorption per increment) showing that if any further heat was evolved after that period, it was evolved too slowly to be detected by that method. The estimated maximum heat quantity that might thus have remained undetected would fall well within the expected precision stated below. Helium was admitted to the outer calorimeter jacket 30 minutes after vapor admission to speed up final temperature equilibration. After a further period of 30 min. no significant changes in vapor pressure were detected so that equilibrium was taken to have been reached one hour after vapor admission.

In order to calculate water vapor pressures, the partial pressure of helium in the system had to be subtracted from the total observed pressure. Table I shows a selection of pressure values from run 3 together with an estimate of the accuracy achieved in the final partial pressures of water vapor. Column 1 shows the total equilibrium pressures read on the manometer, column 2 the calculated partial pressures of helium, column 3 the partial pressures of water vapor, *i.e.*, the difference between columns 1 and 2, and column 4 the estimated per cent. accuracy of the values of column 3.

TABLE I

CALCULATION OF WATER VAPOR PRESSURES

(1) Obsd. pressure, mm.	(2) Partial pressure of helium, mm.	(3) Partial pressure of water vapor, mm.	(4) % Accuracy
0.699	0.319	0.380	1.3
2.097	.267	1.83	0.7
6.026	.205	5.82	.3
10.617	.145	10.47	.2

Except for the somewhat smaller increments in the first half of run 1, the amount of water vapor admitted to the system ranged between 20 and 30 mg. per increment. The estimated precision is between 1 and 2% in the weighing of each increment, and no worse than 5% in the measurement of the heat evolved per increment.

Results and Discussion

The results of runs 2 to 5 are shown in Figs. 1 and 2 (isotherms), and Figs. 3 and 4 (calorimetric heats of adsorption). Those for run 1 show too much scatter to be entirely reliable and have, therefore, been omitted.

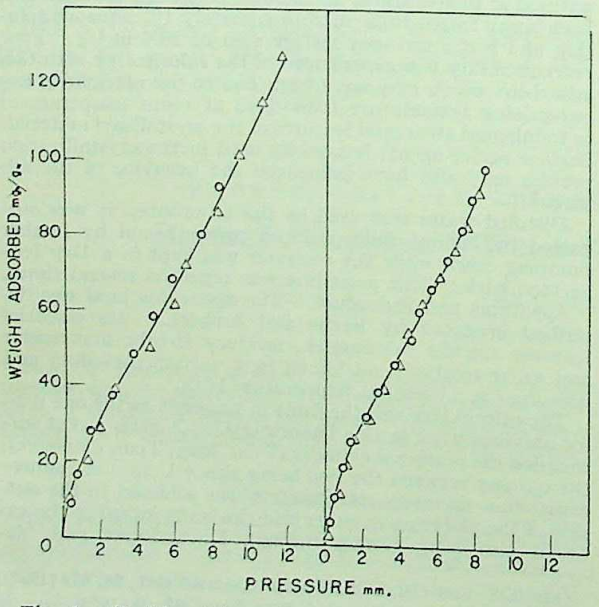

Fig. 1. (Left).—Adsorption of water vapor on bovine serum albumin, fraction V, at 20.0°: run 2, O; run 3, △; outgassed at 50°.

Fig. 2. (Right).—Adsorption of water vapor on bovine serum albumin, fraction V, at 20.0°: run 4, O; run 5, △; outgassed at 100°.

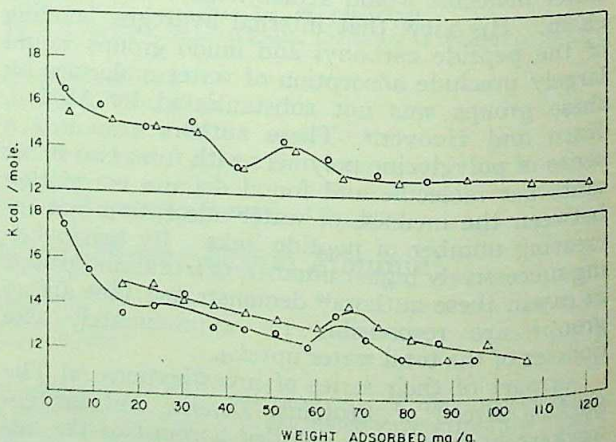

Fig. 3. (Top).—Heats of adsorption of water vapor on bovine serum albumin, fraction V, at 20.0°: run 2, O; run 3, △; outgassed at 50°.

Fig. 4. (Bottom).—Heats of adsorption of water vapor on bovine serum albumin, fraction V, at 20.0°: run 4, O; run 5, △; outgassed at 100°.

The two preliminary runs with crystalline egg albumin are not recorded because of very low reproducibility in both the isotherms and heat curves. It may, however, be stated that the heats of adsorption were of about the same magnitude as those for the bovine albumin.

The isotherms shown in Figs. 1 and 2 are of the S-shaped (Type II) variety. Amounts adsorbed are given on the basis of the initial protein weight. By duplicating as closely as possible the actual drying conditions, it was found in a separate experiment that at 50° the albumin was dehydrated to the extent of 5.07% of the initial weight. Nevertheless, as this was done in a separate adsorption system with the albumin in a simple adsorption bulb rather than the calorimeter, it was felt that the efficiency of dehydration may have differed somewhat in the two cases. Because of this uncertainty the initial weight of protein was not corrected to "dry weight." Low and Richards[19] have shown in the case of human serum mercaptalbumin mercury dimer that the extent of dehydration is relatively insensitive to the temperature of outgassing. While a total of 10% of water was removed by pumping to constant weight over P_2O_5 at temperatures up to 100°, all but about 1% of this was removed at 25°. The slight shift toward higher adsorption at a given vapor pressure when the present system was outgassed at 100° is very likely due to a similar small increase in the extent of dehydration. It was unfortunately not possible to determine whether the expected simultaneous degradative changes in the protein at 100° also affected the adsorption of water vapor. Both isotherms agree reasonably well with that of Seehof, Keilin and Benson[11]; their values were only slightly lower.

B.E.T. surface areas calculated from the isotherms shown in Figs. 1 and 2 were 204 m.²/g. on the average, differences being within experimental error. This corresponds to an amount of 58.2 mg./g. of water vapor adsorbed at the B.E.T. monolayer. (Accepting the above correction to "dry weight" of protein, 61.2 mg./g. would be the resulting corrected value.) Here again it should be pointed out that the meaning of such figures is obscure. If calculated from the adsorption branch of an isotherm showing hysteresis they will represent a minimum area significant, at best, on a comparative basis. In view of the uncertainties involved in applying the B.E.T. equation, it is most surprising that the c-value computed by the B.E.T. method from Fig. 2 resulted in a heat of adsorption term only some 500–600 cal./mole below that measured calorimetrically at the "monolayer."[11] This may well be regarded as fortuitous; McLaren and Rowen[4] have examined in some detail the applicability of equations of the B.E.T. form to water sorption by proteins and compared B.E.T. heats with Clausius–Clapeyron heats. In general they found poor agreement between the two, as is to be expected from the simplifying assumptions involved in the B.E.T. function.

The heats of adsorption plotted against amount adsorbed are shown in Figs. 3 and 4. Initially they are in the region of 16 to 18 kcal./mole as measured. It was not possible by the method employed to determine heats down to very low coverages; the heats for such initial increments might well be higher. After a fairly rapid decrease the curves flatten out in the neighborhood of 15 kcal./mole. For runs 2 and 3 there occurs a minimum at 43 mg./g. of vapor sorbed, rising from about 13 kcal./mole by 1 kcal. to a maximum at 53 mg./g. and then decreasing fairly rapidly to flatten out again at 13 kcal./mole and 68 mg./g., and then decreasing very gradually. Run 4 follows the same pattern, except that the whole curve is shifted by some 15 mg./g. toward higher amounts adsorbed. A further small shift is indicated by run 5. These shifts may again be explained on the basis of improved dehydration, their order of magnitude being consistent with the data of Low and Richards[19] and with the percentage dehydration determined in this Laboratory; this was discussed above.

The molar heat of vaporization of liquid water at 20° is 10.54 kcal. All heats measured calorimetrically were larger than this, which clearly confirms the view of Benson and co-workers,[11,13] that their calculated negative "net" heats of adsorption were anomalous. On the other hand, the curves computed by Davis and McLaren[8] from Bull's data[5] do not show any evidence of negative "net" heats. They are, moreover, qualitatively similar to the curves obtained in this Laboratory, in that they have initially high heats and also a maximum in the B.E.T. monolayer region, notably in the case of egg albumin and lyophilized lactoglobulin. Their absolute heat values are somewhat lower, but in view of the fact that they were obtained on proteins other than bovine serum albumin, and in view of the irreversible nature of these systems, this has probably little significance.

Frey and Moore[20] have measured the adsorption of water vapor on the amino acids glycine and leucine and on the cyclic anhydride of glycine, diketopiperazine, at 15, 25 and 40°. They obtained reversible isotherms and calculated isosteric heats that agreed well with the values for bovine serum albumin at half the B.E.T. monolayer coverage, but then decreased slightly more rapidly. They estimated that at the monolayer there would be one molecule of H_2O sorbed per polar group (NH_3^+ and COO^-) for glycine and leucine and one molecule of H_2O per carbonyl group in the diketopiperazine.

Following Pauling[6] several workers have correlated the number of polar side chains in the protein with the number of H_2O molecules adsorbed at the B.E.T. monolayer and have found an approximate one-to-one correspondence. Such data were collected and critically reviewed by McLaren and Rowen.[4] They report a water sorption value of 3.74 mmoles per gram of serum albumin and a polar group content of 4.24 mmoles per gram. The first figure was obtained by Bull[5] (using horse rather than bovine albumin[6]), the second was calculated from the amino acid analysis of Brand, Kassell and Saidell.[21] A summation of hydroxy and carboxyl side chains together with cationic nitrogens carried out by Klotz and Urquhart[22] on the basis of analytical data by Brand[23]

results in the slightly lower value of 4.06 mmoles/g. If one takes our monolayer value to be 61.2 mg./g. of dry protein, *i.e.*, 3.40 mmoles/g., a molar ratio of 0.84 is obtained for water adsorbed per polar group in the adsorbent. It is not surprising that this ratio differs somewhat from unity, even if one accepted the B.E.T. monolayer value as an exact measure of the coverage of all high energy sites. (Being probably a minimum value when determined from the *adsorption* branch of a hysteresis loop, one might expect a corrected ratio to be closer to unity.) It is very likely that not all polar groups are available for the binding of H_2O molecules, either because of intramolecular and intermolecular hydrogen bonding or because of spatial restrictions. Furthermore it may be assumed from the evidence with other proteins[4] that the peptide linkage will take part in the adsorption of water before the monolayer is complete. One must therefore regard the above ratio as including a partial compensation of these two phenomena by each other.

Hydrogen bonding of the O–H . . . O and N–H . . . O type is often assumed to be largely responsible for the binding of water molecules to polar sites in the protein. It is difficult to assign energies to such bonds in a structure as complex as is that of a protein molecule. Undoubtedly the interaction energy of any polar group will be influenced by neighboring groups. Nevertheless the initial high differential heats of adsorption (up to 17 kcal./mole) are not likely to be due to the formation of only one hydrogen bond per molecule of water for which the highest values quoted[24] do not appear to be in excess of one-half of the above value. One is, therefore, faced with two possible explanations, not necessarily mutually exclusive: (1) Two hydrogen bonds may be formed per molecule of water. This may take place between suitably spaced native polar centers or between a polar group and a water molecule already present. One must not lose sight of the fact that even dried proteins contain a residual quantity of firmly held water. An acceptance of this type of mechanism would even further invalidate the 1:1 correlation of water molecules to polar groups mentioned above. (2) The second explanation would be the existence of bonds in which the hydrogen does not take part; these would be of the ion–dipole type, *i.e.*, they would constitute a hydration of ions. The heats would be of a plausible order of magnitude for such bonds, and again the existence of the residual fraction of water in the "dehydrated" protein is also compatible with this concept.

The minimum for the heats of adsorption and rise by 1 kcal./mole to a maximum observed near the monolayer is in qualitative agreement with the curves calculated by Davis and McLaren.[8] It is clear that previously bound water molecules must be involved in causing the heats to increase with further adsorption, otherwise these more stable bonds would have been formed at much lower coverage. One way in which this could take place is through adsorption on two polar side chains which protrude from one protein helix (or adjacent helices) with spacing appropriate for a third water molecule to wedge between two adsorbed molecules, thus forming two hydrogen bonds. As is indicated by Figs. 3 and 4 about one-sixth of the quantity of water needed to complete the "monolayer" would be bound in this manner. It is interesting to note that this quantity corresponds almost exactly to that needed to account for the 0.84:1 ratio of water molecules to polar groups estimated above. Whether this is significant is again subject to the qualifications expressed in connection with that estimate.

An involvement in some way of the peptide linkage at this stage of the adsorption process cannot be entirely discounted. Marshall and Moore[25] examined the adsorption of ammonia on silk fibroin, which contains only 2 mole % of polar side chains. Nevertheless, a maximum similar to ours in the heat curve was obtained in the region of monolayer coverage. It should be noted, however, that both the isosteric heats as well as the surface area were calculated from a system showing marked hysteresis and, as pointed out by the authors, are therefore only apparent values. Yet it is quite likely that such apparent values are at least a qualitative representation of reality.

Several of the isosteric heat curves calculated by Davis and McLaren[8] show a second maximum in the region of about one mole of water adsorbed per 100 g. of protein, notably so for egg albumin, β-lactoglobulin, gelatin and wool. Unfortunately, calorimetric measurements in this Laboratory were not carried out at that coverage because the rate of adsorption became too low. It is conceivable that a process similar to that postulated above occurs for a second time. Interestingly enough, Buchanan, Haggis, Hasted and Robinson[26] estimated that in an aqueous solution of bovine serum albumin the same amount of water, *i.e.*, one mole per 100 g. of protein, is irrotationally bound; this was on the basis of dielectric measurements in the 1–10 cm. region.

Acknowledgments.—The author wishes to express his gratitude to Dr. R. A. Beebe, in whose laboratory this work was carried out, for his continued interest and valuable advice, to Dr. J. L. Oncley for the gift of a sample of bovine serum albumin and to him and to Dr. B. W. Low for discussions. He is indebted to Dr. R. M. Dell for design of part of the apparatus and to Mr. W. B. Spencer for carrying out one of the runs.

Infrared Spectra of α,β-Unsaturated Esters

BY W. L. WALTON AND R. B. HUGHES

RECEIVED AUGUST 13, 1956

A number of ester families have been shown to have characteristic absorptions in the 10–15 μ region. These absorptions are quite constant in wave length for all members of the ester family (*i.e.*, esters derived from the same acid). The esters which show such absorptions are those that have unsaturation α,β- to the ester group. It is postulated that the vibration responsible for the most prominent of the absorptions is an out-of-plane deformation at the ester carbon atom. However, the interaction of this vibration with other out-of-plane vibrations is probable and, therefore, more or less of such other vibration is also presumed to be involved. Some evidence suggests that the vibration type may be general for 4-atom systems with a given "Y" structure even including some saturated types. However, the vibration is not necessarily so prominent in the saturated types and the more limited generalization that the absorption is prominent in coplanar unsaturated types is thus of greater value for prediction purposes.

Introduction

The recognition of esters by their infrared spectra generally is based on the observation of strong absorption bands resulting from the C=O and the two C–O–C stretching modes. The bands due to the latter two modes may overlap, however, and appear as one. Therefore, with two, or at most three, bands to utilize, recognition of esters in mixtures frequently is quite unsatisfactory and further characteristic bands are needed. If in addition to locating such bands the vibrational modes giving rise to them can be elucidated, then their applicability can be defined more readily and their utility enhanced.

Recent work[1] on the spectra of maleates and fumarates showed that the fumarates have a fixed absorption at 12.9 ± 0.05 μ which is insensitive to the alcohol of the ester. The maleates, on the other hand, showed no constant absorption bands in the 10 to 15 μ range. This feature was puzzling and merited further investigation. The present paper presents a possible assignment of the 12.9 μ fumarate absorption band which not only explains the difference between maleates and fumarates but also leads to a generalization concerning this type of vibration in α,β-unsaturated esters.

Thompson and Torkington, in a paper[2] treating extensively the C–O stretching vibrations of esters, also noted some peaks in the region beyond 10 μ. There were two peaks of relatively constant frequency for acetate and propionate esters near 16 μ, one of which they associated with the whole ester group skeleton and one with a part of the ester group skeleton. All other constant peaks beyond 10 μ seemed relatable to the hydrocarbon part of the acid moiety—or else these workers simply found no basis for any assignment more specific than to the ester family. The present work attempts to supplement this knowledge of ester spectra by providing more correlations and an assignment in the 10–15 μ region.

Generalization

A step toward the development of the generalization was the theoretical consideration of an effect which was first proposed by Price,[3] that the ester groups are both coplanar with the ethylene in fumarate esters whereas this is not the case in the maleates. (This structual feature was then used by Price to explain the fact that fumarates copolymerize better than maleates. This he explained was due to *absence* of steric hindrance to the approach of a growing free radical to the ethylene linkage in fumarates.) On exploring several types of esters, it was found in the present work that only one ester group conjugated with an unsaturated group was needed to give absorption like the 12.9 μ peak of a fumarate. As detailed below, there is evidence that the liquid maleates have no ester group coplanar with the ethylene structure.

The generalization may be stated as follows: wherever an ester group is conjugated with an unsaturated linkage and the ester group is free to assume one of its normal positions coplanar to that linkage a prominent absorption occurs which is constant for (and therefore *characterizes*) the ester family. By means of polarized infrared coupled with examination of oriented crystal films, this absorption has been shown to be due to an out-of-plane vibration. Further it is postulated that the specific vibration is the out-of-plane deformation at the ester carbon atom.

The following ester families fulfill the requirements of the generalization: fumarates, acetylenedicarboxylates, acrylates, methacrylates and *trans*-crotonates. They all have been found to show strong characterizing absorptions, all in the range 11.8–13.5 μ. Maleates constitute the one well explored negative case (*i.e.*, a case in which a conjugated system is present and the ester groups are constrained from coplanarity by steric and electrostatic forces). Halogenated esters have not been examined and, in general, the question of size or electrical charge of a group in the α-position or β-*cis* position necessary to interfere with coplanarity has not been studied.

The generalization has been investigated briefly for possible application to types other than esters, and it appears that several other types may fit. The types which appear to match the "family" absorptions are the corresponding acids, amides, alkyl amides, acid halides and nitro compounds. Further, the several types have their characterizing peak at approximately the same wave length as the esters. This weakens the analytical value of such a peak as a guide to the recognition of an ester—but it extends the range of its value as a means to the recognition of the grouping which directs the absorption to the region.

TABLE I

ASSIGNED VIBRATIONS COMPARED WITH ACETATE ESTER ABSORPTIONS

Compound	λ, μ	Assignment	λ, μ	Assignment	Reference
Sodium acetate	16.26	⊥ rocking of CO_2	15.50	In-plane deformation of CO_2	5
Acetate esters	16.34	"Part of the ester group skeleton"	15.61	"Ester group skeleton"	2
Nitromethane	16.68	⊥ rocking of NO_2	15.46	In-plane deformation	6

Discussion of Assignment of "Family Absorption"

Since the simplest α,β-unsaturated ester is a many-atomed molecule of low symmetry, it is not surprising that no vibrational analysis of any example of the type has been reported. Thus no wholly trustworthy model is available in the literature for comparison with the compounds treated here. On the other hand, in the case of the particular fundamental which we are proposing, there are a number of parallels worthy of consideration.

If the type be defined broadly as the planar structure illustrated by Fig. 1 in which, first, all atoms are heavier than hydrogen[4] and second, the BC and BD bonds are highly polar, whereas the AB bond is of a low order of polarity, then the models to consider are nitromethane and sodium acetate. Table I shows the assignments compared with the acetate esters.

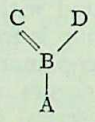

Fig. 1.

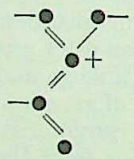

Fig. 2.

An analysis of the equal and opposite actions in the whole molecule permits a mode which is reasonably well described as out-of-plane deformation at the central atom in the Y structure, and this clearly is that which is termed perpendicular "rocking" (Table I), in the cases of sodium acetate and nitromethane.

Now since, in α,β-unsaturated esters, a degree of double bond character is present at the bond between the central atom and the α-atom, added restraint against bending is present and the frequency of the vibration will be greater.[7]

The absorption in the 15.5 μ region of the spectra of nitromethane and sodium acetate was assigned to a vibration which consists of in-plane-bending of the two oxygen atoms. The motion alternately increases and decreases the angle at the central atom with a relatively smaller motion of the central atom itself. Therefore, this second vibration is less subject to influence by the bond strength of the bond between the central and the α-atom.

The fact that *two* peaks are insensitive to the alcohol group in the acetate esters[2] suggests strongly that they are due to the acetate moiety only. That all the frequencies of the table should be so much "of a pattern" would also seem to be more than chance.

If the restriction that the A–B bond in Fig. 1 must be non-polar be discounted, then a number of even better known parallels are available for comparison. The nitrate and carbonate salts are completely symmetrical Y, planar structures. Their fundamental vibrations have all been assigned and besides highly similar absorption patterns are observed for the two types as theory predicts. In the calcium salts containing these ions, the out-of-plane deformation is at 11.54 μ for $CO_3^=$ and at 12.11 μ for NO_3^-, whereas the second vibration noted above is at 14.00 and 14.20 μ, respectively.[8] The out-of-plane vibration is thus found in much the same region as the absorptions we have observed in α,β-unsaturated esters.

Still another similar structure is that of the organic nitrates which were compared with nitric acid and in which the out-of-plane vibration has been assigned[9] to the peak at 13.29 μ.

In summary it seems reasonable to state that the evidence from the literature of similar type compounds indicates that the vibration illustrated in Fig. 2 for α,β-unsaturated esters should be in the region 10–15 μ.

Experimental

Spectra.—The spectra were run on a Perkin–Elmer, model 21, double beam spectrophotometer. Capillary films of pure liquid between optical rock salt plates were used except where otherwise noted. Scanning times (2.0–15.5 μ) were 14–25 minutes with suppression setting of two units. Slit schedule 3 and sodium chloride prism were used.

Films were prepared for the polarized spectra by the steps of: 1, heating the compound in question between square rock-salt plates to slightly above its melting point; 2, differentially cooling the "sandwich"; and 3, seeding the melt at the coldest corner.

The preparation was then checked by microscopic examination between crossed nicols to ascertain that uniform, and nearly parallel, crystal structure was available for study.

The data for Tables II and III were taken mainly from spectra which were accumulated over a period of about two years. Wave length values quoted are believed to be accurate to ±0.5 μ except where otherwise noted.

Compounds.—In the preparation of methyl acetylenedicarboxylate a 15 molar portion of anhydrous methanol was refluxed 15 hr. with 1 mole of acetylenedicarboxylic acid and 0.01 mole of toluenesulfonic acid. The mixture was then cooled, diluted with water and extracted with benzene. The benzene solution was washed with 5% sodium bicar-

(4) Should one of the atoms be hydrogen, mechanical effects would cause the bond to the hydrogen to become the primary site of the vibration and the frequency of vibration would then be substantially increased.

(6) D. C. Smith, C. Y. Pan and J. R. Nielsen, *ibid.*, **18**, 706 (1950).

(7) It has been pointed out by a referee that the out-of-plane bending vibration of the methyl group should interact strongly with the out-of-plane Y-deformation, one result of which would be that the vibrations would move farther apart in frequency. Further, according to the assignments of this methyl frequency,[5,6] the effects would be to *lower* the out-of-plane Y-deformation and increase the out-of-plane methyl bending frequency from what would otherwise have been their normal values. If equally strong interaction is not present in the α,β-unsaturated esters, then the effect will be in the same direction as that argued above. Thus, a second reason for predicting the out-of-plane deformation absorption of α,β-unsaturated esters at a wave length shorter than the 16 μ region of the models above is encountered.

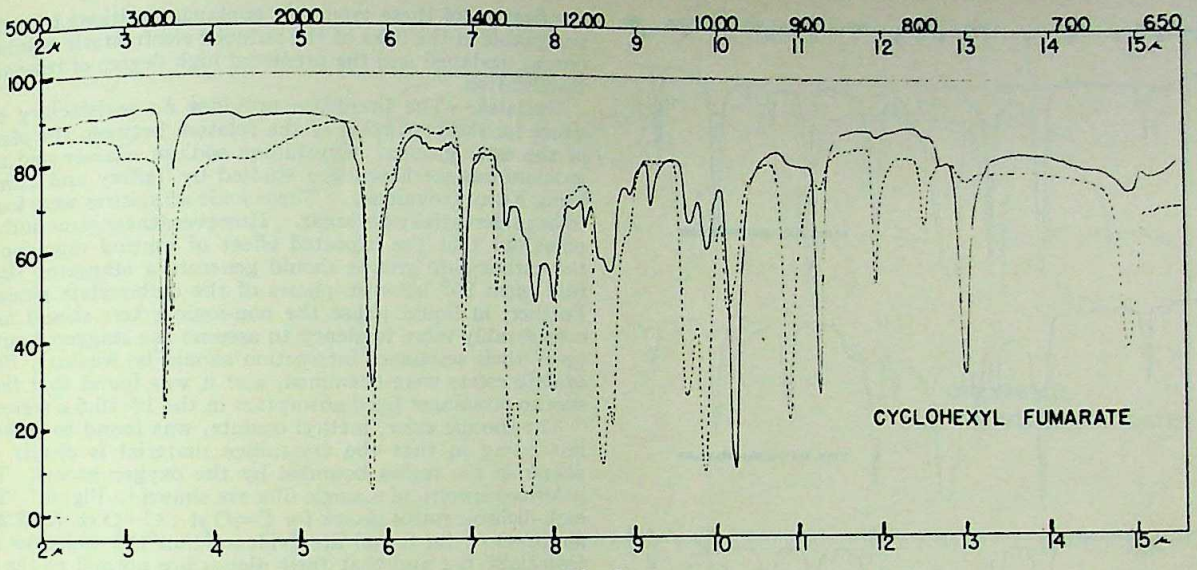

Fig. 3.

bonate solution and then with water and concentrated by distillation, using benzene to dry the ester azeotropically.

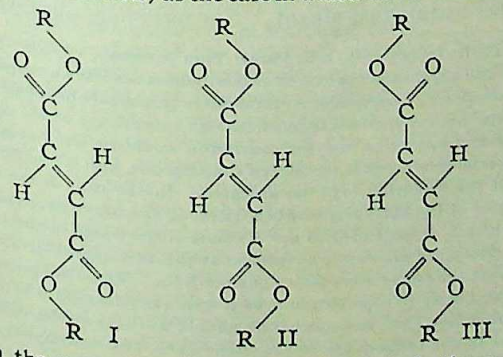
It was found that methyl acetylenedicarboxylate prepared by this method contained a considerable amount of an impurity which was higher boiling. On consulting the literature it was found that this side reaction had been explained.[10] The spectral data are in complete accord with Mommaerts interpretation that methanol added to this triple bond yielding an α-methoxy maleate which was partially removed by distillation with rejection of the higher boiling materials. The spectrum of the methyl acetylenedicarboxylate shown in Fig. 4 shows an absorption at 6.05 μ due to remaining impurity of this methoxy maleate ester.

Other esters of acetylenedicarboxylic acid were prepared by the method of Jeffery and Vogel.[11]

Spectra of Ester Families. Fumarates and Coplanarity.—Coplanarity of the ethylene and carbonyl in conjugated esters is generally accepted in the literature from which it would follow that the ester groups in a diester, such as a fumarate, would also be coplanar. Moreover, in the case of the fumarates some direct evidence of coplanarity can be deduced from the infrared spectra.

The carbonyl stretching absorption is at longer wave length by approximately 0.02 μ than the corresponding maleates. This indicates a greater degree of resonance stabilization.

Further, a peak at about 6.06 μ in maleates and fumarates is assigned to stretching of the C=C bond. With maleates, the 6.06 μ peak is regularly more intense and broader than the corresponding peak of fumarates. This constitutes one point of evidence since, in coplanar fumarate structures, two of the three pseudo-isomers would be centrosymmetric throughout the fumarate part of the structure. Defining *s-cis* (single-bond *cis*) as the case in which the C=C and C=O



lie on the same side of the single bond, it is the *s-cis*, *s-trans* structure II which is non-centrosymmetric. Thus, barring substantial contribution to dissymmetry from the alcohol portion of the fumarates, one would anticipate weaker infrared activity in this band (since only one isomer in three is infrared active) than in the maleates which are incapable of assuming a centrosymmetric configuration.

The third line of evidence that the fumarates are coplanar is based on observations of oriented crystal films with polarized infrared light.

Figure 3 shows the spectra of an oriented crystalline film of cyclohexyl fumarate. The solid curve was run with the polarizer setting such that the electric vector of the polarized beam was parallel to the direction of crystal growth of the sample. The dotted curve was run with the sample in the same position but with the polarizer rotated 90° from the first position. The carbonyl stretching absorption is intense in this preparation, but shows a greater absorption at the polarizer setting 90° from the direction of crystal growth. As both C–O peaks (7.4–8.0 μ and 8.6–8.7 μ) are intense with this same setting of the polarizer, it follows that both ester groups are essentially planar and normal to the direction of crystal growth. This most fortunate circumstance permits an easy analysis of the data, which might otherwise have been very complex. The C–O stretching vibrations are necessarily non-parallel because of the oxygen valence angle and would have yielded low dichroic ratios or considerably different angles of maximum absorption by any other orientation. Thus, this most fortunate orientation is clearly the actual one.

The out-of-plane ethylene hydrogen bending which is that consistently noted at 10.2 μ in fumarate esters is of moderate dichroism and is oriented as expected. The 12.9 μ appears slightly displaced (13.0 μ) but clearly identifiable as the strongest absorption is this region and of approximately the same intensity relative to say 10.2 μ as in liquid spectra. (Its intensity in relation to oppositely oriented peaks is normal as shown by mull spectra or this same crystal preparation without use of a polarizer.)

The spectrum of crystalline cyclohexyl fumarate is not appreciably different from that of the liquid as regards any of the absorptions noted above. It is different in that the C=C absorption at about 6.1 μ is very weak. Thus, evidently structure II above is eliminated in the crystallization process.

Our preparations of crystalline methyl fumarate have not provided high dichroic ratios, but the low ratios which were obtained were qualitatively in the same direction for each of the above-mentioned absorptions.

Acetylenedicarboxylates.—The spectra of six acetylenedicarboxylic esters are shown in Fig. 4. These spectra show peaks at 13.4 and 14.9 μ which are remarkably constant. Further, as in the case of the fumarates,[1] the lower frequency absorption is the less intense.

The first significant theoretical point learned from the acetylenedicarboxylates is that the fixed peaks are clearly not generated by hydrogen atom vibrations. And, since they are quite similar in frequency and intensity to the 12.9

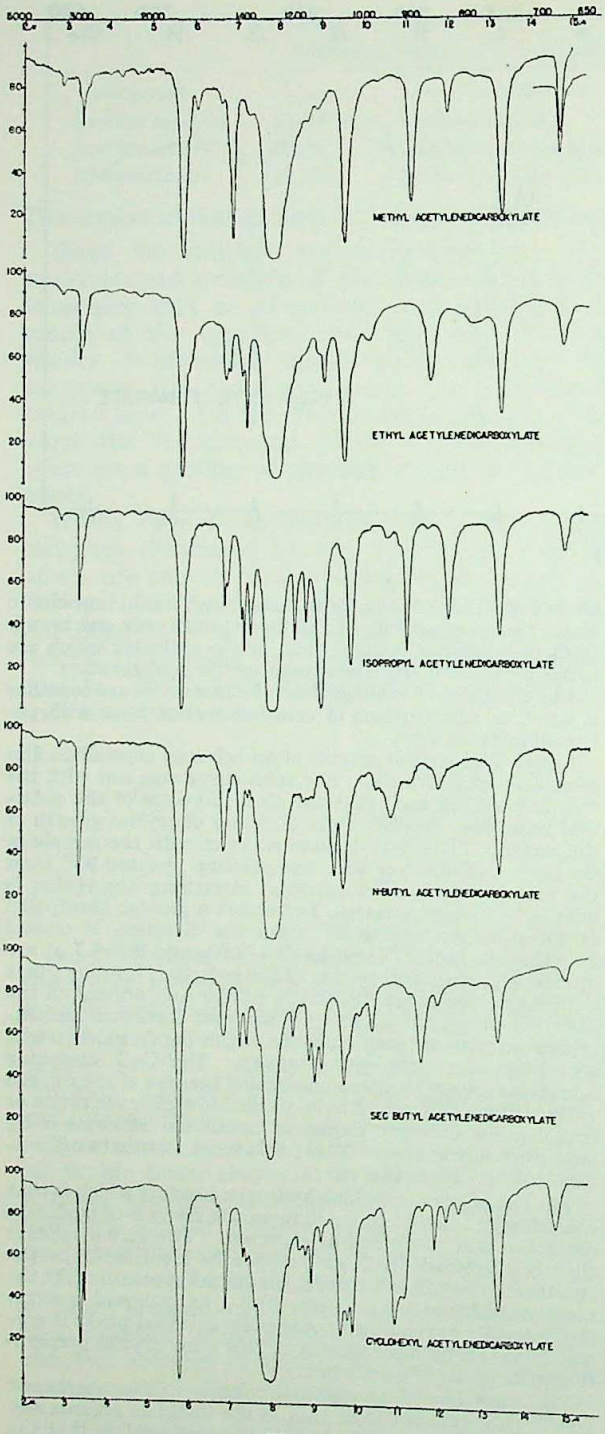

Fig. 4.

and 15.0 μ peaks of fumarates, it was at once apparent that the fumarate peaks were probably not due to hydrogen vibrations.

Figure 5 shows the spectra of cyclohexyl acetylenedicarboxylate run with polarized light. The solid curve is that in which the electric vector of the plane of polarization was parallel to the direction of crystal growth. The dotted curve had the plane of polarization 90° from the first position. Polarizations of the carbonyl stretching and of the complex C–O stretching absorptions are seen to be parallel to each other and at right angles to the 13.4 μ band.

As there obviously can be no steric restraint to free rotation of the ester groups about the linear axis of the four carbons in this compound, it is somewhat surprising to find any evidence of coplanarity of these ester groups. However, the fixation of these groups in coplanar positions is readily acceptable in the light of the reduced electrostatic repulsion (*versus* oxalates) and the predicted high degree of resonance stabilization.

Oxalates.—The literature provides no satisfactory evidence for the prediction of the relation between the planes of the ester groups. Crystalline sodium oxalate and ammonium oxalate have been studied by Jeffrey and Parry[12] using X-ray techniques. These ionic structures were found to be preferentially coplanar. However, these same authors point out that the expected effect of mutual repulsion of the carboxylate groups should generate a staggered structure (near 90° between planes of the carboxylate groups). Further, in liquid phase the non-ionic esters should have considerably more tendency to assume the staggered structure: their resonance interaction should be weaker. Four oxalate esters were examined, and it was found that there was no prominent fixed absorption in the 10–15.5 μ region.[13]

The specific ester, methyl oxalate, was found to be very interesting in that the crystalline material is clearly coplanar in the region bounded by the oxygen atoms. The polarized spectra of a single film are shown in Fig. 6. The high dichroic ratios shown for C=O st., C—O st. (at 8.2 μ) and C–O st. (at 8.6 μ) are evidence that the molecules are essentially flat and that their planes are normal to the direction of crystal growth in the film. The possibility that one carbonyl might be normal to the film plane and the other oriented to give absorption intensity as observed in the polarized spectrum can be disproved, since mull spectra show the same ratio of intensity for C=O st. and C–O st. as in the oriented films. Further, the high dichroic ratios for all three carbon-to-oxygen bond stretching vibrations, coupled with the knowledge of the near 120° angles involved in the ester groups, give additional proof.

Two strong sharp absorptions are observed at 10.81 and 12.81 μ. The former is believed to be out-of-plane deformation of the methyl group (it is not observed in sodium or calcium oxalate whereas the 12.8 μ peak is). The latter is probably a "double, out-of-plane Y-deformation" or essentially a motion of the two central carbon atoms simultaneously above and then below the plane of the oxygen atoms. This should be the only strongly infrared active vibration perpendicular to the plane and common to salts and methyl oxalate.

The methyl groups themselves are nearly in the plane of the molecules. This is clearly indicated by the very definite polarization of the 7.25 μ symmetrical deformation of the methyl groups.

Acrylates and Methacrylates.—In Fig. 7 are shown the spectra of several esters of each of the two series, the acrylates and the methacrylates. It is noteworthy that in both series only the methyl ester shows separation of the second C–O st. absorption into two bands paralleling the slight abnormality noted for the frequencies of the family peaks of these esters in Table II.

As can be seen from the data of Table II and the curves in Fig. 7, certain obvious features of the spectra are available for differentiation of the two families: with acrylates a doublet is resolvable in the 6.1 μ region and fairly constant peaks are noted at 9.4, 10.15 and 10.5 μ, whereas with methacrylates a peak at about 10.65 μ is characteristic and the other features are absent. The foregoing, together with

(12) G. A. Jeffrey and G. S. Parry, This Journal, **76**, 5283 (1954).

(13) The conclusion that an ester family does not have a characterizing absorption in a particular spectral range can be safe based on rather few esters; indeed, it could happen that no coincidence would occur in the first two examined and the conclusion would be valid even then. The reverse, proving that a peak is a constant one, also is readily established if the following logic be accepted. In the case of the 13.4 μ absorption of the acetylenedicarboxylates, all the esters have this peak falling within a range of 0.10 μ. A count of the peaks in the 10–15.5 range, which are one-tenth as intense as the 13.4 μ peak or stronger, shows that the peaks occur about one per 1.1 μ. Thus, the probability of a peak falling in a particular 0.10 μ wide range is only 0.1/1.1, and the probability that six such esters should all have peaks falling by accident in the same range is less than $^1/_{10}{}^6$. Two assumptions have been made: that each increment along the wave length scale is equally likely to find an absorption falling in it and that the absorption to be counted should have a certain minimum intensity. The first of these is probably fallacious but no doubt an arbitrary choice with order of magnitude accuracy when limited to the 10–15 μ range. The second is arbitrary and undoubtedly conservative as to its effect on the answer.

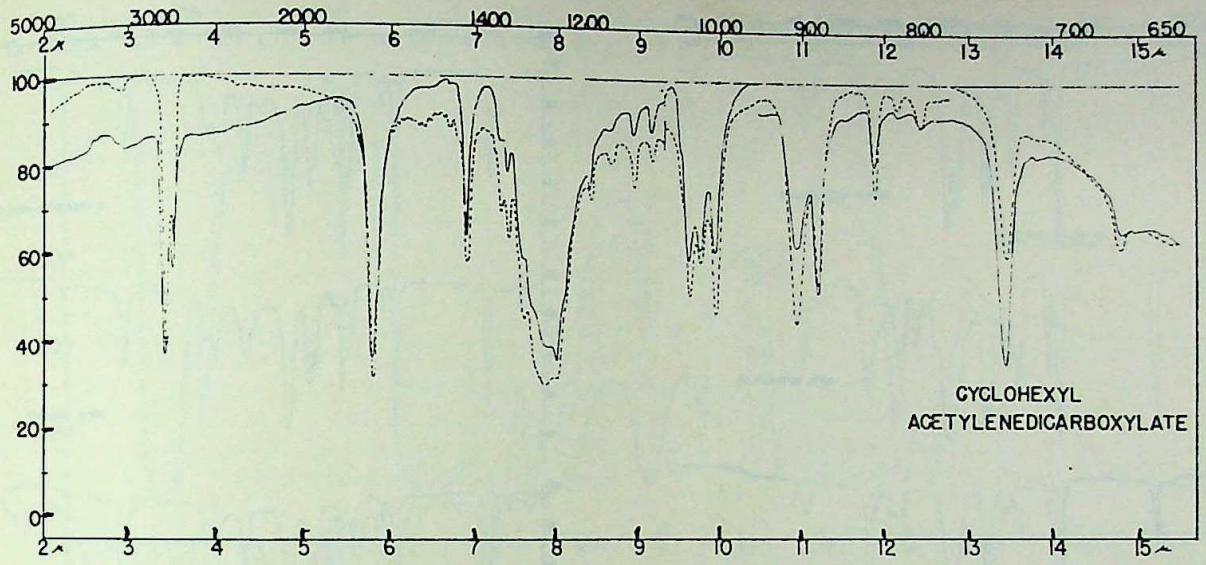

Fig. 5.

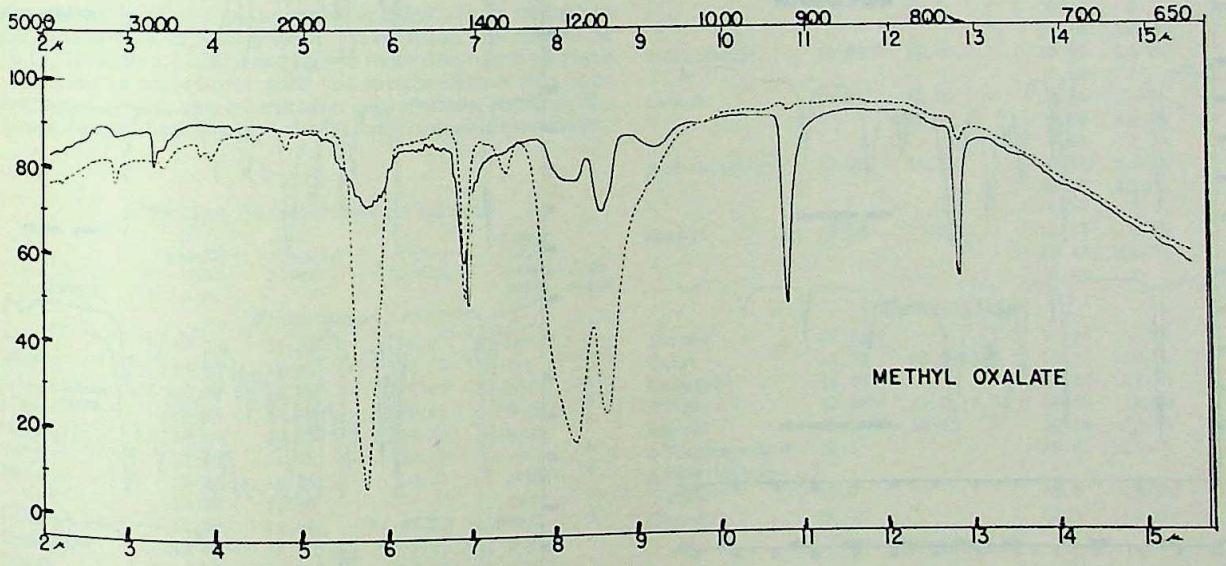

Fig. 6.

the information from an accurate measurement of the 12.3 μ absorption, can serve to distinguish the families rather conclusively. The moderately fixed absorption at around 15 μ is sometimes noted in the table and sometimes not. In general, this peak has offered less of analytical value—being somewhat weaker, less constant in a family and therefore not readily identified. It is probable that in some cases, not listed in the table, it will be found only if sufficiently thick samples are employed in searching for it.

The identification of the hydrogen vibrations has proved difficult. However, an interpretation which is marred by only one inconsistency has been developed: first, it is assumed that (1) vibrational coupling occurs between the hydrogen out-of-plane bending and the ester out-of-plane deformation, (2) coupling results in greater wavelength shifts when the mass of two hydrogen atoms instead of one is vibrating and (3) the theoretical positions of the bands (without coupling effects) would have been only slightly different from the positions in the hydrocarbons. Now, since methacrylates have a structure RR'C=CH_2 for which in hydrocarbons a peak at 11.22 μ is assigned, it is proposed that this peak is shifted to 10.65 μ. A "pattern" has been assigned to α-alkyl acrylates,[14] namely, peaks at 10.6 and 12.2 μ. Thus, the present interpretation for methacrylates is probably applicable to the broader class on which empirical correlation is not new. The acrylates are compounds of the structure R—HC=CH_2 for which in hydrocarbons an absorption at 10.95 μ is assigned to the H_2 bending and an absorption at 10.05 μ is assigned to the H. (These are, of course, not presumed to be free of coupling in the hydrocarbon but rather must be spread to some extent already by the coupling effect.) The H_2 bending is then shifted to 10.5 μ and the H bending to 10.15 μ. The latter is in line with the small shifts observed as the result of both chemical-shift (variation between ester type and hydrocarbon) and coupling-shift in *trans*-crotonates, *trans*-cinnamates and fumarates. With the acrylates, however, it must be assumed that the chemical effect and coupling effect are in opposite directions and that the chemical effect is the greater.

The one seriously discordant observation is that acrylic acid in liquid form shows three broad peaks at 10.2, 10.8 and 12.3 μ. Possibly the identity of the peaks is in the same order except that for some reason their frequencies are not as true.

There is a basis for believing that the vibrations in question are all directed normal to the plane in the planar molecules, namely, that their structures are essentially similar to that of acrylamide.

Acrylamide.—Figure 8 shows the spectra of acrylamide (in oriented crystals) run on the same film but with two settings of the polarizer. The CH stretching vibrations and the carbonyl stretching vibration show their strong absorption at the same position of the plane of polarization. Thus these absorptions, and therefore most of the atoms of

the molecule, lie in a plane which incidentally is normal to the direction of crystal growth. The three absorptions at 10.17, 10.42 and 12.30 μ are shown to be due to out-of-plane vibrations in accordance with the interpretation that they are, respectively, the α-hydrogen out-of-plane bending, the β-out-of-plane bending and the Y out-of-plane deformation.

Cinnamates	13.00–13.10	Cinnamic acid	13.04
		trans-β-Nitrostyrene	13.00

[a] R. W. Stafford, R. J. Francel and J. F. Shay, *Anal. Chem.*, 21, 1455 (1949). [b] This is a near comparison, in the light of both compounds being *trans*-1,2-disubstituted ethylenes.

Polarized Spectra of Other Esters.—Cyclohexyl maleate was examined in oriented crystal film; it showed rather high dichroic ratios for the C–O stretching absorptions. Further, those absorptions were strong at the same setting of polarizer that gave strong absorption by the C=C stretching vibration. Thus, a high degree of coplanarity for the ester group and the ethylene exists. Significantly, the absorption at 8.2 μ which was shown to be characteristic of maleates[1] was absent. Thus, this molecule is preferentially oriented in crystallization and could be substantially unlike *normal* maleates. Another point of abnormality recorded in the earlier paper is that the melting point of the maleate is in this case higher than the fumarate: 86° *vs.* 35–36°.

Methyl cinnamate was studied; it yielded only moderate dichroic ratios in any assigned peaks. However, such ratios as were noted were again qualitatively in accord with expectations based on our generalization.

Tabulated Spectral Data.—Table II shows the wave lengths of the family-constant peak for the various ester families. Other peaks of interest also are shown.

Several ester families were examined to see if constant peaks were present in the 10–15 μ region and none were found. These included succinates, acetates and oxalates. However, the propionates have a peak that is remarkably constant at 12.4 μ as had been noted by Tompson and Torkington in 1945.[2] This absorption is very near the wave length of the peaks of the acrylates and the methacrylates. It is, however, much less prominent than that in the unsaturated esters. Possibly the explanation of this absorption could be that a low degree of double bond character exists at the C–C bond between the carbonyl and α-carbons and that some portion of the molecules at a given instant assume the conformation that most nearly matches that of the acrylates.

Types Other Than Esters.—It was noted early in this investigation that the corresponding acids have peaks which match the family-constant ester peak. As the study progressed more compounds of related types were examined and confidence increased in the greater breadth of the generalization. Table III lists other types in comparison with the esters.

Acknowledgments.—The authors are grateful to Drs. R. S. McDonald, J. F. Brown, Jr., and A. Pozefsky for helpful comments on the theoretical aspects of this work. They are also grateful to Dr. J. Rosenberg for valuable help in obtaining many of the compounds used in this study and to Dr. J. F. Brown, Jr., for the data on the nitroethylene spectra.

Light Induced Spectral Shift of the Thiazine Dyes in the Bound State[1]

BY NEIL WOTHERSPOON AND GERALD OSTER

RECEIVED MARCH 8, 1957

We have found that thiazine dyes in the presence of polymethacrylic acid or polyacrylic acid undergo a spectral shift when irradiated with visible light. A combined recording spectrophotometer and irradiation apparatus was used to follow the reaction either at a fixed wave length or by scanning the spectrum repetitively. Two photo products are formed, one in the absence of oxygen and the second by the photoöxidation of the first. The rate of formation of the second product is retarded by small amounts of paraphenylenediamine or by potassium iodide suggesting that long-lived excited states are involved. The final photoproduct is the same for all the thiazine dyes studied and is identical to thionine. The reaction requires a polyacrylic acid but does not take place in the presence of other high polymeric acids or of dibasic acids.

Introduction

During the course of our studies on the photochemical properties of methylene blue, we observed that a purple species having a bright red fluorescence was formed when a solution of the dye containing polymethacrylic acid was illuminated. It is the purpose of the present study to investigate the nature of this photochemical reaction. In particular, we are concerned with determining which dye and high polymer combinations exhibit this phenomenon.

The photochemical properties of many dyes

bound to high polymer substrates are different from those of the free dyes.[2,3] The present work differs from previous studies of the photochemistry of bound dyes, however, in that only one class of dyes, namely, the thiazines, exhibits the light induced spectral shift. Furthermore, the high polymeric substrate for the reaction is highly specific and is apparently confined only to polyacrylic acid and polymethacrylic acid.

Experimental

Materials.—Methylene blue, Merck, zinc free, was used without further purification. All other thiazine dyes were histological grade from National Aniline Division of Allied Chemical and Dye Corp.

Polymethacrylic acid (PMA) was prepared by polymerizing 10 g. of distilled methacrylic acid in 200 ml. of water containing 0.2 g. of potassium persulfate at 90° for 30 minutes. The mixture was previously degassed by bubbling with nitrogen. The polymer solution was dialyzed against distilled water for three days, and then freeze-dried.

Apparatus.—The equipment was conveniently arranged for both irradiating the dye solutions and simultaneously recording the absorption spectrum (Fig. 1).

The light source for the photochemical reactions was a 1000 watt Kodak Master slide projector. A Variac was used to reduce the input voltage to 65 volts in order to provide a convenient light intensity and to prolong the life of the lamp. Constancy of illumination was assured by a 500 VA Sola constant voltage transformer. Filters could be inserted in the projector slide carrier. The optical cells were made by cementing Pyrex plate glass disks (2.25 inch diam.) to a half inch section of 2.25 in. heavy wall Pyrex tubing in which two capillary tubes were sealed to permit bubbling with helium. Araldite epoxy resin was used as cement. The reaction cell and a blank cell filled with water were mounted on a transverse sliding block which allowed either cell to be irradiated.

The measurement of monochromatic radiant flux incident upon the cell was carried out with a calibrated Eppley thermopile whose output was read on a Leeds and Northrup Microvolt Amplifier No. 9835-A. This is a chopper stabilized amplifier inherently capable of high precision and freedom from zero drift.

The spectrophotometer consisted of a Bausch and Lomb 250 mm. grating monochromator in conjunction with a Leeds and Northrup Speedomax recorder. The recorder was modified by the inclusion of a special high impedance amplifier for use with an RCA 1P22 multiplier phototube. The recorder was adapted to permit direct mechanical coupling *via* gears and a pair of universal joints to the monochromator grating screws. In this way a linear relationship between the chart paper movement and wave length was obtained. A microswitch provided marker pulses to operate a marker pen at the right-hand side of the chart at intervals of 100 mμ. By reversing the chart motor and rescanning, a series of curves could be superimposed on the same chart for comparison. The recorder contained controls for dark current suppression and for sensitivity which could be made as high as 10^{-10} amp. per mm. A Scientific Specialties Corp. Regulated High Voltage Power Supply, Model PS-22M, was used to provide from 500 to 1000 volts for the phototube. The stability was such that phototube sensitivity drift was negligible over a period of an hour.

For kinetic studies the monochromator was set at the wave length of an absorption band of either a reactant or a product and the transmission of the solution recorded as a function of time of irradiation. Spectra of photosensitive systems were obtained by placing the solutions in the cell compartment between the monochromator and the phototube where the light intensity is very low.

Fluorescence spectra were recorded by rearranging the light source and optical cell. Either the mercury arc or the ribbon filament lamps supplied with the Bausch and Lomb Monochromator were used to illuminate a square optical cell which was placed near the entrance slit collimating lens. This lens formed an image of the fluorescence cell on the slit and thus excluded almost all of the scattered light. Only the front edge of the cell was imaged on the slit in order to avoid self absorption effects. The chart record of the fluorescence intensity *vs.* wave length had to be corrected for the unequal phototube sensitivity at each wave length. This was done by determining the phototube response to a ribbon filament lamp whose color temperature was measured by the National Bureau of Standards. From the Planck energy distribution equation and the phototube response, the absolute phototube sensitivity was calculated. This method eliminated the effect of anomalies in the transmission of the grafting monochromator.

Procedure.—The kinetic transmission curves were recorded at a given wave length by setting the blank transmission at or near the full scale of the recorder after adjusting the dark current to zero. The initial rate of disappearance of dye was used to calculate the quantum yield. In some experiments atmospheric oxygen was permitted to participate in the reaction. In order to prevent air oxidation helium (Airco) was used to degas the solution.

In order to determine the quantum yield for the conversion of methylene blue, a solution of the dye and PMA was irradiated by the light from the 500 watt projector lamp filtered by a Baird Associates interference filter with a peak transmission of 63% at 665 mμ and a half band width of 10 mμ. The rate of disappearance of the methylene blue absorption band at 665 mμ was obtained from the initial slope of the transmission *vs.* time curve as plotted by the recorder. The slope was converted into a rate by the use of the absorbancy index of the dye and of the initial transmittance. From the measured radiant flux (659 μw./cm.²) obtained by the use of the thermopile and the rate of dye conversion, the quantum yield was obtained.

Results

Methylene blue at concentrations of the order of 10^{-5} *M* is stable to visible light of intensities

considered in the present work. In the presence of excess polymethacrylic acid (PMA) the dye undergoes a photochemical change to give a species having an absorption band at shorter wave lengths (Fig. 2). The quantum yield of the disappearance

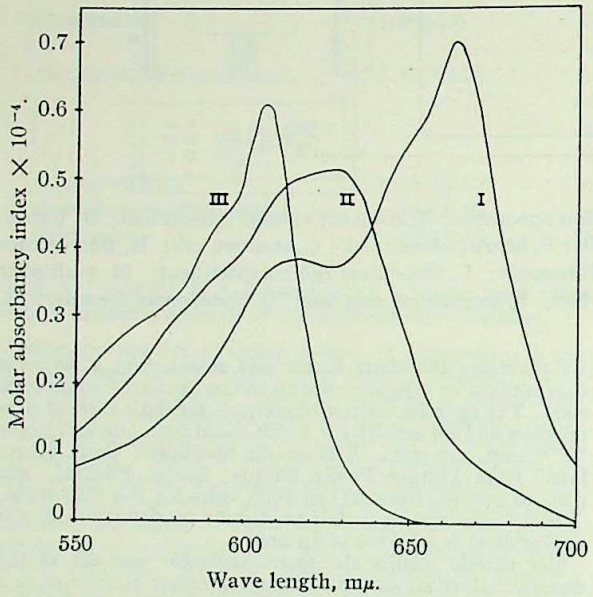

Fig. 2.—Light induced spectral shifts in methylene blue; dye concentration 10^{-5} *M*, PMA concentration 5×10^{-4} *M* (monomer basis), *p*H 7: I, unirradiated; II, irradiated in the absence of oxygen; III, irradiated in the presence of oxygen.

of methylene blue is 0.0035. If the irradiation is carried out with oxygen present, the dye (curve I) is converted to a purple species (curve III). Whereas methylene blue free or bound is only feebly fluorescent (quantum yield less than 1%), the light produced species exhibits a strong red fluorescence with a quantum yield greater than 10%. An intermediate species is produced because the initial rate of disappearance of species I is greater than the appearance of species III. This is more clearly seen by carrying out the reaction in the complete absence of oxygen. Under this condition, a substance with an absorption band (curve II) intermediate between the other two is produced and no purple species is formed. If now a solution containing species II is irradiated in the presence of oxygen the purple species (curve III) is produced. It appears, therefore, that methylene blue undergoes an anaerobic photochemical transformation to species II which, in turn, undergoes a photoöxidation to species III.

The rate of production of species III was reduced to about one-half its normal value in the presence of either 10^{-5} *M* of KI or of *p*-phenyldiamine. The rate of production of species II, on the other hand, was not influenced by the addition of these substances up to a concentration of 10^{-2} *M*.

A number of high polymeric acids including desoxyribose nucleic acid (molecular weight about 5×10^6), alginic acid, hyaluronic acid, polyglutamic acid, hydrolyzed maleic anhydride–vinyl methyl ether copolymer, and agar were tested with methylene blue. None of these substances produced the light induced spectral shift and only polyacrylic and polymethacrylic acid were effective. A homologous series of dibasic acids (oxalic, malonic, succinnic, glutaric, adipic, pimelic and suberic acids) were tested and found to be ineffectual.

Representative dyes (mainly cationic) from several classes (azo, triphenylmethane, xanthene, azine, etc.) were irradiated in the presence of PMA but no spectral shift occurred. On the other hand, all members of the thiazine class of dyes which we tested exhibited the phenomenon. In all cases, the absorption bands of the thiazine dyes were shifted to shorter wave lengths on irradiation in the presence of PMA and oxygen resulting in a strongly red fluorescent species (Table I). The absorption spectra of the photo-product is for all these cases identical with that of thionine. Similarly, the fluorescence spectrum of the photo-product is identical with that of thionine (Fig. 3). The photo-

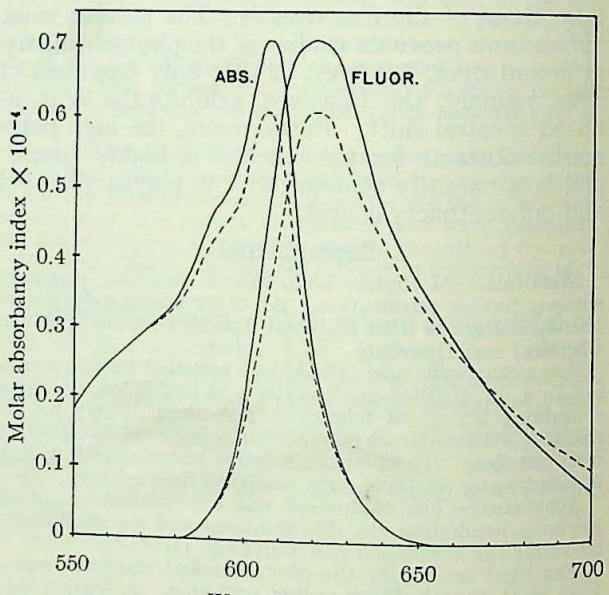

Fig. 3.—Absorption and fluorescence spectra of thionine and of the photoöxidation product: solid curves, thionine; dotted curves, photoöxidation products of methylene blue. Fluorescence curves are drawn to arbitrary ordinates.

product (species III) is an acid–base indicator and changes reversibly from purple to red in basic solutions. Thionine behaves similarly but methylene blue does not show this reversible color change at high *p*H values.

Discussion

The phenomenon of light induced spectral shift in dye–polymer mixtures has not heretofore been observed as far as we have been able to ascertain. It differs from light induced *cis–trans* conversions in that a specific polymer must be present and furthermore the reaction is irreversible.[4]

It is clear that in all cases the photo-product is identical with thionine. This is shown from the close resemblance between species III and thionine as regards their absorption spectra, fluorescence spectra and behavior as a *p*H indicator. This fact,

(4) Compare, for example, G. M. Wyman, *Chem. Revs.*, **55**, 625 (1955).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

together with the necessity for oxygen in the reaction, indicates that species III is a photooxidation product of the thiazine dyes in which the methyl substituents were removed resulting in the formation of thionine. It is known that methylene blue may be demethylated by non-photochemical oxidation in alkali to give dyes with fewer methyl substituents.[5]

TABLE I

ABSORPTION MAXIMA OF PHOTO-PRODUCTS

Dye	Wave length of absorption max. Free dye	Photo-product with PMA
Thionine	599	607
Azure C (monomethylthionine)	616	607
Azure A (u-dimethylthionine)	620	608
Azure B (trimethylthionine)	652	605
Methylene blue (tetramethylthionine)	665	606

The highly specific nature of the polymer required for the reaction implies that the polyacrylic acids serve as substrates for a very special type of dye binding. In the dye–polymer complex the transition from the ground to the first electronic excited state does not differ from that of the free dye since the absorption spectra are virtually identical. Transitions from the first electronically excited state to other states must, however, be profoundly affected by the complexation with the specific polymers. It appears that the spatial arrangement of the carboxyl groups on the polyacrylic acids is particularly suited to complex with the thiazines *via* their amino groups to distort the electron configuration of the excited dye molecules. This arrangement does not exist for any of the other polymeric acids which were tested nor for the dibasic acids studied.

There are two distinct photochemical processes involved in the light induced spectral shift of the complexed thiazine dyes. The first process to give species II does not require oxygen. It is possible that the absorption of light by the original dye imparts a certain electron configuration which enables the dye molecule to be bound to the substrate in a manner which allows it to be readily photooxidized to give species III. This first process does not require oxygen and probably does not involve long-lived states. On the other hand, the second process involves long-lived states because very small amounts of KI or *p*-phenylenediamine retard the reaction. From the observed retardation we estimate, using the Stern–Vollmer expression and the calculated diffusion controlled encounter frequency in solution,[6] that the lifetime of the excited species which reacts with oxygen to be about 10^{-5} sec. By analogy with other dyes whose rate of photochemical conversion is influenced by O_2, KI and *p*-phenylenediamine, we propose that this long-lived excited state is a triplet state. It has been shown with triphenylmethane dyes[3] that binding can encourage triplet formation. Here, however, it appears that a specific substrate is required and that the binding takes place only after the dye is excited. The low quantum yield observed is probably accounted for in terms of internal conversion to the ground state which are competitive to transitions to the long-lived state.

Diketene: Infrared Spectrum and Structure. II[1]

BY FOIL A. MILLER AND GERALD L. CARLSON

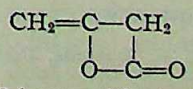
RECEIVED MARCH 16, 1957

Earlier temperature-dependence measurements on the infrared spectrum of diketene vapor by Miller and Koch have been repeated, and have been found to be incorrect. There is no evidence from the vapor spectrum for an equilibrium between two forms. Furthermore the spectrum of the solid, the liquid and the vapor are essentially the same. It follows that diketene in all its states exists predominantly or entirely in a single form, which other X-ray and nuclear magnetic resonance spectra studies have shown to be the 3-buteno-β-lactone structure. It appears that the five strong bands in the double bond stretching region, long a stumbling block to understanding the structure, are due to two fundamentals and three combination tones.

Introduction

Some time ago Miller and Koch[2] studied the infrared spectrum of diketene vapor as a function of temperature between 30 and 180°. They found reversible changes which were attributed to the existence of two forms of diketene in equilibrium. This conclusion helped explain the presence of five strong bands in the region 1650–1950 cm.$^{-1}$, and was attractive for understanding the welter of other conflicting evidence concerning the structure of diketene.

Since then an X-ray diffraction study by Katz and Lipscomb[3] has shown that crystalline diketene has the 3-buteno-β-lactone structure



3-buteno-β-lactone

This was confirmed by a nuclear magnetic resonance spectra study of crystalline diketene by Ford and

Richards,[4] which demonstrated that the protons occur only in CH_2 groups. More recently Bader, Gutowsky, Williams and Yankwich,[5] also using nuclear magnetic resonance, concluded that this same form is the only significant one existing in the liquid between 25 and 120°.

Because these results for solid and liquid directly contradict the earlier conclusions drawn for the vapor, it was deemed desirable to repeat the earlier work to see whether it was in error or whether the vapor really does have a different composition from the liquid and solid. This has been done, and the finding is that the earlier infrared work was in error. There is no temperature dependence to indicate an equilibrium between two forms.

Experimental

Commercial diketene (obtained from the Carbide and Carbon Chemicals Company through the courtesy of R. C. Miller of Mellon Institute) was distilled at reduced pressure (b.p. 43.5° at 48 mm.). It was then further purified by fractional crystallization. Because this appears to have been an especially effective method, the procedure will be described. Diketene melts at −7°. A cold-bath was prepared from a 1:1 solution of sodium thiosulfate in water, and cooled with Dry Ice until slushy. The sample was immersed in this slush, and stored in a Dewar flask in a cold room at −5°. In about 24 hr. large crystals of diketene had formed. Cooling was allowed to proceed until about half of the sample had crystallized. The remaining liquid was decanted, and the pure sample was stored at −5° under nitrogen until used; $n^{20}D$ 1.4376.

A Perkin–Elmer model 112 infrared spectrometer (single beam, double pass) was used with a NaCl prism, and with a slit servo accessory to approximately level out the 100% line. The instrument was completely flushed with dry, CO_2-free air, and the range 700–4000 cm.$^{-1}$ was covered.

The spectrum of the solid was obtained in a low temperature cell, similar to one described by Lord, McDonald and Miller,[6] which had a conventional vapor-tight liquid cell about 0.05 mm. thick attached to the Housekeeper seal. The liquid sample was slowly solidified in this cell by adding Dry Ice slush to the coolant reservoir. After the spectrum of the solid had been obtained, the sample was melted and the liquid spectrum was measured in the same cell.

The system for handling and heating the vapor was similar to that used by Miller and Koch,[2] but a considerable improvement was made in the manner of sealing the windows onto the cell. The ends of the 5-cm. long Pyrex cell body were flanged and ground flat. Rocksalt windows were clamped against the flanges with metal rings and tie rods. A very satisfactory grease was compounded of 10% extremely fine silica (Monsanto's Santocel 54) and 90% Dow-Corning No. 200 silicone oil. This grease, used on both the flanged surfaces and the stopcocks, gave a vacuum-tight system at temperatures up to at least 250°. Because the windows are not attached to the glass with a rigid seal, but are merely pressed against the flanges, there is no problem with differential expansion.

In this work the temperature of the vapor was varied between 40 and 180°. A sample pressure of 19 mm., measured at 40°, was used. There was no evidence of any decomposition of the sample after hours of heating. Another grease, compounded from lithium stearate (10 g.) and No. 60 lubricating oil (40 g.),[7] caused sample decomposition at temperatures as low as 100°. Carbon dioxide was a product, but there was no ketene, allene nor methylacetylene.

Results and Discussion

The infrared frequencies agree well with the earlier results of Whiffen and Thompson[8] and Miller and Koch[2] and references cited by them. Whiffen and Thompson's spectrum shows the 1130 band to be considerably more intense than 1106, whereas our finding is that it is only slightly more so. This is certainly due to an impurity in their sample, for the spectrum of our crude material matched theirs in this region, whereas purification diminished the 1130 cm.$^{-1}$ band.

Our spectra for the liquid and for the solid were essentially the same, as shown in Table I. The cell (0.05 mm.) was far too thick for some of the bands, which makes it impossible to locate their maxima accurately. This also is the reason why only two bands are reported in the double bond region; the four strong bands have merged into two very broad ones. The significant finding is that the liquid and solid spectra are essentially the same. This reinforces the conclusion of Bader, Gutowsky, Williams and Yankwich[4] that diketene has the same single structure in the liquid as in the solid.

The spectrum of the vapor at room temperature already has been shown to be essentially identical with that of the liquid.[2] It must therefore be concluded that it too consists of a single form of diketene.

Table I

Infrared Frequencies (in Cm.$^{-1}$) of Solid and Liquid Diketene

(solid, *ca.* −40°; liquid, *ca.* 25°)

Solid	Liquid	I^a	Solid	Liquid	I^a
812	810	vs	1520	1517	w
862–884[b]	832–884[b,c]	vs	..	1538	w
959	960	s	1555	1555	w
1024	984–1017[b,d]	vs	1572	..	m
1060	1050	m	1704[b]	1704[b,e]	vs

1458 }	1463	m	3065	3075 }	m
1474 }			3181	3163 }	

[a] w, weak; m, medium; s, strong; v, very; sh, shoulder. [b] Too intense to measure accurately in 0.05 mm. cell. [c] Thinner sample gives band at 870 with shoulder at 840. [d] Thinner sample gives band at 1011. [e] See Table II.

The earlier evidence for an equilibrium between several forms—the change of the vapor spectrum with temperature—could not be repeated. A careful comparison of the spectrum at 40° with that at 180° over the range 700–4000 cm.$^{-1}$ showed no significant differences, but only the expected flattening and broadening of the bands at higher temperature. An especially careful study was made of the regions where Miller and Koch had noted marked changes, and no such changes were observed. There was no band at 1797, at 1133 nor at 1185 cm.$^{-1}$. It has already been mentioned that much of the 1133 cm.$^{-1}$ intensity could have been due to an impurity. None of the other effects were duplicated. It is con-

cluded that the earlier work was incorrect, and that diketene exists in the 3-buteno-β-lactone form only.

An attempt was made to explain the temperature-induced changes observed by Miller and Koch. Their raw curves were re-examined, and there is no doubt that changes were clearly indicated. One possibility is that some component of the glyptal seal distilled into the cell at high temperature and condensed out at low temperature, even though a blank run was made to test this possibility. Since it is known that phthalic anhydride can be distilled out of glyptal, its vapor spectrum was determined. A glyptal resin (General Electric Company's No. 1202) also was examined by placing a sample at the bottom of the evacuated gas cell and heating to 200°. Neither material accounted for the earlier observations, and we are at a loss to explain them.

There is still the problem of accounting for the five strong bands in the 1650–1950 cm.⁻¹ region on the basis of the single 3-buteno-β-lactone structure. This structure would be expected to have only two fundamentals there. One is the carbonyl stretching frequency, which will be abnormally high because of being external to a 4-membered lactone, and which we can guess will be about 1830 cm.⁻¹.[9] The other is the olefinic stretching frequency, which also will be abnormally high because of being exocyclic to a four-membered ring.[9] We would predict it to be about 1720 cm.⁻¹. Actually the C=O frequency must be the band at 1900 in solution (1922 in the vapor) while the C=C stretch must be 1708 in solution (1720 in the vapor) (see Table II.) The intensity of the latter is remarkably high for an olefinic stretch.

The remaining three strong bands are then presumably to be explained as combination tones, in spite of their considerable intensity. Table II shows that this can be done as far as the frequencies are concerned, although it is still hard to understand their high intensity. It will be noted that in the pure liquid there are only four bands. The double bond frequency appears to be lower than its value of 1708 in the solution, and it apparently merges with the 1675 band to give a single very broad band at 1689.

Hydrogen Peroxide–Olefin Reactions in the Vapor Phase

BY E. R. BELL, W. E. VAUGHAN AND FREDERICK F. RUST

RECEIVED MARCH 2, 1957

Hydrogen peroxide has been decomposed in the presence of ethylene, propylene and isobutylene at temperatures between 435 and 630°. The products are traceable to an initial attack by hydroxy radical involving either addition to the double bond or abstraction of a hydrogen atom from the olefin. As a consequence of the latter process diallyl and dimethallyl are major products from propylene and isobutylene, respectively. Many other compounds must originate from radical association reactions. Much fragmentation of the olefins seems to have had its genesis in the initial addition of a hydroxy radical to the olefin double bond. In cases where the carbon skeleton has been retained, hydrogenation and dehydrogenation processes can be significant. Reaction steps which logically interpret the data have been proposed.

Introduction

Hydrogen peroxide has a thermal stability much greater than that of the organic peroxides and for this reason its significance to combustion phenomena in temperature regions beyond the cool flame zone is substantially greater. Moreover, this stability suggests that hydrogen peroxide may have useful properties as a high temperature reactant.

Its thermal decomposition is apparently a complex of both heterogeneous and homogeneous processes. McLane[1] has reported that the decomposition in nitrogen begins to be essentially homogeneous only above 470° in reactors whose walls have been treated with boric acid. Although the reaction showed first-order kinetics in the temperature range 470–540°, the activation energy increased from 40 kcal. in a reactor whose surface to volume ratio was 7 cm.⁻¹ to 50 kcal. in one with a ratio of 3 cm.⁻¹. (A boric acid-coated reactor of surface–volume ratio 0.4 cm.⁻¹ has been chosen for these studies.)

The near coincidence of this high activation energy with the O–O bond strength in hydrogen perox-

ide (53 kcal.[2,3]) suggests that this decomposition should be an effective source of hydroxy radicals.

Since it is known that hydrogen peroxide can be a significant product of hydrocarbon oxidation at temperatures in the region of 475°[4,5] a study of the high temperature peroxide–hydrocarbon reactions which must be proceeding concomitantly with the oxidation processes leading to hydrogen peroxide formation would seem to be desirable. One of the principal objectives of this investigation was to gain some insight into the behavior of certain of the simpler olefins when exposed to the radicals from decomposing hydrogen peroxide.

Experimental

A flow system was used in these experiments. The flow of hydrogen peroxide (30% aqueous solution) through a capillary was calibrated against the air pressure above the peroxide. The peroxide was then fed onto a vertically descending spiral glass rod (about 2 mm. o.d.) fused onto the inner wall of a 44 mm. glass tube. The outer wall of this tube was heated by a flexible tape heater. Its temperature was measured by a thermocouple between the heater and tube in the lower third of its length. For low peroxide flows, (0.3–0.5 g./min.) the wall was heated to 100°; for high (*ca.* 2.0 g./min.) the wall was heated to 180°. Tests of this vaporizer showed that negligibly small amounts of peroxide were decomposed. The hydrocarbon was metered as vapor and flowed through the vaporizer into the reactor.

The latter was a glass tube 48 mm. o.d. by 75 cm. long sealed directly to the vaporizer and heated by a "Hevi-Duty" furnace. This reactor was periodically soaked overnight with a saturated boric acid solution and then drained. For the experiment at 630° and high flow rates a "Vycor" reactor 18 mm. o.d. by 20 cm. long was used. It was found necessary to provide a baffle near the inlet to cause turbulence which accelerated the attainment of reaction temperature by the vapors.

The product collection system consisted of a water condenser followed by a trap at 0° and then a series of traps at −78°. The non-condensable gas was collected over brine. When the non-condensable gas was excessive, as with ethylene, an aliquot of the gas was collected by means of an interval timer and a solenoid valve arrangement while the remainder was vented through a wet test meter.

Product work-up consisted of the following steps: (1) the contents of the Dry Ice traps were distilled through a 3 ft. Vigreux column until the C_4 hydrocarbons had been taken overhead; (2) the bottoms from this distillation were combined with the contents of the 0° trap; (3) the aqueous and oil phases were separated and the oil phase washed several times with ice-water; (4) the oil phase, after it had been dried with anhydrous potassium carbonate, was distilled through a Piros–Glover micro-spinning band column or through a 20 theoretical plate helices-packed column; (5) the combined aqueous phase and washings were titrated iodometrically for residual peroxide; (6) the residual peroxide was decomposed by gentle warming of the aqueous phase over platinum oxide; (7) the aqueous phase was then analyzed by standard methods for acid, ester, α-glycol, formaldehyde, total carbonyl, saturated carbonyl, total hydroxyl and saturated hydroxyl; on occasion the aqueous phase was flashed to an overhead temperature of 100°, and the distillate redistilled through the 20-plate column to provide material for identification; (8) all gas samples and low temperature distillation cuts were analyzed by both mass spectrometric and Orsat methods; (9) the analysis of the C_5 fraction was obtained by Podbielniak distillation coupled with appropriate chemical and spectroscopic analyses of the fractions; (10) the other hydrocarbon fractions were characterized by boiling point, refractive index and infrared spectroscopy.

The products of reaction of hydrogen peroxide with ethylene, propylene and isobutylene are summarized in Tables I, II and III. The oxygenated compounds have been identified by derivative preparation and quantitatively estimated by functional group analyses of the appropriate fractions. The gaseous products—C_1 to C_4—were analyzed by mass spectrometry. Fractionation of the higher boiling hydrocarbon components and infrared analysis of the fractions are the bases for the identification and estimation of the higher hydrocarbons.

Discussion and Mechanism

A major problem in the study of the reaction of hydrocarbons with hydrogen peroxide is the known proclivity of hydrogen peroxide to decompose to water and oxygen by way of the chain reaction steps 1–4.[6]

$$H_2O_2 \longrightarrow 2HO \qquad \text{Initiation} \qquad (1)$$

$$HO + H_2O_2 \longrightarrow H_2O + HO_2 \qquad \text{Propagation} \qquad (2)$$

$$HO_2 + H_2O_2 \longrightarrow H_2O + O_2 + HO \qquad (3)$$

$$HO + HO_2 \longrightarrow H_2O + O_2 \qquad \text{Termination} \qquad (4)$$

When a hydrocarbon is present, its reaction with the most reactive species, hydroxy, becomes an important characteristic of the new system.

$$HO + RH \longrightarrow H_2O + R \qquad (5)$$

In principle, since the reaction of hydroxy with hydrocarbons is the subject of interest, step 5 and related reactions are promoted at the expense of 2–4 by operation with high hydrocarbon concentrations and the lowest practical peroxide concentrations. In practice it is not easy to conclude that this has been accomplished successfully since many products of the reaction of hydrocarbons with hydrogen per-

A further complication in interpretation arises because the high temperature oxidation of hydrocarbons is presumed to propagate to a significant extent by means of hydroxy radicals. Thus the distinction between the two systems is one of degree; oxidation involves a low concentration of hydroxy radicals in the presence of a high concentration of oxygen while the present system is designed for the study of a high concentration of hydroxy radicals in the presence of little or no oxygen.

The success in achieving this end must be judged in terms of those products which are peculiar to the hydrogen peroxide–hydrocarbon system and the trends of the product distribution with hydrocarbon to hydrogen peroxide ratio. It is felt that the results presented indicated a satisfactory suppression of hydrocarbon–oxygen reactions.

Two alternatives are open to hydroxy, *viz.*, hydrogen abstraction or addition to the olefinic double bond. Most of the products are ultimately traceable to one of these two initial modes of reaction.

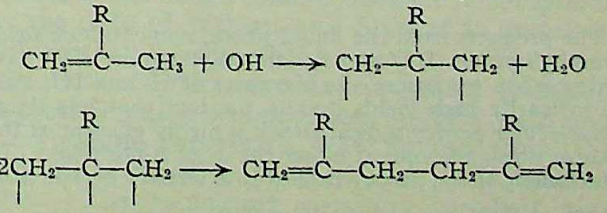
[a] Calculated on a loss-free basis. [b] Distilled +15–37°. [c] Distilled +38–90°. [d] Distilled +90–111°. [e] Distilled 111–118°; $n^{20}D$ 1.4300–1.4310; lit. dimethallyl 114.3°; $n^{20}D$ 1.4293. [f] Distilled 118–164°. [g] Bottoms.

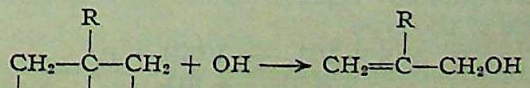
Depending upon the olefin and the point of attack, the resultant radical R will be either an allylic or vinylic radical—in the case of ethylene entirely vinylic, and for propylene and isobutylene largely allylic, although it should be borne in mind that the selectivity of attack customary at lower temperatures will be less obvious at 500°.

The high yields of diallyl from propylene, and dimethallyl from isobutylene are probably the most notable characteristics of the high temperature reactions with hydrogen peroxide. They present probably the most convincing evidence that molecular oxygen from decomposing peroxide is an insignificant factor in these studies because these diolefins have never been reported to be formed in the presence of oxygen. There can be little doubt that formation of these diolefins takes place as



where R is H or CH_3.

Allyl (or methallyl) alcohol is then a logical consequence of



CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

and the olefins, which are formed in substantial quantity, of

$$\cdot CH_2-\underset{R}{\overset{|}{C}}-CH_2 + R \longrightarrow CH_2=\underset{R}{\overset{|}{C}}-CH_2R$$

1-butene from propylene by way of allyl and methyl is an example of the foregoing.

At a temperature of 630° the hydrogen peroxide–propylene reaction is noticeably productive of C_3H_4 (allene). Inasmuch as radical–radical association reactions are important paths to some end products, it is not unreasonable to ascribe other compounds, *e.g.*, allene, to radical–radical disproportionations.

$$CH_2-CH-CH_2 + R \longrightarrow CH_2=C=CH_2 + RH$$

The importance of allyl radical reactions in the case of propylene is demonstrated by the fact that 55 and 70% of the reacted propylene at 530 and 630°, respectively, yields products traceable to allyl radical precursors. Products which stem from initial abstraction of vinylic hydrogen atoms are evident, particularly in the case of ethylene and in the higher temperature region.

$$CH_2=CH_2 + OH \longrightarrow CH_2=CH- + H_2O$$
$$2CH_2=CH- \longrightarrow CH_2=CH-CH=CH_2$$
$$CH_2=CH- \longrightarrow CH\equiv CH + H$$

Although vinyl radicals can be postulated as intermediates in other reactions, butadiene and acetylene seem to be devoid of reasonable alternate antecedents. A significant yield of acetylene (5.4%) from propylene seems likewise to be a result of vinyl hydrogen removal.

$$CH_3CH=CH_2 + OH \longrightarrow CH_3CH=CH- + H_2O$$
$$CH_3CH=CH- \longrightarrow CH_3 + CH\equiv CH$$

Addition of a hydroxy radical to the double bond must be the single most important reaction with ethylene even at 525° and must be progressively less important with propylene and isobutylene. The resultant hydroxyalkyl radicals can be stabilized as alcohols by hydrogen capture, but evidently the more usual evolution of hydroxyalkyl leads to eventual fragmentation of the molecule. Methane, carbon monoxide and formaldehyde are important products of the hydrogen peroxide–ethylene experiments and in the propylene studies these plus, in particular, ethylene must be accounted for. The initial hydroxyethyl radical which seems to be a step in the breakdown of ethylene, shows little evidence of instability and, in fact, rather limited reaction opportunities. The complete absence of hydrogen at 435° precludes a β-scission of a carbon–hydrogen bond so that it can only be concluded that hydroxyethyl is a hydrogen donor. That some donor of considerable efficiency is present can be deduced from the important yields of ethane. The reaction steps suggested then become

$$-CH_2CH_2OH + X \longrightarrow CH_2=CHOH + XH$$
X = olefin or radical
$$CH_2=CHOH \longrightarrow CH_3CHO$$
$$CH_3CHO + R \longrightarrow CH_3\dot{C}O + RH$$
$$CH_3\dot{C}O \longrightarrow CH_3 + CO$$

At 435° acetaldehyde is a significant product and its decomposition to methyl and carbon monoxide frequently has been demonstrated.[7] Thus, this course of fragmentation for ethylene—and for propylene—seems reasonable.

The production of hydrocarbons of higher carbon number is surely a consequence of radical addition to olefin double bonds. Indicative of the number of processes yet to be explored is the analysis of a broad product fraction boiling from 15 to 57°—identified among the products as C_5's. The C_5 hydrocarbons in the fraction were identified as pentanes 2.9%, amylenes 32.2%, pentadienes 32.8%, cyclopentane 2.5%, cyclopentene 13.2% and cyclopentadiene 2.1%.

Intramolecular Oxidation. The Autoxidation of Some Dimethylalkanes

BY FREDERICK F. RUST

RECEIVED MARCH 2, 1957

The products from the liquid phase, non-catalytic oxidations of 2,3-dimethylpentane (I), 2,4-dimethylpentane (II), 2,5-dimethylhexane (III) and 2,6-dimethylheptane (IV) have been identified and related to one facet of the mechanism of hydrocarbon oxidation. In the cases of II and III, the 2,4- and 2,5-dihydroperoxides, respectively, were made in extraordinarily high yields despite the fact that less than 10% of the hydrocarbons reacted. The results show that intramolecular peroxy radical attack is highly efficient at the β-position, somewhat less so at the γ-position and apparently of little or no significance at either the α- or Δ-positions. The efficiency of intramolecular oxidation appears to be favored by attachment of the peroxy radical to a tertiary carbon atom.

Introduction

Although the oxidation of aliphatic hydrocarbons is conventionally represented as an intermolecular process of the type

$$RO_2 + RH \longrightarrow RO_2H + R$$
$$R + O_2 \longrightarrow RO_2$$

increasing evidence indicates that an oxidation chain does not necessarily propagate from molecule to molecule, but, depending on conditions, can propagate from one point to another within the molecule. The formation of β-dicarbonyl compounds and oxirane rings in the gas phase oxidation

of pentane,[1] hexane[2] and 2,2,4-trimethylpentane[3] and the production of a 2,5-dihydroperoxide from the cobalt catalyzed liquid phase oxidation of 2,5-dimethylhexane[4] have been interpreted on this basis.

The present study covers the liquid phase non-catalytic oxidation of hydrocarbons of the general structure C–C–(C)$_x$–C–C, where x was varied from 0 to 3. From the reaction products of this series of hydrocarbons can be deduced some of the characteristics of intramolecular oxidation.

Materials

The 2,3- and 2,4-dimethylpentanes were obtained from Phillips Chemical Company. The first was the technical grade, 95+%, which was further fractionated. A center cut was collected at 89.0–89.5°; n^{20}D 1.3917. The 2,4-dimethylpentane was research grade and used without further treatment (b.p. 80.6°, n^{20}D 1.3811). The 2,5-dimethylhexane was prepared by a Grignard coupling reaction with methallyl chloride followed by separation and hydrogenation of the dimethallyl. The product used distilled at 108.6–109.6°; n^{20}D 1.3928. 2,6-Dimethylheptane was obtained by dehydrating diisobutylcarbinol over alumina at 390° and then hydrogenating the resulting olefin. A fraction, 133.5–135.2°, n^{20}D 1.4013, was oxidized.

Experimental

The hydrocarbons were oxidized in a closed system comprised of a Pyrex reactor, an all-glass pump, a hydraulically pressured steel oxygen reservoir fitted with a sight gage, and Dry Ice-cooled traps in the system immediately following the reactor and the reservoir. Oxygen at 35 p.s.i.g. was circulated through the hydrocarbon at 115–120°. The oxygen consumption was measured at constant pressure by following the rising water level in the calibrated reservoir.

The peroxide in the product was determined iodimetrically by reduction with acidified (acetic acid) potassium iodide in isopropyl alcohol solution under reflux for five minutes.

The hydrocarbon charge was usually 400 cc. of which from 5–8% was oxidized and in general the product was concentrated to *ca.* 70 cc. by flashing off the unreacted hydrocarbon. If necessary, pressure was reduced during concentration to keep the kettle temperature below 60° in order to minimize peroxide breakdown. The concentrate was diluted to *ca.* 300 cc. with isopropyl alcohol and reduced with hydrogen and platinum oxide catalyst. The products were then separated by fractional distillation. Where small amounts of product were to be analyzed, separation was effected on a Piros–Glover spinning band micro-still. Significant departures from this procedure are discussed under the individual hydrocarbons.

In most cases the oxidation product had two phases, but after topping off the traces of water and a substantial fraction of the unreacted hydrocarbon under reduced pressure, a single phase usually was obtained. In the case of 2,5-dimethylhexane the dihydroperoxide is a crystalline solid which readily can be separated by filtration.

Results

2,3-Dimethylpentane.—The autoxidation of this hydrocarbon resulted in a 52.5% yield of peroxide based upon consumed oxygen—the lowest for the four hydrocarbons investigated. Following the removal of the hydrocarbon, water and the low boiling scission products, an analysis of the residue for total oxygen and peroxide oxygen showed 0.340 g. atom of combined oxygen of which 0.214 was in peroxide groups. The remainder, 0.126 g. atom, is essentially carbonyl and hydroxyl and, as such, is assumed to have its genesis in a radical–oxygen association. This remainder, therefore, requires 0.126 g. mole of oxygen for its formation or 0.252 g. atom. This, with the peroxide oxygen, gives a total of 0.466 g. atom of oxygen required to form the high boiling products. The difference between this value and the 0.27 mole of oxygen reacted (0.54 g. atom) is 0.08 g. atom. This last figure indicates the magnitude of the scission reactions and other losses. Small amounts of acetone and methyl ethyl ketone are produced.

A peroxide concentrate was obtained in sufficient quantity for distillation in a falling-film molecular still by combining the products of two runs. Four fractions totalling 40.2 g. were collected.

Fraction no.	Grams	% C	% H	% O (diff.)	Empirical formula	% Peroxide (ROOH)
I	4.0	65.1	12.2	22.7	$C_7H_{15.8}O_{1.83}$	63.7[a]
II	32.5	63.4	11.8	24.8	$C_7H_{15.7}O_{2.02}$	73.4[a]
III	2.0	58.7	10.4	30.9	$C_7H_{14.9}O_{2.76}$	55.0[b]
IV	1.7	57.4	10.0	32.6	$C_7H_{14.7}O_{3.0}$	55.7[b]

[a] Calculated as $C_7H_{16}O_2$. [b] Calculated as $C_7H_{14}O_3$.

2,3-Dimethyl-2-(and-3)-hydroperoxypentane, which is a principal component, has 63.6% carbon, 12.1% hydrogen. Fraction II which accounts for more than 80% of the total, shows an average of two oxygen atoms per molecule although only 73.4% of all molecules contain a peroxide group. Infrared inspection shows a significant amount of carbonyl. When the peroxide groups are hydrogenated to hydroxyls, a carbonyl analysis indicates that at least 16% of this product has two oxygen atoms per molecule and evidently is largely 4-hydroxy-3,4-dimethyl-2-pentanone because as indicated by a very low periodate value the ketone and hydroxyl groups are for the most part non-adjacent.

2,4-Dimethylpentane.—The oxidation of 2,4-dimethylpentane is the least complicated of any in this series. Under comparable conditions this hydrocarbon takes up oxygen to give an 89% peroxide yield. Hydrogenation of the peroxide concentrate gives 2,4-dimethyl-2,4-pentanediol in 95% yield based on the input oxygen. The remainder is accounted for by 2,4-dimethyl-2-pentanol; 2,4-dihydroperoxy-2,4-dimethylpentane crystallized from the sirupy product after standing for about a week.

2,5-Dimethylhexane.—The cobalt stearate catalyzed oxidation of 2,5-dimethylhexane is computed from the data of Wibaut and Strang[4] to give 2,5-dihydroperoxy-2,5-dimethylhexane in 15% yield. In the non-catalytic autoxidation system discussed here total peroxide was produced in 83% yield and the crystalline diperoxide was filtered from the hydrocarbon in 50% yield—based on consumed oxygen. The remaining peroxidic product was concentrated by distilling off unoxidized hydrocarbon under reduced pressure and then hydrogenated in 2-propanol solution at not above 50° with platinum oxide catalyst. The 2,5-dimethyl-2-hexanol was isolated by distillation. The high boiling residue amounting to 20% mole of the product had an empirical formula, based on carbon and hydrogen

analyses, of $C_8H_{16.8}O_{2.9}$. A small amount of crystalline material was separated from this residue which showed a strong test for ketone and gave a carbon–hydrogen analysis in agreement with a 40–60 molar mixture of 2,5-dimethyl-2,5-hexanediol and 2,5-dimethyl-3-keto-2,5-hexanediol.

When about 30% of the hydrocarbon charge was oxidized and the volatile components removed at 70° under vacuum pump pressure a clear peroxidic residue was obtained. This was run through a falling film molecular still at 56°. The distillate was treated with 30% sodium hydroxide, the solid precipitate filtered off, dissolved in a minimum of water and the pure peroxide released by bubbling carbon dioxide into the solution. This peroxide layer was extracted with an isopentane–ether mixture and the mixed solvent then removed under vacuum. Upon standing for a week the somewhat viscous peroxide crystallized. Carbon and hydrogen analyses (59.0% C and 11.0% H) and mol. weight of 159, computed from peroxide determination, showed it to be 2,5-dimethyl-5-hydroperoxy-2-hexanol (theory 59.3% C; 11.1% H; mol. wt. 162). Reduction in 2-propanol with hydrogen and platinum oxide catalyst gave 2,5-dimethyl-2,5-hexanediol (m.p. and mixed m.p. 87.5°). The diperoxide obtained at low levels of hydrocarbon conversion is apparently partially reduced or becomes difficult to recover as the oxidation proceeds.

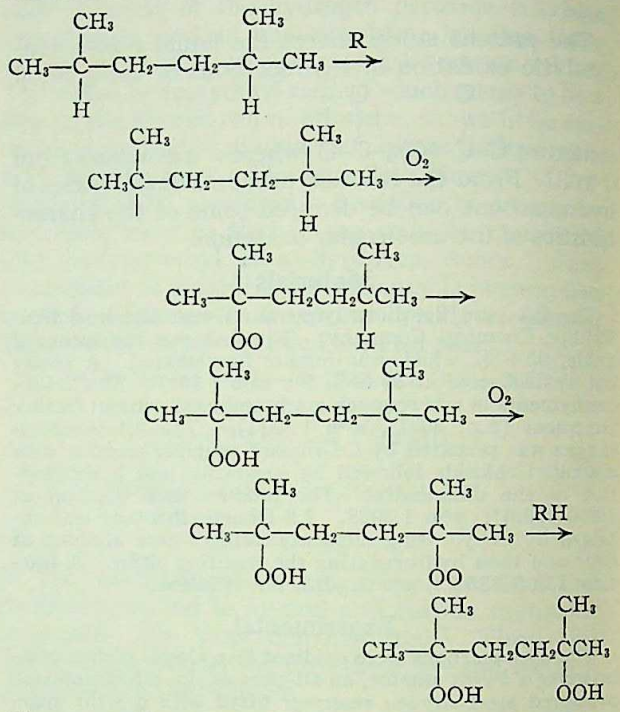
2,6-Dimethylheptane.—In contrast to the oxidations of 2,4-dimethylpentane and 2,5-dimethylhexane, the oxidation of 2,6-dimethylheptane is far less clear cut. The evidence is strong, however, that intramolecular oxidation is an important determinant. Under conditions where not more than 8% of the 2.25 mole input hydrocarbon was oxidized, there was isolated from the hydrogenated product 0.038 mole of 2,6-dimethyl 2-heptanol and 0.087 mole of higher boiling products with an empirical formula $C_9H_{19.1}O_{2.4}$. Of the total combined oxygen in this mixture only 10% was associated with ester and acid groups which would be a consequence of carbon skeleton cleavage reactions. Calculating on the basis that one oxygen molecule was required to place one atom of oxygen in the final reduced product an approximate oxygen balance can be struck.

From 2,6-dimethyl, 2-heptanol	0.038 mole O_2
From $C_9H_{19.1}O_{2.4}$ (0.087 × 2.4)	0.209 mole O_2
	0.247 mole O_2
Total oxygen consumed	0.273 mole

Efforts were made to isolate 2,6-dimethyl-2,6-heptanediol and although fractions were isolated which showed the correct carbon and hydrogen analyses, these results were inadequate because the product was a thick clear liquid rather than crystals of the 2,6-diol (m.p. 76°). In one experiment crystals were collected from an unhydrogenated concentrate which had both peroxide and carbonyl groups and an empirical formula of $C_9H_{18}O_4$ (% carbon 57.2; % hydrogen 9.5; theory 56.8% and 9.5%). The structure $(CH_3)_2COOHCH_2COCH_2COH(CH_3)_2$ is proposed.

Discussion

As pointed out by Wibaut and Strang the liquid phase oxidation of 2,5-dimethylhexane can best be interpreted by an intramolecular attack of the initially formed tertiary peroxy radical upon the remaining tertiary hydrogen atom followed by formation of a second peroxy group.



The crystalline diperoxide was the same as that first prepared by Tannenberger[5] from the glycol and hydrogen peroxide.

This study has sought to arrive at some assessment of the importance of intramolecular oxidation to liquid hydrocarbon systems and accordingly has concerned itself with autoxidation rather than the cobalt-catalyzed reactions which are less favorable to peroxide preservation.

By selecting a series of hydrocarbons in which the reactive tertiary hydrogen atoms are separated by interposing up to three methylene groups, it has been possible to estimate the preferred positions of intramolecular oxidative attack. By far the most favored pattern of reaction involves attack of the peroxy radical in the β-position. This is exemplified by the oxidation of 2,4-dimethylpentane which resulted in about 90% of the product being substituted by oxygen in both the 2- and 4-positions. This preparation of a β-diperoxide by autoxidation is believed to be novel, although this compound has been prepared recently from hydrogen peroxide and the glycol by Criegee and Paulig.[6]

The oxidation of 2,5-dimethylhexane, which gives high yields of the 2,5-diperoxide demonstrates that intramolecular attack in the γ-position by the peroxy radical is the next most favored possibility.

In the case of 2,6-dimethylheptane such a preponderant fraction of the oxygen consumed was involved in the production of polyoxygenated products that it seems improbable that these products could have been formed by other than an intramolecular mechanism similar to that discussed for the other dimethylalkanes. However, the case for Δ-attack by a peroxy radical was not conclusively re-

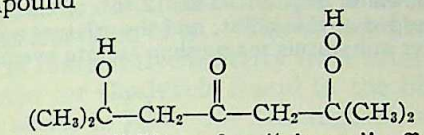
solved. Thus, despite the apparent inability of a peroxy radical in the 2-position to remove a hydrogen atom in the 6-position—at least with any facility—there is considerable indication that removal of hydrogen from the 4- and 5-positions is occurring with considerable regularity. In this connection the tentative identification of a crystalline compound



suggests the possibility of a "zipper" effect in the oxidation of certain linear hydrocarbons. The amount of this compound was, however, too small to suggest that such an effect would be important in any but special situations.

When 2,3-dimethylpentane is oxidized and the peroxides reduced, 2,3-dimethyl-2-(and 3)-pentanol are the principal and almost equally important products. It is significant that 3,4-dimethyl-2-pentanone-4-ol, which is the only reduction product which would be expected by a β-oxidation mechanism, is the most important of the remaining products retaining the original carbon skeleton. α-Attack by a peroxy radical seems to be of no significance.

In view of the foregoing results it seems reasonable to relate much of the formation of keto-acids, lactones, etc., in conventional paraffin oxidation to intramolecular chain propagation. However, no such extensive intramolecular reaction has been observed in the oxidation of the normal paraffins as was found for these branch chain hydrocarbons. Therefore, it is concluded that the well recognized effect of a gem-dimethyl grouping[7] in favoring ring closures is important here in intramolecular attack by peroxy groups.

Free Radicals from the Heterogeneous Decomposition of Butane[1]

BY SYDNEY W. FLEMING AND K. A. KRIEGER

RECEIVED OCTOBER 11, 1956

A method which provides information about the nature of certain adsorbed intermediates is described. Essentially the method consists in observing the decomposition of a hydrocarbon (butane) into free radicals on a heated wire acting as a catalyst. The reaction is carried out at pressures of 1–2 μ in a vessel whose walls are coated with radioactive iodine. The alkyl iodides formed are separated and their activities measured. Catalyst temperatures ranged from 305 to 1490°. Both aluminum (oxide) and tungsten catalysts produce free radicals ranging in complexity from methyl to *sec*-butyl. The radicals formed depend upon the catalyst used and on the temperature. Platinum produces no free radicals under these conditions.

Introduction

A major problem in catalysis is that of discovering the nature of the intermediates whose formation is critical in determining the course of the reaction. In the case of heterogeneous catalysis the methods of studying the intermediates are especially limited, owing to the necessary presence of a catalyst, most often a solid, on whose surface the critical intermediate is formed, and which greatly interferes with the usual methods of observation. In seeking a solution to this difficulty some success has been attained by the use of infrared spectroscopy, which, in suitable circumstances, is able to detect alterations in chemical bonds attendant on adsorption.

The present paper is an attempt, along quite different lines, to approach the observation of adsorbed intermediates. Unfortunately, the method is not quite direct, as the description will show, but it does apparently succeed at least in detecting certain immediate products of desorption, before their nature has been changed by subsequent reaction.

The results reported here are limited to a single reactant and three catalysts, and it is difficult with these limited data to make with certainty any very broad generalizations. The collection of future data, with more varied reactants and catalysts, is expected to remedy this defect. Additional work utilizing this method is in progress in this Laboratory, but this report is made now in the hope that others may find the technique useful.

(1) Based on a thesis submitted to the University of Pennsylvania, 1954 in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

Experimental

Briefly, the method involves production of free radicals by decomposition of butane on catalysts in the form of metal wires and trapping of the free radicals released by the catalyst into the vapor phase by means of a radioactive iodine mirror, followed by fractional distillation and determination of the activities of individual fractions. These activities give the relative quantities of the alkyl iodides formed from the original free radicals trapped by the mirror.

Apparatus.—The experimental apparatus, shown in Fig. 1, consisted of a reaction chamber, L, with a wire catalyst suspended in the center and equipped with electrical connections for heating the wire. Associated apparatus was provided for metering butane into the reaction chamber at the very low rates required. The mirror was formed on the walls of the reaction vessel, and in order for free radicals formed on the wire to reach the wall without suffering collision with butane molecules, the butane pressure was kept between 1 and 2 μ, giving a mean free path on the order of the tube diameter of 5 cm.

During each run the vessel containing the iodine mirror was maintained at Dry Ice temperature. At the end of each run the reaction vessel was warmed to room temperature to allow the product along with the excess free iodine to dis-

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

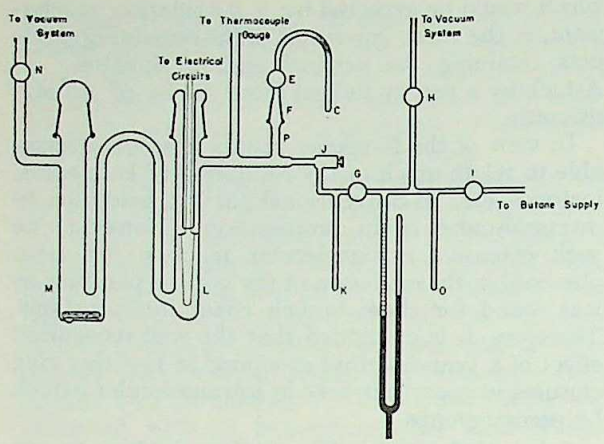

Fig. 1.

til over into M, held at liquid air temperature, after which the carrier alkyl iodides were added to the mixture. The unreacted free iodine was removed by extraction with aqueous sodium sulfite and the alkyl iodides removed, dried and distilled. Following distillation, the activities of the individual fractions were determined in a counting device designed to accommodate the tube in which the fractions were collected. This device consisted of six Nuclear Instrument and Chemical Corp. Type D76 Geiger–Mueller tubes held vertically and arranged in a circle nearly touching each other. A space of just over one-half inch in the center of these tubes was available to accommodate the fraction tube, which was supported so that the sample itself was nearly centered in the active counting space. With this arrangement, counting efficiency was approximately independent of exact sample shape and placement so that all of the many sample tubes used were effectively identical.

Reagents.—The radioactive iodine was obtained from The Atomic Energy Commission, Oak Ridge, Tennessee. The solution as received was diluted so that each ml. contained about 1 millicurie of activity, and appropriate amounts of this solution were withdrawn for each run.

The butane was research grade *n*-butane obtained from Phillips Petroleum Company. This butane was $99.78 \pm 0.08\%$ pure and was used directly from the cylinder as received.

The alkyl iodides came from Eastman Kodak Company, Mathieson and Bell, and Paragon Laboratories. In each case, the iodides were distilled once through a glass packed column about one meter long before being used. In the case of ethyl iodide, where special purity was required, the material was distilled twice and further purified by shaking it with red phosphorus and by passing it through a column of activated silica gel. Blank runs were made on each batch of ethyl iodide to make sure that the blank activity was suitably low in each case.

The No. 30 platinum wire used for filaments was obtained from Bishop Platinum Company. The No. 24 soft-drawn aluminum wire of approximately 98% purity was obtained from Arthur H. Thomas Company, and was treated by immersion in dilute KOH solution before initial use.

The tungsten filaments were cut intact with their attached leads from 150 watt electric light bulbs made by the Westinghouse Electric Corporation, and were used without treatment.

Procedure.—Approximately 2 mg. of iodine having an activity of about 0.5 millicurie was distilled into finger C at liquid air temperature, after which the finger was assembled into the main apparatus as shown in Fig. 1. The entire apparatus then was evacuated thoroughly, after which C was allowed to warm slowly as a vessel of liquid air was being raised around reaction vessel L. In this way a fairly uniform mirror of iodine was deposited on the walls of L; the liquid air was replaced by a Dry Ice–acetone mixture before proceeding with the run.

Butane was admitted during each run from finger K, held at the melting point of methylcyclohexane, by means of needle valve J at such a rate as to maintain a pressure of 1 μ in vessel L as recorded by a thermocouple vacuum gage. Throughout the run vessel M was held at liquid air temperature to trap any materials, including unreacted butane, that might escape from L.

At the conclusion of a run, stopcock N was closed and vessel L warmed to allow all reaction products to condense on the bottom of vessel M. The cap to M was then removed and 12 ml. of ethyl iodide carrier[2] and an aqueous sodium sulfite solution containing small quantities of potassium iodide and sodium bicarbonate was added. After stirring and removing this aqueous layer, followed by several washings, 12 ml. each of propyl and butyl iodides were added, and the organic layer removed by means of the pipet shown in Fig. 2. The 12 ml. of carrier methyl iodide was added at this point, and the mixture was allowed to stand over anhydrous magnesium sulfate overnight.

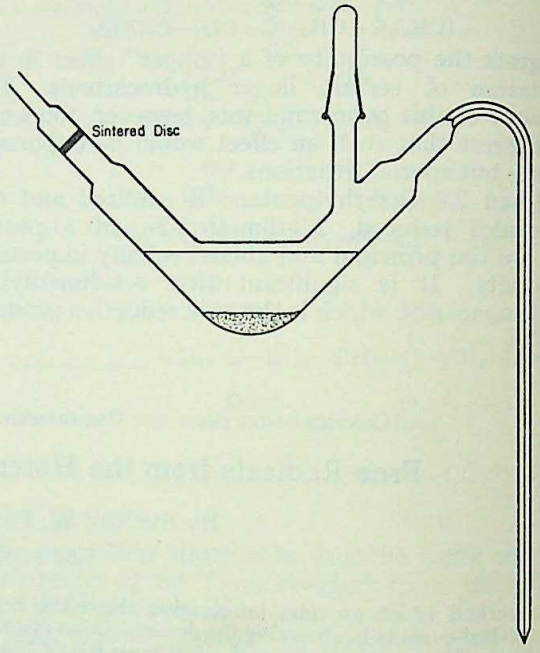

Fig. 2.

The liquid was charged into the still pot for distillation by tilting the pipet so that the liquid ran out through the sintered glass disc which retained the drying agent; the process was hastened by applying gentle air pressure over the liquid.

Distillations were made in a conventional glass-packed column of approximately 12 mm. inside diameter and 1 meter length. Take-off was controlled by a timer-operated solenoid valve. Two-ml. samples were collected in calibrated tubes made from 12-mm. Pyrex tubing.

In each run 12 ml. each of methyl, ethyl, *n*-propyl and *n*-butyl iodides were used as carriers, so that with normal losses, five samples of 2 ml. each could be obtained for each carrier after distillation. In each distillation the methyl and ethyl fractions were taken off at atmospheric pressure, after which 20 ml. of *n*-amyl iodide was added to serve as a chaser, and the pressure reduced to approximately 210 mm. before continuing the distillation. At this pressure the maximum temperature reached was about 112° for the amyl fraction, so that decomposition was minimized. The activity of each fraction was determined immediately after removal from the column; counting was usually complete before the subsequent fraction was ready to be counted. When necessary, suitable correction was made for radioactive decay.

Results and Discussion

The results of several of the runs reported are presented in the form of graphs on which are plotted the activities of the fractions collected and the corresponding boiling point curves. The various fractions are identified across the bottom of each graph, and the boiling point curves serve to define

(2) When a mixture containing all alkyl iodides was added at this point, high spurious activities were found in the methyl iodide fraction. Addition of ethyl iodide only at this time, followed by the others later, resulted in lower blanks than any other method tried.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the transitions between them. The boiling points are shown in °C. along the right-hand ordinate, with the jagged line indicating the point at which the distillation pressure was reduced from atmospheric to approximately 210 mm. Relative activities are plotted along the left-hand ordinates, the highest activity found in a given run being taken as unity and all others in that run being plotted as fractions of it. The values used for calculation of this relative activity were total activities uncorrected for the levels found in the blank runs, and the absolute value for the highest activity is shown in counts per minute (c.p.m.) in each graph. The activity labeled R in the graphs was that of a 2-ml. sample of the pot residue at the end of the distillation.

Blank Runs.—Blank tests of various kinds were made as follows.

Pure lead tetraethyl vapor was passed at a low pressure through the reaction chamber, a short section of which was heated to 200°. A platinum filament heated to approximately 400° was employed to make decomposition more nearly complete. An iodine-131 mirror of the usual type was entirely consumed in about an hour, and the activity appearing in the ethyl fraction was extremely high, demonstrating that when free radicals are present they can be detected. Results are shown in run 35, Fig. 3.

The appearance of radicals which were not in fact formed from butane by the action of the catalyst might have been simulated by: (a) exchange between free radioactive iodine and the alkyl iodides used as carriers; (b) exchange between labeled alkyl iodides and carrier iodides; (c) reaction between primary free radicals and the reactant (butane) or a second primary radical to form new (secondary) free radicals; (d) radiolysis of butane or carrier iodides before extraction of excess radioactive iodine.

That (a) did not occur to a significant extent (provided ethyl iodide only was added as carrier before the excess radioactive iodine was removed) was shown by blank runs, 29 and 44, Fig. 3.

These are the blanks which showed the highest and lowest activities, respectively, of all blanks run. It was at first thought that the activities observed in the blanks were caused by exchange, but this could not account for the butyl peak when only ethyl iodide had been in contact with radioactive iodine or significant concentrations of radioactive iodide ion. The other possibility was that the ethyl iodide underwent radiolysis by the high-energy β- and γ-rays emitted by iodine-131 itself. The work of a number of authors supports this conclusion.[3,4] A number of different materials were tried as the extracting medium, but carefully purified ethyl iodide was found to result in the lowest blanks.

As noted, the possibility of radiolysis of alkyl iodides cannot be entirely eliminated, but it is clearly at worst a minor source of radicals, insufficient to interfere with the observation of appreciable quantities of authentic free radicals.

(4) L. H. Gevantman and R. R. Williams, *J. Phys. Chem.*, 56, 569 (1952).

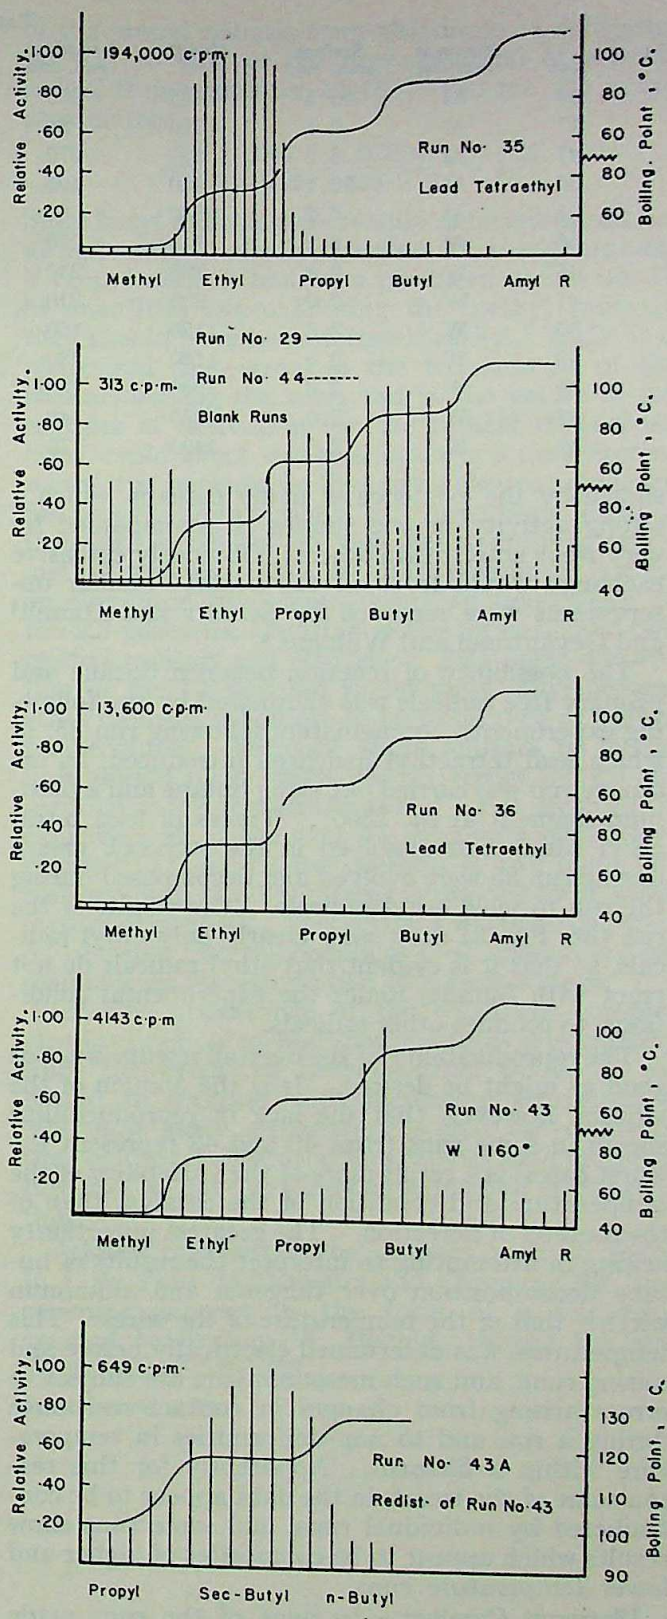

Fig. 3.

To make certain that no radiolysis of butane was occurring either during a run or after a run when all materials were distilled into the extraction vessel, run No. 44 was performed exactly as a normal run, except that the wire was left cold. After distillation the activities of all fractions were found to be considerably below the level of run no. 29, the standard reference blank.

Exchange between labeled and carrier alkyl iodides cannot occur to any considerable extent, as is

38	W	2.0	1335	140	3.6	16	13	6	
42	W	2.0	1490	70	2.3		35	26	16

shown by the existence of many cases in which a strong activity in one species is accompanied by very weak activities in others. Obviously extensive exchange would level off the peaks. Similar observations were recorded by Schuler and Hamill[3] and Gevantman and Williams.[4]

The possibility of reaction between butane and primary free radicals was eliminated by the following experiment. Immediately following run 35, in which lead tetraethyl had been introduced, an ordinary run was carried out using butane and a platinum filament at *ca.* 1300°. Traces of lead tetraethyl which had dissolved in the stopcock grease during run 35 were evolved and decomposed during the run to yield ethyl radicals. The results of the run (36, Fig. 3) show very clearly only ethyl radicals, so that it is evident that ethyl radicals do not react with butane, under the experimental conditions, to produce other radicals.

The reproducibility of the over-all results is not as good as might be desired. It is the opinion of the writers, however, that the lack of reproducibility shown in some runs (runs 40 and 43 represent the worst cases) is a result more of the variability of the temperature and condition of the catalyst than of the method of detection. The greatest uncertainty arising in attempting to interpret the results of butane decomposition over tungsten and aluminum wires is that of the temperature of the wires. This temperature was determined electrically before and during runs, and such measurements are subject to errors arising from changes in contact resistance during a run and to non-uniformities in temperature within a filament. Apparently for this reason some of the trends in the data appear to be contradicted by individual runs, and some runs show results which appear to be composites of higher and lower temperature runs.

Platinum Catalyst.—In none of the runs made with platinum wires were significant quantities of free radicals detected, and so these runs are not individually reported. The temperatures used ranged from 400 to 1200°, and platinized platinum wires as well as smooth wires were tried. The negative results obtained indicate that if decomposition occurred, it proceeded through a mechanism not involving free radicals, or by a mechanism in which free radicals did not leave the surface of the wire. It would seem reasonable to assume that the principal products of any decomposition that might have occurred were unsaturated compounds rather than free radicals.

Tungsten Catalyst.—The results of all runs performed with tungsten and aluminum catalysts are presented in Table I. The apparent collision efficiency shown in this table is the ratio of the number of radicals found to the number of butane molecules colliding with the catalyst, and is therefore a measure of the relative tendency of the catalysts to form radicals of the kind shown.

Examination of Table I will show that the tungsten filaments produced ethyl radicals at all temperatures, and that at the higher temperatures secondary butyl radicals were produced in significant amounts. In none of the runs was secondary butyl iodide added as a carrier; this radical showed up between the propyl and *n*-butyl fractions as a sharp peak rather than a broad plateau. Figure 3 (run 43) shows the boiling point and activity curve obtained, and a subsequent redistillation (run 43A) of a small cut of the secondary butyl peak with the addition of carrier secondary butyl iodide. This redistillation supports the identification of the peak as due to secondary butyl radicals, although isobutyl radicals remain an unlikely possibility.

Aluminum (Oxide) Catalyst.—The results of the aluminum runs may be summarized by saying that at temperatures around 300° only methyl radicals were detected in significant amounts, while at somewhat higher temperatures (430–440°) only normal butyl radicals (and some indication of secondary butyl) were detected, and at the highest temperatures (approximately 540°) principally secondary butyl radicals were detected.

Conclusions

In spite of some irregularities in individual runs, some generalizations emerge from the data as a whole.

(a) The character of the products *in general terms* is a function of the temperature. Thus, both Al and W produce chiefly products of C–C bond scission at lower, and of C–H bond scission at higher, temperatures. This result is to be expected on purely energetic grounds, and it is noted that the catalytic effect of these metals is not sufficient to produce deviations from the expected result. However, the failure of products of C–C bond scission to appear in the case of Pt may mean that C–H bond scission occurs to such an extent, even at low

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

temperatures, that unsaturates (which would not be detected in this procedure), rather than free radicals, are formed. Unfortunately we can produce no direct evidence for this process.

(b) The character of the products *in detail* is affected by the catalyst used, and hence it is clear that the effect being observed is not purely thermal. Individual differences have been pointed out in the preceding section. An explanation for the apparent tendency of W to produce ethyl radicals and for Al to produce methyl radicals, at the lowest temperatures, for example, is not readily forthcoming, however.

(c) The favoring of those radicals which have been generally regarded as most stable is noted. Thus *sec*-butyl radicals in preference to *n*-butyl are observed at the highest temperatures. Whether the disappearance of *n*-butyl and the appearance of *sec*-butyl reflects a changing activity of the catalysts with temperature, or whether it is a result of isomerization of the *n*-butyl radicals originally formed is not entirely certain, but it should be noted that *n*-butyl radicals were observed in some runs and there is therefore some reason to suppose that the shift to *sec*-butyl is a property of the catalyst and not merely a result of isomerization.

The failure to detect propyl radicals of any kind in significant amounts is a striking result, especially in the face of quite high methyl activities, which suggest a 1,2 C–C bond scission. There appear to be at least three possible explanations for their nonappearance: (1) propyl radicals may be formed, along with methyl, but may remain adsorbed. Since the energy required to desorb a propyl radical would be expected to be little different from that for methyl, this assumption does not appear tenable; (2) propyl radicals may be formed but undergo decomposition into ethylene plus methyl radicals. A comparison of the energies of activation[5] for the reactions

$$C_3H_7\cdot \longrightarrow C_2H_4 + CH_3\cdot \qquad E = 20 \text{ kcal.}$$
$$n\text{-}C_4H_9\cdot \longrightarrow C_2H_4 + C_2H_5\cdot \qquad E = 23 \text{ kcal.}$$
$$n\text{-}C_4H_9\cdot \longrightarrow C_3H_6 + CH_3\cdot \qquad E = 23 \text{ kcal.}$$

leads to the conclusion (assuming equal frequency factors) that the ratio of the rate of decomposition of the propyl radicals from aluminum at 360° (run no. 17) to that of the decomposition of *n*-butyl radical from aluminum at 430° (run no. 47) is approximately

$$\exp\left(\frac{23{,}000}{703 \times 2} - \frac{20{,}000}{633 \times 2}\right) = 1.75$$

Since butyl radicals were readily detected in run no. 47 and methyl radicals in run no. 17, it appears that if propyl radicals had been produced in run no. 17 in quantities approximating the methyl radicals, they should have been detected easily. While it is recognized that errors in the temperature of the radicals leaving the wire, and in the values of the energies of activation for the radical decompositions, could affect this conclusion in a quantitative sense, it is improbable that some clearcut evidence for propyl radicals would not have been found if they are produced in quantities approximating methyl radicals. (3) The third possibility is that on aluminum two point adsorption takes place at the 2,3-positions, resulting in the formation of two methyl radicals and ethylene. Two point adsorption in the 1,2-position would yield ethylene and ethyl radicals, which are in fact observed at higher temperatures. Although there appears to be no firm ground upon which the preference for 2,3-adsorption at low temperatures and 1,2 at high can be explained, all of the data on aluminum which correspond to C–C scission conform to two point adsorption, and this hypothesis is the one most satisfactory at present. It is perhaps worth noting that on tungsten also the results of C–C scission are explainable on the assumption of 2,3-adsorption.

(d) The appearance of the relatively complex *sec*-butyl radical at high temperatures is surprising since the extent of decomposition would be expected to increase with increasing temperature. The most likely explanation is that the residence time on the catalyst decreases rapidly with temperature, but we have no direct experimental evidence of this.

Radical Production in the Radiolysis of Liquid Butane[1]

BY CHARLES E. McCAULEY AND ROBERT H. SCHULER[2]

RECEIVED FEBRUARY 12, 1957

The distribution of radical species produced during the radiolysis of liquid butane has been studied by the radioiodine scavenging method. While the radiation yield for formation of total alkyl iodide product increases from a value of 5.6 molecules per 100 electron volts at an iodine concentration of 2×10^{-3} M to a value of 9 at 2×10^{-2} M, the yield for each of the monoiodide products is constant. These yields are, respectively, 0.4, 0.9, 0.1, 0.0, 1.0 and 2.1 for methyl, ethyl, *n*-propyl, isopropyl, *n*-butyl and *sec*-butyl iodides. The increase in yield of total organic iodides at the greater iodine concentrations is due to a large increase in the yield of higher boiling material which most probably represents diiodide products. The constancy of the yields for the less complex products appears to be an additional indication of the validity of the iodine scavenging method since hydrogen abstraction reactions of the radicals are not affected by changes in the scavenger concentration in the region studied.

Radical production in the radiolysis of liquid hydrocarbons has previously been studied by employing iodine at low concentrations to scavenge the radicals formed.[3-6] It has been shown that the radiation yield for uptake of iodine is independent of concentration below 5×10^{-3} M and is presumably a good measure of the yield of radicals produced. The present investigation was undertaken in order to obtain information on the fragmentation pattern in the radiation decomposition of a typical liquid aliphatic hydrocarbon. Liquid butane was chosen since previous experience had shown it possible to obtain adequate separation of the expected alkyl iodides with boiling points up to that of *n*-butyl iodide[7,8] while at the same time the butane molecule is complex enough to allow for the possibility of several different modes in the resulting decomposition. In this work, radioiodine has been used as the detector and the yields of individual products have been determined by carrier isolation methods similar to those originally employed by Gevantman and Williams in studies of the radical distribution in the radiolysis of hydrocarbon vapors.[9]

Experimental

Materials.—Matheson C.P. *n*-butane, stated to be 99.0% pure, was used without further purification. Partition chromatograms of this material showed two barely detectable impurities below the butane peak and none above it, the indicated impurity being of the order of several tenths of a per cent. The alkyl iodides used as carriers were purified by washing with aqueous thiosulfate, drying over anhydrous magnesium sulfate and distilling at reduced pressures through a six foot packed column.

Sample Preparation and Irradiation.—A weighed quantity of radioiodine (5–45 mg.) was placed in the irradiation cell which was then cooled in liquid nitrogen and evacuated. Butane was condensed into a reservoir on the vacuum line and the desired quantity (7–9 cc.) distilled into the irradiation cell. The sample was frozen in liquid nitrogen, evacuated and sealed and the exact weight determined upon opening the cell after irradiation. The irradiation cells consisted of 8.5 mm. i.d. heavy-walled tubing 150 mm. long. Irradiations were carried out at 25° inside a cylindrical Co^{60} source of 30,000 roentgens per hour intensity.[10]

Product Analysis.—The extent of reaction of iodine was determined, as in previous work,[6] by measuring the fraction of iodine found to be organically combined after thiosulfate extraction. The radiation yield was calculated from this information combined with knowledge of the initial iodine concentration and energy absorbed by the sample. Together with the ratios of the activity of the individual components to that of the total sample this served to give the yields for each of the products.

After irradiation, the sample was cooled to about −40°, opened and added to a total of about 250 cc. of precooled mixed carriers. In general, transfer of the sample to the carriers appeared to proceed with little difficulty. The carrier mixture was allowed to come to room temperature and a portion taken for measurement of the ratio of *organic* activity to *total* activity. The bulk of the mixed carriers was then extracted with thiosulfate solution and a portion of this extracted mixture reserved for measurement of the specific activity. The remainder was separated into the individual components by fractional distillation at reduced pressure in a manner similar to that employed in earlier work.[7,8] The relative activities of the various fractions were measured in an annular jacketed geiger counter after a tenfold dilution with carbon tetrachloride. Because of this dilution, differences in the density of the various solutions were slight and resulted in correspondingly small variations in the counting efficiency. Appropriate corrections were, however, applied where necessary. The total activity of a particular component was determined from its specific activity and the volume of carrier initially added. The carriers consisted of 25–50 ml. of each of the suspected components together with about 5 g. of inactive iodine which was added to the mixture for the purpose of diluting any possible reaction between the active iodine present and the carriers. Of the butyl iodides, only *n*-butyl and *sec*-butyl iodide were added as carriers. Since the formation of isobutyl and *t*-butyl iodide involve somewhat complicated rearrangements, these iodides are not expected in any appreciable yield. However, any isobutyl iodide formed would have been carried in the *sec*-butyl iodide fraction while *t*-butyl iodide would have exchanged with the large amount of inactive iodine added[7] and hence would not appear as organic activity. In addition to the activity found in the added carriers, it was observed that the residue remaining in the stillpot after take off of a representative methylene iodide fraction had a higher specific activity than the methylene iodide itself. The activity in excess of the methylene iodide component is here referred to as the residue and presumably consists largely of high boiling diiodides. The total activity in this fraction was determined from the volume of material remaining in the stillpot and the specific activity of this residue.

[a] Molecules of product per 100 e.v. of absorbed energy.

reaction of iodine are given in Table I along with the corresponding specific rates observed in each of the experiments. These rates are expressed in units of moles of total alkyl iodide product per gram of sample per minute of exposure in the 30,000 roentgens/hr. source. Absolute radiation yields were determined by comparison with the specific rate of ferrous iron oxidation in the Fricke dosimeter. Correction has been made for decay of the Co^{60} source to November 1, 1955, at which time the rate of ferric ion formation was 8.25 μM/min. The corrected irradiation periods are given in Table I. Assuming that $G(Fe^{+++})$ is 15.5 and that energy absorption is proportional to the electron density of the irradiated material, a value of 3.30×10^{16} e.v./g./min. is obtained for the rate of energy dissipation in the butane. The absolute radiation yields calculated from this figure are given in Table II.

Possible Importance of Self-radiolysis.—Since the addition of carrier materials results in a 50-fold dilution of the activity and since only a small fraction of the total activity appears in any particular component, it is necessary to use high specific activity radioiodine, at least in the case of experiments carried out in more dilute solutions. The possibility therefore arises that appreciable reaction will result from self-radiolysis of the sample due to the radiations from I^{131}. With this in mind, contact between the radioiodine and the liquid butane was kept to a minimum and, in general, the standing periods were not more than a few days. However, some estimate of the extent of this self-radiolysis is in order. In these experiments the activity level was approximately 0.1 millicurie per gram of sample. Taking the average absorbed energy per disintegration as 0.2 Mev., it is estimated that the I^{131} dissipates energy in the butane at the rate of 6.4×10^{16} e.v./g./day. This compares with a total energy deposition in the sample of the order of 3.3×10^{19} e.v./g. from the Co^{60} field. It is seen, therefore, that the effects of self-radiolysis are negligible here (~1%) but that they must be taken into account if one were to use an appreciably higher specific activity material.

Product Distribution.—The distribution of activity among the various products is given in Table I along with the material balance obtained by comparing the sum of the total activities found for each component to that of the mixed carrier sample. Essentially all of the activity is accounted for. The radiation yield for each individual component is given in Table II.

Effect of Iodine Concentration.—The radiation yields for ethyl, *n*-propyl, isopropyl, *sec*-butyl and *n*-butyl iodides are essentially independent of iodine concentration over the region studied. The observed yield of activity in the methyl iodide shows a considerably greater scatter than appears in any other of the iodides. This scatter makes determination of the functional dependence of the radiation yield upon iodine concentration somewhat elusive although it is believed that here too the yield is substantially independent of iodine concentration and has a value of about 0.4.

The cause for the scatter in the case of methyl iodide is unknown but apparently does not originate in the fractionation procedure since quite adequate fractionations have been obtained in other investigations.[7,8,11,12] Although the higher iodides exhibit a negligibly small rate of thermal exchange

with radioiodine, methyl iodide, especially if impure, reacts at a considerably higher rate. Because of the low fractional reactions in these radiolysis studies, several tenths of a per cent. pickup of the activity by the methyl iodide carrier would amount to an appreciable increase in the apparent yield. It is probable, therefore, that the high yields of methyl iodide in the experiments at 0.0112 and 0.0230 *M* are due to some defect in the experimental procedure, possibly to reaction of radioiodine with an impurity present in the batches of carrier used in these particular experiments. Two experiments in which only methyl iodide was determined were carried out as specific checks on the methyl iodide yield and are also reported in Table I. Here the activity was separated as quickly as possible after addition of the sample to the carrier mixture to minimize any possible exchange.

Discussion

Although the amounts of the simpler alkyl iodide products are independent of concentration, it is seen that the radiation yield of total combined iodine increases in the concentration region studied from 5.6 to about 9. This observed increase is due to the formation of methylene iodide and more importantly to the formation of other high boiling products and is about twice as large as that found in similar studies with cyclohexane.[6] The constancy in the yields of monoiodide products is a somewhat surprising fact in view of the drop in the hydrogen yield resulting from these scavenger concentrations in the case of cyclohexane.[13] The radical products are unaffected by changes in the physical and chemical processes which cause the drop in hydrogen and increase in diiodide yields and, therefore, appear to be formed in the early stages of the radiation decomposition. Of particular importance is the indication from the constancy of the *n*-butyl and *sec*-butyl yields at high iodine concentrations that production of butyl radicals by abstraction reactions such as

$$H\cdot + C_4H_{10} \longrightarrow H_2 + C_4H_9\cdot \qquad (1)$$

is unimportant. It seems likely therefore, as has also been indicated in other studies, that the observed hydrogen gas is produced by an ultimate molecule reaction rather than by an abstraction reaction similar to 1.

The increase in diiodide products interestingly occurs in the concentration region of 10^{-2} *M* where it has been shown[13] that the molecular hydrogen yield drops. Williams and Hamill[14] have called attention to the importance of electron traps in this region of solute concentration and have suggested that iodine can act as an electron scavenger. This change in the primary species might permit the production of stable diiodide products by a direct radiation-induced reaction between the iodine and the hydrocarbon.

Relative Importance of Various Modes of Fragmentation.—The interaction of radiation with matter produces as primary fragments both radical and ionic species, the chemical importance of each being as yet undetermined. Although there has been a theoretical indication that charge neutralization takes place in the case of liquids before chemical reactions come into play,[15,16] recent work with the mass spectrometer has shown that the cross-sections for ion–molecule reactions are very large[17] and has indicated that these reactions may be important intermediary processes in the radiation chemistry of liquids.[18] The present study includes at least one indication that ionic mechanisms play an important role. If the radiation decomposition involves radicals but not ions, equivalent amounts of methyl and *n*-propyl radicals would be expected to result from the radiolysis of butane. It is seen here that the yield of *n*-propyl iodide is only one fourth that of methyl iodide. This low value can scarcely result from the thermal dissociation of propyl radicals since if such were an important process, the measured propyl iodide yield should be dependent on the concentration of iodine. It thus seems necessary to include in the mechanism some step other than simple homolytic dissociation of butane molecules into radicals.

Although comparison of results obtained from the mass spectrometer and from the irradiation of liquid systems cannot be simple, it is worth noting that the most abundant ion in the mass spectrum of butane is $C_3H_7^+$ and that the ratio $C_3H_7^+/CH_3^+$ is about 17. The ratio of the complementary radicals will thus be presumably considerably larger than unity in qualitative agreement with data of Table II. Gevantman and Williams[9] have pointed out that such a complementarity is observed between the relative abundance of radicals detected by radioiodine and of ions formed in the mass spectrometer in the case of propane, *n*-pentane, and neopentane vapors. Present data on liquid butane are quite analogous to the results of Gevantman and Williams on pentane vapor but show no correlation with their results for butane vapor.

It is seen that the ratio for formation of *sec*-butyl and *n*-butyl radicals is about two to one, although the ratio of primary to secondary hydrogen atoms is about three to two. A similar preferential rupture for particular bonds has, of course, already been shown in the case of alkyl iodides, alcohols and carboxylic acids. This appears to be in accord with semi-quantitative theories for mass spectra of polyatomic molecules,[19] where it is postulated that decomposition occurs only after the positive ions have undergone a number of vibrations which effectively distribute the energy throughout the whole molecule.

The carrier distillation method employed here is quite tedious and of limited scope due to the difficulties of separating the iodides. However, the introduction of simpler vapor chromatographic proce-

dures now available should make the radioiodine detection method more generally useful. Since it has been shown recently that carrier-free mixtures of the organic bromides can be separated on partition columns,[20] use of this technique may avoid difficulties due to failure to add proper carrier components. It is hoped that extension of these studies may reveal much more in the way of the fine structure of the radical spectrum produced by radiation.

The Evaluation of Inductive and Resonance Effects in Reactivity. II. Thermodynamic Properties of Hydrogenation of Non-conjugated Olefins, Aldehydes and Ketones[1]

BY ROBERT W. TAFT, JR., AND M. M. KREEVOY

RECEIVED JANUARY 25, 1957

The effect of unconjugated (α,β-saturated) substituents on the enthalpies of hydrogenation of mono- and *trans*-disubstituted ethylenes, $\Delta\Delta H°$, and on the free energies of hydrogenation of carbonyl compounds, $R_1R_2C{=}O$, $\Delta\Delta F°$, are found to follow with acceptable precision eq. 2: $\Delta\Delta H°$ (or $\Delta\Delta F°$) $= (\Sigma\sigma^*)\rho^* + (\Delta n)h$. This empirical relationship is suggested by and is correlated with the hypothesis that polar and hyperconjugative effects of the substituents contribute approximately additively to give the observed effect on the thermodynamic property. This hypothesis unifies diverse observed effects of substituents with theory. An important polar contribution to the thermodynamic properties for these reactions is expected in view of the change from the sp^2 to the sp^3 valence state of carbon which accompanies the hydrogenation. Evidence is obtained that hyperconjugation stabilization is much less susceptible to electron demand at the reaction center than is stabilization by inductive electron-release. The hyperconjugation stabilization per α-hydrogen atom in an open chain olefin or carbonyl compound is found to be about 0.5 kcal./mole.

The effect of alkyl substituents on the enthalpies of hydrogenation of olefins has been commonly attributed to hyperconjugation of the group with the C–C double bond.[2,3] If the entire effect of the substituent on the enthalpy of hydrogenation is attributed to hyperconjugation or conjugation in the olefin, the resulting hyperconjugation energies obtained for alkyl groups appear to be unreasonably large compared to the conjugation energies obtained for α,β-unsaturated substituents.[4]

Adkins and students have determined the free energies of hydrogenation of numerous aldehydes and ketones in dilute toluene solutions at 60°.[5] Hyperconjugation of alkyl substituents with the carbonyl group is reasonably expected to make at least as important contribution to these hydrogenation equilibria as those for olefin hydrogenation. However, the effects of alkyl groups on the free energies of hydrogenation of aldehyde and ketones do not show a distinct hyperconjugation order. In fact, conjugation effects of unsaturated groups on the free energies of hydrogenation are frequently not (or only slightly) discernible.

The hydrogenation of double bonded compounds is accompanied by a marked decrease in the intrinsic electronegativity of the atoms at the double bond.[6] This results from the fact that the sp^2 valence state of a given atom is appreciably more electronegative than the sp^3 state. Rates and equilibria for reactions which involve a substantial change in the electron demand at the reaction center show large susceptibilities to the electron attracting and releasing powers of substituent groups. That is, polar effects of substituents are large for reactions of this kind.

Important inductive, as well as hyperconjugation, effects are therefore expected to contribute to the observed effects of substituents on the enthalpies and free energies of hydrogenation of olefins, aldehydes and ketones.

In paper I it was shown that the very large effects of substituents on the rates of hydrolysis of diethyl acetals and ketals (of non-conjugated aldehydes and ketones) are correlated in an approximately quantitative manner by an equation which attributes the total effect of the substituent on the free energy of activation to the sum of independent inductive and hyperconjugation effects.[7] The acid-catalyzed rate constants in this reaction series follow with acceptable precision the equation

$$\log (k/k_0) = (\Sigma\sigma^*)\rho^* + (\Delta n)h \qquad (1)$$

where $\Sigma\sigma^*$ is the sum of the polar substituent constants, σ^*, for the substituents, R_1 and R_2, of the acetal or ketal of the general formula $R_1R_2C(OC_2H_5)_2$. These polar substituent constants were ob-

tained by Taft from data on the acid-catalyzed hydrolysis and the alkaline saponification of esters, $RCO_2C_2H_5$.[8] n is the total number of hydrogen atoms in R_1 and R_2 of the general compound (for which k is the rate constant). Δn is the difference between n and n_0, where n_0 pertains to the standard of comparison (for which k_0 is the rate constant). The standard was chosen so that $R_1 = R_2 = CH_3$ ($\Delta n = n - 6$, $\Sigma\sigma^* = 0.000$). The empirical reaction constant, ρ^*, measures the susceptibility of the hydrolysis reaction to polar effects. The empirical constant h is interpreted as a measure of the hyperconjugative stabilization of the reaction transition state by a single α-hydrogen atom.

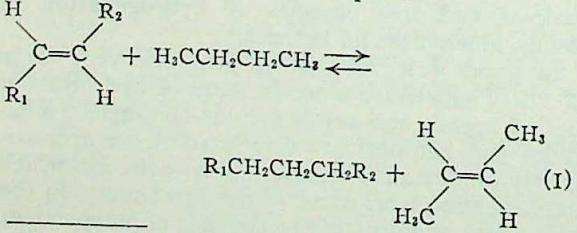
In this paper we report the correlation of the effect of substituents on the enthalpies of hydrogenation of *trans*-substituted, unconjugated olefins, $\Delta\Delta H°$, and of free energies of hydrogenation of unconjugated aldehydes and ketones, $\Delta\Delta F°$, by the equation

$$\Delta\Delta H° \text{ (or } \Delta\Delta F°) = (\Sigma\sigma^*)\rho^* + (\Delta n)h \qquad (2)$$

The empirical correlation eqs. 1 and 2 provide a simple, self-consistent theory of the effects of substituents on these rates and equilibria. In paper III it is shown that the evaluation of hyperconjugation and inductive effects by eqs. 1 and 2 can be used to obtain approximately quantitative values of the conjugation effects of α,β-unsaturated substituents.[9] The relative magnitudes of the hyperconjugation and conjugation effects obtained in this manner are quite reasonable.

Enthalpies of Hydrogenation of Gaseous Olefins.—Kistiakowsky and co-workers[10] have determined calorimetrically the vapor phase enthalpies of hydrogenation for a number of olefins. In addition a number of enthalpies of hydrogenation can be derived from accurate data on heats of formation.[11-13] The largest body of reliable data is available at 355°K.

The effect of structure on the enthalpy of hydrogenation of mono- and *trans*-disubstituted ethylenes is given by the enthalpy change, $\Delta\Delta H°_{355}$, of the following reaction, using *trans*-2-butene ($\Delta n = n - 6$) as the standard of comparison



$$R_1CH_2CH_2CH_2R_2 + \text{(trans-2-butene)} \qquad (I)$$

(13) The fact that heats of hydrogenation derived from several types of measurements are all correlated by eq. 2 lends additional support to the validity of the treatment.

where R_1 or R_2 is any substituent which is not conjugated with the functional group (hereafter referred to as an α,β-saturated substituent). The 21 available enthalpies of hydrogenation, $\Delta\Delta H°_{355}$, of this class cover a range of 5.2 kcal./mole, and are correlated by eq. 2 with a mean difference between calculated and observed values of 0.1 kcal. The latter figure is approximately the same as the estimated experimental uncertainty.[10-12]

The values of ρ^* and h which give the best fit of the data to equation 2 are: $\rho^* = -2.409 \pm 0.151$ and $h = 0.437 \pm 0.51$ (with a residual of $+0.1$ kcal./mole). Table I also lists the corresponding enthalpies at absolute zero, $\Delta\Delta H°_0$. It is important to note that corresponding values of $\Delta\Delta H°_{355}$ and $\Delta\Delta H°_0$ are nearly the same, and that eq. 2 therefore holds for the enthalpies at absolute zero.

The enthalpies of hydrogenation of *cis*- and vicinally disubstituted ethylenes and cyclic olefins are not generally fitted with precision by eq. 2. Deviations from eq. 2 for a number of typical olefins of this kind are given in Table II.

For the *cis*- and vicinally disubstituted olefins the deviations are reasonably attributed to steric effects which result from the shorter bond lengths and greater rigidity of the olefins as compared with the saturated hydrocarbons. For the cyclic olefins the deviations can be attributed to changes in the number of eclipsed carbon–hydrogen bonds on going from the unsaturated to the saturated compound.[14]

The enthalpies of hydrogenation of conjugated olefins also do not follow eq. 2. In this case the positive differences between the calculated and the observed enthalpies are thought to be close measures of the increase in resonance stabilization resulting from conjugation (*cf.* paper III).[9]

Free Energies of Hydrogenation of Aldehydes and Ketones.—Adkins and co-workers[5] made an extensive study of the equilibrium constants (which we shall denote by K/K_0) for the general reaction

$$R_1R_2C{=}O + (CH_3)_2CHOH \rightleftharpoons R_1R_2CHOH + (CH_3)_2CO \qquad (II)$$

The reactions were carried out in dilute toluene solution, and were catalyzed by aluminum *t*-butoxide. Most of the data were obtained at 60° but a few data at other temperatures are included since the position of equilibrium does not appear to be appreciably temperature dependent. Seventeen available free energies, $\Delta\Delta F^0 = -2.303RT \log (K/K_0)$, for unconjugated aldehydes and ketones have a total spread of nearly 6 kcal./mole. These free energies are correlated by eq. 2 with an average deviation between observed and calculated values of 0.4 kcal., a figure of the same magnitude as the experimental uncertainty.[2,3] The standard of comparison is acetone ($\Delta n = n - 6$; $\Sigma\sigma^* = 0.000$) and the values of ρ^* and h which give the best fit of the data to eq. 2 are: $\rho^* = -6.39 \pm 0.26$, and $h = 0.54 \pm 0.06$ (with a residual of $+0.6$ kcal./mole).

Table III illustrates the fit of these free energies to eq. 2. The values given by Adkins, *et al.*, for dimethoxyacetone, formaldehyde and chloral have

[a] Ref. 1; $\Delta H°_{365}$ for *trans*-butene-2 is −27.6 kcal. [b] Ref. 12. [c] Ref. 11. [d] The σ^* value for $CH_3CH{=}CHCH_2$ was used. [e] Average value for seven different esters; mean deviation ±0.8 kcal./mole. [f] The values of $\Delta\Delta H°_{355}$ and $\Delta\Delta F°_{355}$ differ by terms involving partition functions for translational, rotational and vibrational motions. (*Cf.* ref. 18, pp. 563–564): $\Delta\Delta H° - \Delta\Delta F° = RT^2\,[\mathrm{d}(\ln \pi Q)/\mathrm{d}t] + RT \ln (\pi Q)$; $(\pi Q) = \frac{q_P q_{R_0Y}}{q_{P_0} q_{RY}}$, where q's are partition functions for the substances involved in reactions I and II and generalized by the notation: $RY + P_0 \rightleftarrows R_0Y + P$. The similarity of products and reactants in reaction I or II suggests that the partition functions will be nearly the same for products and reactants, *i.e.* $(\pi Q) \cong 1$, except that in a number of cases the "symmetry numbers" which enter into rotational partition functions (*cf.* ref. 23, p. 296) will be different. These "symmetry numbers" have no effect on $\Delta\Delta H°$ but they may alter $\Delta\Delta F°$ appreciably. The effect is calculated readily and can be subtracted from the observed values of $\Delta\Delta F°$. For olefin hydrogenation the resulting "corrected" values of $\Delta\Delta F°_{355}$ are generally more nearly equal to corresponding $\Delta\Delta H°$ values than the uncorrected $\Delta\Delta F°_{355}$ values.

α,β-Unsaturated substituents are not included in the correlation because of expected conjugation effects. The difference between the free energies calculated by eq. 2 and the observed values for such system are taken as measures of the energies of conjugation stabilization in the aldehyde or ketone (*cf.* paper III[9]).

Discussion and Conclusions

In accord with expectations based upon the greater electron demand made by the sp^2 than the sp^3 valence state, the correlation of the enthalpies and free energies of hydrogenation by eq. 2 provides evidence of an appreciable polar contribution to these thermodynamic properties.

The hydrogenation of aldehydes and ketones is much more favored by electron-withdrawing substituents ($\rho^* = -6.39$) than is the hydrogenation of olefins ($\rho^* = -2.41$). This result is reasonably attributed to a significant contribution from the form $>C^+—O^-$ which makes a carbonyl carbon atom more electron deficient than those of the olefin C–C double bond. The magnitude of the ρ^* values as well as that of the difference between them is perhaps larger than expected but since a quantitative theory for prediction of ρ^* values has not been developed further comment is unwarranted.

In contrast to the marked difference in susceptibilities (ρ^*) of the thermodynamic properties of hydrogenation to inductive electron-releasing power of substituent groups, the hyperconjugation parameter, h, is the same within the combined uncertainties for olefins ($h = 0.44 \pm 0.05$) as for aldehydes and ketones ($h = 0.54 \pm 0.06$). This result is in line with other evidence (*cf.* paper III) which indicates that the resonance stabilization in these systems is much less susceptible to electron demand at the reaction center than is stabilization by inductive electron-release.[9] The availability of an open orbital for conjugation or hyperconjugation appears to be the important variable contributing to resonance stabilization.

The empirical parameter, h, measures the hyperconjugation stabilization due to a single α-H atom in an olefin, aldehyde or ketone in kcal./mole since the effect on the hydrogenation equilibrium is assumed to be associated entirely with the unsaturated state.

Kreevoy and Eyring have recently adopted a model for theoretical consideration of hyperconjugation. Their results are in approximate accord with the values of the h parameter and the linear dependence of hyperconjugation energy on the number of α-hydrogen atoms.[16]

While the correlations of eq. 1 and 2 provide no apparent evidence of C–C hyperconjugation, it is quite probable that such interactions exist. Evaluation of the effects due to such interaction requires more critical data than are presently available.

Dewar and Pettit have recently suggested that enthalpies of hydrogenation of olefins (and several similar reactions) can be explained without involving the concept of hyperconjugation.[17] From certain simplified theoretical considerations, these authors conclude that all olefins having the general formula $H_2C=CH(CR_1R_2R_3)$ should have a characteristic enthalpy of hydrogenation, as should olefins of the given general formula $(R_1R_2R_3C)CH=CH(CR_4R_5R_6)$, etc. However, this conclusion is not in accord with available data, unless the R groups are confined to alkyl groups. Thus, the hydrogenation of  is 1.2 kcal. more exothermic than that of  , and the hydrogenation of  is 2.0 kcal. more exothermic than that of  . The free energy of hydrogenation of  is 3.1 kcal. more negative than that of  .

According to eq. 2 these differences are due to polar contributions to the thermodynamic properties.

The near constancy of the enthalpies of hydrogenation for a given structural type with substitution of only *alkyl groups* is typical of a number of similar observations. In terms of eq. 1 and 2, which consistently describe the behavior of other types of substituents, this constancy results from an approximate cancellation of opposed polar and hyperconjugation effects of the *alkyl groups*.

An interesting feature of the correlation of the free energies of hydrogenation of the carbonyl compounds by eq. 2 is that the classical distinction between aldehydes and ketones is not required. In terms of eq. 2, the more positive free energy of reduction displayed by a ketone than the corresponding aldehyde results from the greater electron-releasing power of alkyl groups (than a hydrogen atom) through both inductive and hyperconjugative interactions with the carbonyl group.

The effects of α,β-saturated substituents on rates and equilibria for a number of other reactions are correlated by eqs. 1 and 2. These reactions are of such character that hyperconjugation effects are expected and it is reasonable that steric effects should be nearly constant within the reaction series. Unfortunately, the available data do not cover either a wide enough range in the polarities of the substituent groups or in hyperconjugation effects to provide a convincing test of eq. 1 or 2. Examples are summarized in Table IV. Reaction series 1 and 2 of Table IV have been previously correlated (less precisely) with σ^* values alone.[18,19]

It was noted earlier that the effects of substituents on the enthalpies of hydrogenation of olefins at 0°K are also correlated satisfactorily by eq. 2. Evidence is thus provided that the thermodynamic

2. Rate of solvolysis of *t*-carbinyl chlorides $R(CH_3)_2CCl$, aq. ethanol, 25°	$\log (k/k_0) = (-3.40)\sigma^* + (n - 3)(0.25)$[b]; k_0, rate constant for *t*-butyl chloride	*Cf.* ref. 19
3. Rate of solvolysis of 3-substituted 1,1-dimethylprop-2-ynyl chlorides, $RC{\equiv}C(CH_3)_2CCl$, aq. ethanol, 25°	$\log (k/k_0) = (-3.79)\sigma^* + (n - 3)(0.45)$[c]; k_0, rate constant for $CH_3C{\equiv}C(CH_3)_2CCl$	20
4. Vapor phase hydrogenation of substituted acetylenes, $R_1C{\equiv}CR_2$, 355°K.	$\Delta\Delta H°_{335} = (-5.53)(\sigma^*) + (n - 6)(0.59)$[d]; $\Delta H°_0$, enthalpy of hydrogenation of dimethylacetylene	12, 21

[a] Mean deviation of calcd and observed values ± 0.05 log units for 18 acids covering a range of 3.75 log units. [b] Mean deviation of calcd. and observed values ± 0.18 log units for 12 compounds covering a range of 3.8 log units. [c] Mean deviation between calcd. and observed values ± 0.05 log units for 5 compounds covering a range of 3.3 log units. [d] Mean deviation been calculated and observed values ± 0.2 kcal./mole for 8 compounds covering a range of 9.5 kcal./mole.

properties are good estimators of potential energy terms.[22]

For hydrogenation of aldehydes and ketones, $\Delta\Delta H°$ values are not generally available. However, $\Delta\Delta F°_{333}$ values for acetaldehyde and methyl ethyl ketone, −4.4 and +0.3 kcal./mole, respectively, may be compared with corresponding $\Delta\Delta H°_{355}$ values determined directly in the vapor phase,[10] −3.4 and +0.2 kcal./mole, respectively. The nature of the agreement lends support to the conclusion that the $\Delta\Delta F°_{333}$ values are significant measures of potential energies.

Equations 1 and 2 provide evidence that polar and hyperconjugation effects contribute independently (at least approximately) to the free energies. This conclusion bears an analogy to first order perturbation theory, which gives the following relationship.[23]

$$E = E_0 + \lambda_n \int \psi_0^* H_n \psi_0 d\tau$$

In this equation E_0 is the energy of the unperturbed system, λ_n is a parameter characteristic of the perturbation n, ψ_0 is the eigenfunction of the unperturbed system, and H_n is an operator characteristic of perturbation n. E is the energy of the slightly perturbed system. If more than one kind of perturbation is made, E is obtained from the sum of independent small perturbation energies. Since the effects with which eq. 1 and 2 deal are in the order of 0–10 kcal./mole, while bond energies are of the order of 50–100 kcal./mole, the assumption of the independent character of polar and hyperconjugation terms is apparently equivalent to the use of first order perturbation theory.

Calculation of Parameters Giving Best Fit of Data to Eq. 2.—The values of ρ^* and h giving best fit of the experimental data to eq. 2 have been obtained from the generalized equations of Anderson and Bancroft.[24] Pavelich has set these equation into a form convenient for determining best fit of data to an equation (*e.g.*, eq. 2) in two variables.[25]

The Evaluation of Inductive and Resonance Effects in Reactivity. III. Extra Resonance Energies of Conjugation[1]

BY MAURICE M. KREEVOY AND ROBERT W. TAFT, JR.

RECEIVED JANUARY 25, 1957

The extra resonance energies of conjugation of α,β-unsaturated substituents in aldehydes, ketones and mono- or *trans*-disubstituted ethylenes have been evaluated by correcting the observed free energies and enthalpies of hydrogenation for polar and hyperconjugation effects. The results show the following systematic relationships to structure: (1) substitution of an α,β-unsaturated substituent at a C–C or C–O double bond leads to about 6 kcal. of extra resonance energy. This figure has been found to hold for a wide variety of α,β-unsaturated substituents within which resonance varies markedly, *e.g.*, $CH_3CH{=}CH-$, $C_6H_5CH{=}C-$, C_6H_5-, $-\overset{H}{\overset{|}{C}}{=}O$, $-\overset{O}{\overset{\|}{C}}-OC_2H_5$. (2) Substitution of two α,β-unsaturated substituents at the $>C{=}O$ bond, or *trans* in the $-C{=}C-$ system, leads to about 11 kcal. of extra resonance energy. (3) The extra resonance energy of mono-conjugation of an α,β-unsaturated substituent is approximately ten times greater than that of hyperconjugation by an α-hydrogen atom. All of these structural relationships are correlated by theoretical calculations based upon the LCAO–MO method. The extra resonance energies of conjugation for the transition states for the acid-catalyzed hydrolysis of diethylacetals and ketals are evaluated and discussed. Some applications to rates of addition of carbonyl compounds are discussed.

In papers I and II, the effects of unconjugated (α,β-saturated) substituents, R, on (1) the acid-catalyzed rates of hydrolysis of diethyl acetals and ketals, $R_1R_2C(OC_2H_5)_2$; (2) the enthalpies of hydrogenation of gaseous *trans*-substituted ethylenes, $\begin{matrix} R_1 \\ H \end{matrix}\!\!>\!C{=}C\!<\!\!\begin{matrix} H \\ R_2 \end{matrix}$, and (3) the free energies of hydrogenation of aldehydes and ketones $R_1R_2C{=}O$, were shown to follow the equation[2]

$$\Delta\Delta F^\circ \text{ (or } \Delta\Delta H^\circ, \text{ or } \Delta\Delta F^\ddagger) = (\Sigma\sigma^*)\rho^* + (\Delta n)h \quad (1)$$

The effects of α,β-unsaturated substituents on the thermodynamic properties deviate from eq. 1 in the direction expected for extra resonance stabilization in the conjugated system.[2] In the present paper these deviations are considered in detail.

We define a thermodynamic property conjugation effect parameter ($\Delta\Delta F_\psi$, for example) by the relationship

$$\Delta\Delta F_\psi = \Delta\Delta F^\circ - (\Sigma\sigma^*)\rho^* - (\Delta n)h \quad (2)$$

The utility of this definition depends upon the degree of approximation attending the following assumptions: (1) the substituent effect on the thermodynamic property ($\Delta\Delta F^\circ$, for example) is equal to the sum of independent polar, hyperconjugation and conjugation ($\Delta\Delta F_\psi^\circ$) effects[3]; (2) the polar and hyperconjugation effects are evaluated by the terms $(\Sigma\sigma^*)\rho^*$ and $(\Delta n)h$, respectively; and (3) the steric effects of substituents are constant within the reaction series.

The polar effect susceptibility parameter, ρ^*, and the hyperconjugation parameter, h, are determined for each reaction series by the substituents which do not have α,β-unsaturation (*cf.* papers I and II). The fact that the effects of α,β-saturated substituents of markedly varying steric requirements are successfully correlated by eq. 1—without the inclusion of a steric effect term—strongly suggests that steric effects specific to α,β-unsaturated substituents are small.

Polar effects are implied to make important contributions to the thermodynamic properties for α,β-unsaturated substituents since σ^* values are appreciably more positive (electron-withdrawing) for this type of substituent than for the methyl group (for example, $\sigma^* = 0.600$ for C_6H_5 and 0.360 for $CH_3CH{=}CH-$), and ρ^* values of large magnitude have been established.[2]

The quantity $[(\Sigma\sigma^*)\rho^* + (\Delta n)h]$ may be regarded by the present treatment as the effect on the thermodynamic property expected for the hypothetical α,β-unsaturated substituent without conjugation stabilization. It is apparent from eq. 2 that the conjugation effect parameter is obtained as the difference between the observed and this hypothetical value of the substituent effect on the thermodynamic property.

Each of the reaction series treated in papers I and II (and in this paper) involves a state for which the reaction center is saturated. In accord with the usual convention that conjugation and hyperconjugation interactions are considered to be negligible at saturated centers,[4] the conjugation effect parameter obtained from eq. 2 may be taken as a measure of the extra resonance energy of conjugation between substituent and unsaturated center involved in each reaction.

Although the conjugation energies derived by eq. 2 are rough because of the approximations listed above, the results (given in Tables I, II and III) are obtained from a reasonable extension suggested by earlier correlations and interpretations of reactivity. It will be shown in this paper that the results are uniquely more systematic and self-consistent than earlier estimates. The results are also reasonably correlated by calculations from simple molecular orbital theory.

(1) The work herein reported was carried out on Project NR055-328 between the Office of Naval Research and The Pennsylvania State University. Reproduction in whole or in part is permitted for any purpose of the United States Government.

(2) (a) M. M. Kreevoy and R. W. Taft, Jr., THIS JOURNAL, **77**, 5570 (1955); (b) R. W. Taft, Jr., and M. M. Kreevoy, *ibid.*, **79**, 4011 (1957).

(3) This same model has been employed earlier by P. B. D. De la Mare (*J. Chem. Soc.*, 1602 (1952)) and also L. Bateman and J. I. Cunneen (*ibid.*, 2283 (1951)), in procedures for empirically calculating enthalpies of hydrogenation. However, these authors were unable to deal adequately with polar effects and, as a result, their resonance parameters are unrelated to those reported in this paper.

Other				
$C_6H_5CH{=}CHCH{=}CHC_6H_5$[j,k]	+10.8	−8.3	19.1	19.4 (1.40 β)

[a] σ^* value of +1.65 used for −CH=O group. [b] $\Delta\Delta H°_{355}$ value obtained by subtracting value for hydrogenation of ethylbenzene from that for complete hydrogenation of styrene. [c] $\Delta\Delta H°_{355}$ value obtained by subtracting the value for hydrogenation of 1-butene from that for complete hydrogenation of 1,3-butadiene. [d] σ^* value of +0.360 used for $HC{\equiv}C-$ group. [e] $\Delta\Delta H°_{355}$ value obtained by subtracting the value for hydrogenation of 1-pentene from that for complete hydrogenation of 1,3-pentadiene. [f] σ^* value of +2.000 used for $-CO_2C_2H_5$ group. [g] $\Delta H°_{355} = -27.6$ kcal./mole for standard of comparison, *trans*-butene-2. [h] M. A. Dolliver, T. L. Gresham, G. B. Kistiakowsky, E. A. Smith and W. E. Vaughan, THIS JOURNAL, 59, 831 (1937); 60, 440 (1938); J. B. Conant and G. B. Kistiakowsky, *Chem. Revs.*, 20, 181 (1937). [i] E. Schjånberg, *Z. physik. Chem.*, 179A, 39 (1937). The values quoted are average values for six esters of the general formula $CH_3CH{=}CHCO_2R$ and for seven esters of the general formula $C_2H_5CH{=}CHCO_2R$. The mean deviations from the average value are ±0.6 and ±0.7 kcal./mole, respectively. [j] Data of R. B. Williams, THIS JOURNAL, 64, 1395 (1942), corrected to 355°K. and the vapor phase by G. W. Wheland, "Resonance in Organic Chemistry," John Wiley and Sons, Inc., New York, N. Y., 1955, p. 80. [k] The tabulated values pertain to the sum of successive hydrogenations of the two non-benzenoid double bonds. Effectively this compound provides a triconjugated system. [l] The conjugation effect parameters, $\Delta\Delta H_\psi$, are obtained from the equation, $\Delta\Delta H°_{355} - [(\Sigma\sigma^*)\rho^* - (\Delta n)h]$, using values of $\rho^* = -2.41$ and $h = 0.44$ given in paper II,[2b] and the available data[h-j] on the gas phase enthalpies of hydrogenation of conjugated *trans*-substituted ethylenes. The enthalpies of hydrogenation of α,β-saturated cyclic and *cis*-substituted ethylenes do not follow eq. 1.[2b] Therefore, no *cis* or cyclic conjugated olefins have been included in Table I since eq. 2 is of questionable applicability.

TABLE II

EXTRA RESONANCE ENERGY OF CONJUGATION FROM FREE ENERGIES OF HYDROGENATION OF ALDEHYDES AND KETONES[g]

$C_6H_5COC_6H_5$	+0.1	−10.9	11.0	11.2 (.83 β)
	+0.3	−10.9[f]	11.2	12.6 (.93 β)
	+0.6	−10.9[f]	11.5	11.1 (.82 β)
$C_6H_5COCO_2\text{-}i\text{-}C_3H_7$	−7.0	−19.8[d]	12.8	11.2 (.83 β)

[a] From ref. 5; standard of comparison is $(CH_3)_2C{=}O$. [b] Calculated on the basis of reduction of the faster reacting ketone carbonyl group. [c] Value of $\sigma^* = +1.35$ used for the −C=O group. [d] Value of $\sigma^* = +2.00$ used for $CO_2C_2H_5$ and $CO_2\text{-}i\text{-}C_3H_7$ groups. [e] Value of $\sigma^* = 1.00$ used for $CH(OCH_3)_2$ group. [f] Value of $\Sigma\sigma^* = +1.200$ used, as for two phenyl substituents. [g] The conjugation effect parameters, $\Delta\Delta F_\psi$, are obtained from the equation, $\Delta\Delta F_\psi = \Delta\Delta F°_{333} - [(\Sigma\sigma^*)\rho^* + (\Delta n)h]$, using the values of $\rho^* = -6.39$ and $h = 0.54$ in paper II,[2b] and the available data on the substituent effects on free energy taken from the work of Adkins, *et al.*[5] (which was carried out in dilute toluene solutions at 60°). Cyclic α,β-unsaturated substituents have not been treated (for the reason given in the previous section), except in the cases of fluorenone and xanthone. The latter compounds do not appear to involve much bond deformation, and the systems are planar for both the ketone and the alcohol.

TABLE III

EXTRA RESONANCE ENERGY OF CONJUGATION IN THE TRANSITION STATES FOR THE ACID-CATALYZED HYDROLYSIS OF DIETHYL ACETALS AND KETALS[a]

Compound	$k_1^{25°}$, l. mole sec.$^{-1}$	$\Delta\Delta F^{\ddagger}_{298}$, kcal./mole	$(\Sigma\sigma^*)$ $(+4.91) + (\Delta n) (-0.73)$	$-\Delta\Delta F^{\ddagger}_\psi$, kcal./mole
Monoconjugated				
$CH_2CH{=}CHCH(OC_2H_5)_2$[a]	2.98×10^2	0.55	7.85	7.3
$C_6H_5CH{=}CHCH(OC_2H_5)_2$[a]	1.52×10^2	0.95	8.10	7.1
$C_6H_5CH(OC_2H_5)_2$[a]	7.07	2.77	9.77	7.0
$p\text{-}NO_2C_6H_4CH(OC_2H_5)_2$[b]	1.12×10^{-1}	6.59	13.60[c]	7.0
$C_6H_5C(C_2H_5)(OC_2H_5)_2$[b]	7.40×10	1.38	5.40	4.0
Diconjugated				
$(C_6H_5)_2C(OC_2H_5)_2$[b]	3.27×10^{-1}	4.58	10.31	5.7
	4.38	3.06	10.31[d]	7.3

[a] Data of paper I, ref. 2a. The standard of comparison is acetonal, $k_2 = 7.52 \times 10^2$. [b] New data, *cf.* Experimental. [c] The value of σ^* for the $p\text{-}NO_2C_6H_4$ is taken as the sum of the σ^* for C_6H_5 plus the Hammett σ value for $p\text{-}NO_2$, *i.e.*, $\sigma^* = +1.38$. [d] The value of $\Sigma\sigma^*$ taken as +1.200, that for two phenyl groups. [e] The conjugation effect parameters, $-\Delta\Delta F_\psi^{\ddagger}$, are obtained from the equation, $-\Delta\Delta F_\psi^{\ddagger} = \Delta\Delta F^{\ddagger}_{298} - [(\Sigma\sigma^*)(+4.91) - (\Delta n)(-0.73)]$, in accord with the results of paper I. The free energies of activation pertain to the second-order rate constants for the acid-catalyzed hydrolysis of diethyl acetals and ketals at 25.0° in 50% dioxane–water.

The essential difference in the conjugation energies derived from eq. 2 and those estimated by earlier methods (the difference in some instances is very substantial—*Cf.* Discussion) is that an explicit basis is proposed for evaluating expected polar and hyperconjugation contributions to the thermodynamic properties. In effect, the present method is more objective than earlier ones in providing an appropriate standard of comparison on which to base the extra resonance energy of the conjugated system.

Conjugation Energies Estimated from Molecular Orbital Theory.—The Hückel method of "Linear Combination of Atomic Orbitals–Molecular Orbital" (LCAO-MO) has been used.[6-8] Several of the values of resonance energies for conjugated olefins obtained by this method have been reported previously.[9]

The resonance energies are obtained in units of β, the resonance integral for p-orbitals on adjacent carbon atoms, *i.e.*, $\int \psi_1 H \psi_2 \, d\tau = \beta$. For compounds having oxygen as part of the conjugated system, the difference between the coulomb integral for a p-orbital on carbon, $E_0^\circ = \int \psi_c \psi_c \, dT$, and on oxygen, $E_0^\circ = \int \psi_c \psi_c \, dT$, must be evaluated, as well as the resonance integral for the carbon–oxygen π bond.

Although there is considerable disagreement as to the appropriate values of these coulomb integrals,[10] the present calculations are not very sensitive to the values chosen.[11] A value of 0.5 β has been used for $E_0^\circ - E_0^c$, a value similar to that used by Jaffé (0.51 β).[12] For the resonance integral for the carbon–oxygen π bond the same value (β) as for the carbon–carbon π bond has been used. For the resonance integral for p-orbitals on carbon and on a *saturated* oxygen atom, a value of 0.5 β has been used (Jaffé has used the value 0.56 β[12]).

Using these values it was found that the calculated resonance energy arising from the conjugation of a double bond with a carbonyl group (0.49 β) is essentially unchanged if a saturated oxygen atom is attached to the carbonyl carbon (the new value is 0.47 β). Accordingly, the calculations for all ester groups were simplified by treating the group as the corresponding aldehyde.

Resonance energies were calculated in the usual manner.[13] The extra resonance energy of the conjugated system was obtained from the difference between the resonance energy of this system and that of the appropriately saturated system. That is, if the product of hydrogenation of the double bond contains unsaturation (*e.g.*, $C_2H_5C_6H_5$), the extra resonance energy of the conjugated system ($C_6H_5CH{=}CH_2$) is obtained as the difference of the resonance energies for the two systems.

Tables I and II list in parentheses values of extra resonance energies in units of β which have been calculated in this manner. Also listed, as ΔE_ψ values, are figures obtained by arbitrarily assigning to β the value 13.5 kcal./mole.

Discussion

A number of striking regularities are apparent from the empirical conjugation energies given in Tables I and II. These regularities are well illustrated by "mean" values of the extra resonance energies of conjugation for systems which we shall refer to as mono- or diconjugated (*cf.* Table IV). The conjugation number is defined as the number of α,β-unsaturated substituents substituted at the unsaturated carbon reaction center ($-\overset{\diagdown}{\underset{\diagup}{C}}{=}\overset{\diagdown}{\underset{\diagup}{C}}-$, for olefins: $>C{=}O$, for aldehyde or ketone: $>C\begin{smallmatrix}\diagup OC_2H_5^+\\ H\\ \diagdown OC_2H_5\end{smallmatrix}$, for the hydrolysis transition state).

The use of "mean" values should not be taken as an implication that individual values should necessarily conform to the mean. Instead the mean values provide a "norm" from which individual values generally do not deviate by more than 1 kcal. (*cf.* average deviations from the mean listed in Table IV). Deviations of individual values from the mean which appear to be significant are discussed below.

TABLE IV

"MEAN" VALUES OF EXTRA RESONANCE ENERGIES FOR MONO- AND DICONJUGATED OLEFINS, ALDEHYDES AND KETONES

	Olefin $\Delta\Delta H^\circ_\psi$, kcal.	Aldehyde, ketone $\Delta\Delta F_\psi$, kcal.
Monoconjugated	5.7 ± 0.8	6.2 ± 0.5
Diconjugated	11.5 ± 0.9	11.6 ± 0.6

Monoconjugation of an aliphatic carbon–carbon double bond, a phenyl group, a cinnamyl group, an aldehyde carbonyl group, or ester carbonyl group with a carbonyl carbon all give rise to nearly the same value of $\Delta\Delta F_\psi$ (*cf.* Tables II and IV). In turn mono-conjugation of these same groups with a carbon–carbon double bond gives rise to nearly the same value of $\Delta\Delta H_\psi$ (*cf.* Tables I and IV). The mean value for the extra resonance energy resulting from monoconjugation with the C=C group is essentially the same (perhaps only slightly less) than that for the C=O group (in spite of the very large difference in the susceptibility to polar effects of the hydrogenation of olefins, $\rho^* = -2.41$ and of carbonyl compounds $\rho^* = -6.39$). *We may thus draw the important generalization that the extra resonance energy of conjugation of the two double bonds in these systems is approximately independent of the nature of these double bonds.*

Secondly, the extra resonance energy resulting from diconjugation is nearly the sum of the monoconjugation energies produced by the groups individually. For example, fluorenone, xanthone and benzophenone give essentially the same value for $\Delta\Delta F_\psi$,

Digitized by Arya Samaj Foundation Chennai and eGangotri

and this is only slightly less than twice the mean $\Delta\Delta F_\psi$ value for monoconjugation (*cf.* Tables II and IV).

A third striking regularity is revealed by a comparison of the extra resonance energies of monoconjugation with the corresponding monohyperconjugation parameters, h, obtained in papers I and II.[3] The ratio of these two parameters, as may be seen in Table V, is essentially constant (approximately 10 to 1) for each reaction series. Thus the polar correction of observed substituent effects, which is the essence of the treatment in the papers of this series, has removed the objection noted earlier that hyperconjugation energies based upon observed substituent effects are unreasonably large compared to the conjugation energies.[14] We conclude from the above figures that hyperconjugation is truly second order compared to conjugation.

TABLE V

COMPARISON OF MEAN ENERGIES OF MONOHYPERCONJUGATION AND MONOCONJUGATION

	Hydrolysis transition state	Olefin	Aldehyde, ketone
Hyperconjugation parameter, h, kcal./mole	0.73 ± 0.08	0.44 ± 0.05	0.54 ± 0.06
Monoconjugation parameter, kcal./mole	7.0 ± 0.1	5.5 ± 0.9	6.6 ± 0.6

The constancy of the ratio of conjugation to hyperconjugation parameters constitutes a limited linear resonance energy relationship. The assumption used in papers I and II that the total hyperconjugation effect is obtained approximately as the product of the number of α-hydrogen atoms times a fixed hyperconjugation parameter, h, for a single α-H atom finds support in the present results, namely, in the fact that the much larger extra resonance energies for monoconjugation also contribute approximately additively to give the extra resonance energy of diconjugation.

The values of the extra resonance energy of conjugation given in Tables I, II and III in general support the basis of eq. 2, *i. e.*, that these resonance energies are independent (within approximately 1 kcal.) of the polarity and the number of α-hydrogen atoms in the substituent groups. The few apparent exceptions are discussed individually in later sections of the discussion. For the acetal hydrolysis transition states, the $-\Delta\Delta F_\psi^{\ddagger}$ values are essentially the same (7.1 kcal.) for benzacetal, cinnamacetal, crotonacetal and *p*-nitrobenzacetal, in spite of the fact that the σ^* values for the substituent groups involved vary from +0.850 to +1.870, and reaction rates vary by more than four powers of ten.

The importance of the polar and hyperconjugation contributions to the enthalpies of hydrogenation of olefins is illustrated by comparing some typical values of the extra resonance energy of conjugation obtained from eq. 2 with corresponding values obtained by Wheland by earlier methods[15] (Table VI).

(14) K. S. Pitzer, "Quantum Chemistry," Prentice–Hall, Inc., New York, N. Y., 1953, p. 184.
(15) Ref. 4, p. 80, 85.

ADDED IN PROOF.—Compare, however, with "obsd. conjugation Energies" calculated by A. Lofthus, THIS JOURNAL, 79, 24 (1957), based upon the method of R. S. Mulliken and R. G. Patt, *J. Chem. Phys.*, 19, 1271 (1951).

TABLE VI

COMPARISON OF EXTRA RESONANCE ENERGIES OF CONJUGATION (KCAL./MOLE) OBTAINED BY THE PRESENT AND EARLIER METHODS

Substance	From eq. 2	From Wheland
1,3-Butadiene	5.1	3.5
Styrene	4.3	0.9
Crotonaldehyde	7.3	2.4
trans-Methylcinnamate	11.8	2.9
trans-Ethyl fumarate	10.1	−2.2

It is apparent from Table VI that none of the generalizations given above may be derived from the earlier values of conjugation energies.

The importance of polar and hyperconjugation contributions to the effects of α,β-unsaturated substituents on the free energies of hydrogenation of aldehydes and ketones is even more dramatic (*cf.* Table II). Thus, for example, the free energy of hydrogenation of benzophenone is within 0.1 kcal. of that of acetone, and the value for benzaldehyde is actually 3.1 kcal. more negative than that of acetone. In themselves, these values provide no evidence of resonance stabilization (a positive value is required) in the conjugated system. Yet the values of $\Delta\Delta F_\psi$ derived from eq. 2 using these values of $\Delta\Delta F^\circ$ are in accord with the generalizations concerning the relationship of extra resonance energies of conjugation to structure.

The simple molecular orbital calculations predict each of the three generalizations established from the empirical values of the extra resonance energy of conjugation obtained from eq. 2. Arbitrarily assigning β the value of 13.5 kcal./mole (a figure somewhat lower than that used to correlate resonance energies of aromatic hydrocarbons) the extra resonance energies of 28 conjugated olefins, aldehydes and ketones, with values varying from 4 to 19 kcal./mole, are obtained with an average difference of less than 1 kcal. between the theoretical and the empirical values. The agreement is considered satisfactory in light of the simplicity of both the theoretical model and of eq. 2.

The accord between the empirical and theoretical values of resonance energies of conjugation establishes a consistency between resonance theory and a theory of structural effects on reactivity which unifies diverse effects of structure on reactivity (compare corresponding values of $\Delta\Delta H^\circ$, $\Delta\Delta F^\circ$ and $\Delta\Delta F_\psi^{\ddagger}$ of Tables I, II and III). These results provide further evidence that steric effects in the thermodynamic properties of olefin, aldehyde and ketone hydrogenations are small, as well as in the formation of the hydrolysis transition state from the acetal or ketal.[2]

Although direct steric effects appear to be absent or small, an indirect one, steric inhibition to resonance in the conjugated systems, apparently is definitely present. "Compression energies," of course, always reduce "observed" values of resonance energies.[16] The value of $\Delta\Delta F_\psi$ for pivalo-

(16) *Cf.* ref. 8, p. 236.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

phenone (3.3 kcal.) is significantly less than the mean value for monoconjugated aldehydes or ketones (6.2 kcal.) indicating (in accord with molecular models) an appreciable steric inhibition of phenylcarbonyl conjugation by the adjacent *t*-butyl group. Judging from the generalizations reached above steric inhibition appears to be small or at least roughly constant in other olefins and carbonyl compounds of Tables I and II.

Steric inhibition of resonance in the transition state also apparently accounts for the lower value of $-\Delta\Delta F_\psi^\ddagger$ for the diethyl ketal of propiophenone (4.0 kcal.) than the mean value (7.1 kcal.) for monoconjugated acetal transition states. The values of $\Delta\Delta F_\psi^\ddagger$ for fluorenone and benzophenone diethyl ketals (7.2 and 5.7 kcal., respectively) are markedly less than that estimated by the additivity rule (14 kcal.). The additivity rule appears applicable since the L.C.A.O.–M.O. calculated extra resonance energy for the $(C_6H_5)_2CH^+$ ion is, for example, nearly twice that for the $C_6H_5CH_2^+$ ion. Two explanations may be invoked to account for the exceptional behavior. First, steric inhibition of resonance in the transition state may reduce the value. Second, there is a probable breakdown in the implied parallelism between corresponding free energies of the hydrolysis transition state and that of the intermediate oxocarbonium ion.[2a] With increased resonance stabilization of the carbonium ion, the transition state is reasonably expected to resemble the carbonium ion less and become more like the conjugated acid of the ketal, which is insensitive to resonance stabilization by conjugation.

The $\Delta\Delta F_\psi$ values obtained from eq. 2 for the hydrogenation of three carbonyl compounds (in addition to pivalophenone) do not fit the general picture: (the values for these compounds were not used in obtaining the "mean" values given in Table IV) dimethoxyacetophenone, phenylmethoxyacetophenone and diethyloxomalonate. The value obtained for the latter (23 kcal.) is appreciably greater than for comparable compounds (and is not listed in Table II). Elofson has noted that these compounds are very slow to equilibrate, and has suggested that the equilibrium value reported for the oxomalonic acid ester may be in error for this reason or because of an interfering side reaction.[17] The marked deviation of these compounds from normal behavior suggests that the reported $\Delta\Delta F°$ values may be in considerable error.

Applications.—The figure of five to seven kcal./mole for the extra resonance energy of monoconjugation has useful application to the effect of structure on reactivity in a number of carbonyl addition reactions. The polar and steric effects of a phenyl group or a hydrogen atom substituted at the carbonyl carbon atom have been found to be very similar in the rates of esterification or hydrolysis of esters.[18] It may be proposed that this close similarity in polar and steric effects holds for other carbonyl addition reactions. Further, it is reasonable that the transition states for most such reactions are nearly saturated at the carbonyl reaction center. It is expected then that the free energy of activation for the conjugated reactant will be increased by an amount nearly equal to its extra resonance energy of conjugation.[18]

Making these assumptions, the difference in the free energy of activation for the corresponding phenyl and hydrogen substituted carbonyl compound, $\Delta F_{C_6H_5}^\ddagger - \Delta F_H^\ddagger$ ($= -2.303RT \log (k_{C_6H_5}/k_H)$), should be approximately 6 kcal./mole. Values of the relative rates $k_{C_6H_5}/k_H$ predicted in this manner and corresponding observed values are listed in Table VII for several reactions. The agreement is considered to support satisfactorily the assumptions made.

Apparently, the extra resonance energy of conjugation of ethyl benzoate (or benzoic acid) is perhaps only slightly less than that of acetophenone (or benzaldehyde, etc.) in spite of the substantial resonance within the ester group itself. This is a result in accord with the M.O. calculation cited earlier, which indicates that the extra resonance energy of conjugation of an α,β-unsaturated carboxylic acid or ester is 0.02 β (0.3 kcal./mole) lower than that of the corresponding unsaturated aldehyde.

In this connection it is also of interest that the extra resonance energy of conjugation of an α,β-unsaturated carboxylate ion is calculated by the M.O. method to be 0.06 β (0.8 kcal./mole) lower than that of the α,β-unsaturated acid. Branch and Calvin,[19] and Taft,[20] by methods which parallel those described in this paper, have estimated from relative ionization constants in water at 25° that the extra resonance energy of conjugation is about one kcal. less in the carboxylate ion than in the acid. The fact that the reduction is small indicates that the energies of the various resonances are roughly independent of one another (only a small saturation effect is shown), in accord with the approximate additivity generalization given earlier. Further, the linear resonance energy relationship, namely, that the hyperconjugation effect of a single α-hydrogen atom is about one-tenth that of the conjugation effect of an α,β-unsaturated substituent is followed, for in paper II the hyperconjugation effect on the free energy of ionization is given as 0.1 kcal. per α-hydrogen atom.[2b]

Applying to a carboxylic ester the linear resonance energy relationship, the hyperconjugation parameter, h, for the free energy of activation for the hydrolysis of the ester may be estimated to be about 0.5 kcal. On this basis, and the model applied above to conjugation effects on rate, the rate of hydrolysis of an acetate ester ($n = 3$) at 25° is expected to be retarded by about 1.1 powers of ten compared to the corresponding formate ($n = 0$). This figure is very close to the factor usually observed for the relative rates of acid-catalyzed hydrolysis or esterification (of the corresponding acids).[21] Taft has ascribed this factor to a steric effect and included it within the steric

substituent constant, E_s.[22] The present results suggest, therefore, that the steric substituent constants include small but significant contributions from hyperconjugation effects. However, in accord with the basic arguments of the method,[23] these effects are not expected to alter Taft's polar substituent constants, σ^*.

Experimental

The technique for measuring acetal and ketal hydrolysis rates and the preparation of the 50% dioxane–water mixture have been previously described.[24] Propiophenone diethyl ketal,[25] b.p. 104° (14 mm.), benzophenane diethyl ketal,[26] m.p. 49–50.5°, and fluorenone diethyl ketal,[27] m.p. 78–80°, are all previously known compounds.[28] The diethyl acetal of *p*-nitrobenzaldehyde, a slightly yellow liquid with b.p. 162–163° (14 mm.), is not a previously reported compound.

The Temperature Dependence of Ion Pair Dissociation Constants. I. *o*-Dichlorobenzene[1]

BY H. L. CURRY AND W. R. GILKERSON

RECEIVED MARCH 18, 1957

The conductances of tetraethylammonium, tetra-*n*-propylammonium and tetra-*n*-butylammonium picrates in *o*-dichlorobenzene have been determined as a function of concentration at 25, 35, 45, 55 and 65°. The ion pair dissociation constants and limiting equivalent conductances have been calculated at each temperature. The variation of the dissociation constant with temperature is discussed with reference to Bjerrum's theory and also a recent one proposed by one of the authors.

As has been pointed out in a recent critical review of the ion pair concept,[2] Bjerrum's[3] theory of ion pair dissociation qualitatively but not quantitatively describes experimental results that have been obtained. His theory gives

$$K^{-1} = \frac{4\pi N}{1000}(\epsilon^2/DkT)^3\, Q(b) \qquad (1)$$

where $b = \epsilon^2/aDkt$. Here, N is Avogadro's number, ϵ is the unit of charge and a is the distance of closest approach, being an empirical parameter. While a, as determined experimentally, is generally larger than the charge separation as determined from dipole moment measurements, it may also be much smaller.

The dependence of K upon the dielectric constant at constant temperature has been investigated in solvent mixtures and while the agreement is quite good for the water–dioxane system,[4] a discrepancy has been observed[5] in nitrobenzene–carbon tetrachloride mixtures. Further, specific solvent effects have been shown when results in ethylene chloride ($D = 10.23$), ethylidene chloride ($D = 9.90$) and *o*-dichlorobenzene ($D = 9.93$) are compared at 25°.[6] The ratio of the dissociation constant of Et_4NPi in ethylene chloride to that in *o*-dichlorobenzene is 13.9, far too large to be accounted for on the basis of the difference in dielectric constant alone. There are very few data available concerning K as a function of temperature. An early study in anisole,[7] while in qualitative agreement with Bjerrum's equation, is of doubtful validity due to approximations that were necessary to evaluate the K values. Studies in ethylene chloride, ethylidene chloride and propylene chloride have been reported.[8] It seemed, in view of the scarcity of information, of interest to extend such studies to other solvents, using salts which have been the subject of previous examina-

tion. The choice of solvent, *o*-dichlorobenzene, was made on the basis of its dielectric constant and the previously noted abnormally low K values found at 25°. The salts chosen were tetraethylammonium, tetra-*n*-propylammonium and tetra-*n*-butylammonium picrate.

Experimental Solvent.—*o*-Dichlorobenzene (Eastman red label) was run through a column packed with silica gel and then fractionally distilled on a three-foot column packed with glass helices. Only the middle fraction was retained. This was received in a two-liter flask protected from moisture by a calcium chloride tube. The purified solvent was stored in a dry-box under an atmosphere of nitrogen. The specific conductivity of the solvent was 3×10^{-10}/ohm cm. at 25°.

Salts.—The hydroxide corresponding to each salt was prepared from the available halide (Eastman) by metathesis with freshly prepared silver oxide in alcoholic suspension. The alcoholic hydroxide was then neutralized with picric acid. The resulting picrates were recrystallized from ethanol three times and dried *in vacuo*. The melting points were: Et_4NPi, 259–261°; Pr_4NPi, 117.0–117.4°; Bu_4NPi, 89.8°.

Conductance Measurements.—The bridge used was similar to that of Eisenberg and Fuoss.[9] Several cells were used, all similar to those of Kraus and co-workers. Cell constants were determined by intercomparison, using a 0.01 D KCl solution[10] as standard. The solutions were made up by weight in an atmosphere of nitrogen, and dilutions of stock solutions were made similarly. The solutions in the cells were stirred continuously, using a Teflon-covered magnet as agitator. The oil-filled thermostat was maintained at the stated temperature within 0.005°. Temperatures were determined with a resistance thermometer calibrated by the National Bureau of Standards. Two series of conductance measurements were run for each salt at each temperature. These agreed within 0.2%.

Physical Constants.—The solvent density and viscosity were determined at each temperature. The latter was measured in a Cannon–Fenske viscometer. The values obtained are listed in Table I.

TABLE I

PHYSICAL CONSTANTS OF *o*-DICHLOROBENZENE

t, °C.	d, g./cc.	$\eta \times 10^2$	D
25.00	1.3007	1.2778	9.939
35.00	1.2885	1.1036	9.571
45.00	1.2784	0.9701	9.202
55.00	1.2674	.8669	8.836
65.00	1.2558	.7720	8.515

The dielectric constant, D, of the solvent was measured, using a General Radio type 716-C capacitance bridge, with a type 716-P4 guard circuit. All measurements were made at 100 kc. The dielectric cell was similar in design to that of Sadek and Fuoss.[5]

Results

The equivalent conductances found for each concentration are given for Et_4NPi at 35° in Table II.

TABLE II

EQUIVALENT CONDUCTANCE OF Et_4NPi AT 35° IN *o*-DICHLOROBENZENE

$C \times 10^4$, M	Λ	$C \times 10^4$, M	Λ
2.419	12.30	0.4998	22.22
2.030	13.22	.4490	22.95
1.453	15.07	.3251	25.37
0.9683	17.50	.2605	27.30

The conductance–concentration data were treated by the method of Shedlovsky[11] both graphically, to determine any inconsistencies, and by least squares to get the best values of Λ_0 and K. The latter are shown in Table III. The values at 25° agree well

TABLE III

VALUES OF Λ_0 AND K IN *o*-DICHLOROBENZENE

Salt	Λ_0 25°	35°	45°	55°	65°
Et_4NPi	47.8	51.56	55.91	65.40	71.38
Pr_4NPi	40.3		50.31	58.33	66.14
Bu_4NPi	36.8	41.45	46.26	53.88	60.53
	$K \times 10^5$ 25°	35°	45°	55°	65°
Et_4NPi	1.23	1.389	1.511	1.343	1.362
Pr_4NPi	1.64		1.710	1.568	1.467
Bu_4NPi	1.92	1.983	2.021	1.820	1.715

with those determined elsewhere.[6] However, the K values found in this work are somewhat higher. A close comparison of the data shows that our Λ are slightly larger than those of Accascina. This may be due to some discrepancy in cell constants. Of more intrinsic interest is the variation of K with temperature. In the cases cited previously[8] for ethylene chloride and ethylidene chloride, the K values decreased with rising temperature. Here, however, they are seen to increase to a maximum at 45° and then decrease.

Values of Bjerrum's parameter, a, have been calculated from eq. 1 and appear in Table IV. It may be seen that these show a definite increase with temperature, except for the last two temperatures, where they remain constant. In ethylene chloride (ref. 8a), a for Bu_4NPi may be calculated at 5.69, 25 and 35° to be 5.83, 5.77 and 5.85 Å., respectively.

TABLE IV

VALUES OF BJERRUM'S PARAMETER, $a \times 10^8$ CM., IN *o*-DICHLOROBENZENE

t, °C.	Et_4NPi	Pr_4NPi	Bu_4NPi
25	3.92	4.03	4.10
35	4.01		4.18
45	4.05	4.11	4.19
55	4.05	4.12	4.20
65	4.09	4.13	4.19

If one is to allow a to vary with temperature, then it would be expected to increase as the temperature increases. However, there seems to be a closer correlation between a and the product DT. In *o*-dichlorobenzene, DT decreases with T; in ethylene chloride, DT increases; in ethylidene chloride, DT again decreases. The a values vary in an inverse manner. A recent study of Et_4NPi in a series of phthlate esters as solvents[12] shows the same trend. Kraus has shown[13] that a values calculated from Bjerrum's are much larger than the separation of charge as determined from the dipole moments of salts in benzene.

An expression for K which takes into account specific ion–solvent interaction has been derived

recently[14] on the basis of Kirkwood's free-volume theory of solutions. This theory gives

$$K = \left(\frac{2\pi\mu kT}{h^2}\right)^{3/2} (gv\sigma) \exp\left(-\frac{E_s}{RT} - \frac{N\epsilon^2}{aRDT}\right) \quad (2)$$

where $\mu = m_+m_-/(m_- + m_+)$, m_i being the mass of the ith ion, $E_s = E_- + E_+ - E_\pm$, E_i being the interaction energy between the ith ion and surrounding solvent, $E_\pm$ being the energy of interaction between solvent and the ion pair, the factor $(gv\sigma) = (g_+g_-v_+v_- \sigma_+\sigma_-)/(g_\pm v_\pm \sigma_\pm)$, g_i being the rotational and vibrational contribution to the partition function of the ith particle, v_i being the free volume available to the ith particle and σ being a factor varying between unity for solids and e for gases. If values of K as a function of T are available, the parameters $(gv\sigma)$ and E_s, characteristic of the solvent and salt, can be chosen so as to give a value of a, the distance of closest approach, which is independent of the temperature and solvent. Using the data obtained in this study, such calculations have been made. The results are shown in Fig. 1, where values of $F = \log K - 3/2 \log T + E_s/T$ are plotted *vs.* $1/DT$. The values of a, E_s and $(gv\sigma)$ for each salt are given in Table V. At this point, no generalizations can be made concerning the variations in E_s and $(gv\sigma)$, due to their complex nature and the lack of more extensive data. It may be said that the free-volume theory accounts for the observed facts as well as Bjerrum's theory. Certainly a constant value of a is more satisfying than one which varies in an unpredictable manner. It may be noted that the a value for Bu_4NPi in this solvent is the same as that found[14] in the solvents ethylene chloride, ethylidene chloride, propylene chloride and anisole. This work is being extended to other solvent systems in an effort to accumulate data which may lead to some correlation for the values of E_s and $(gv\sigma)$ thus obtained.

TABLE V

SALT PARAMETERS IN *o*-DICHLOROBENZENE

Salt	$a \times 10^8$, cm.	E_s, cal./mole	$(gv\sigma)$, cm.^{3}
Et_4NPi	1.59	4800	1.2×10^{-13}
Pt_4NPi	1.88	2880	2.4×10^{-17}
Bu_4NPi	2.51	1903	2.2×10^{-19}

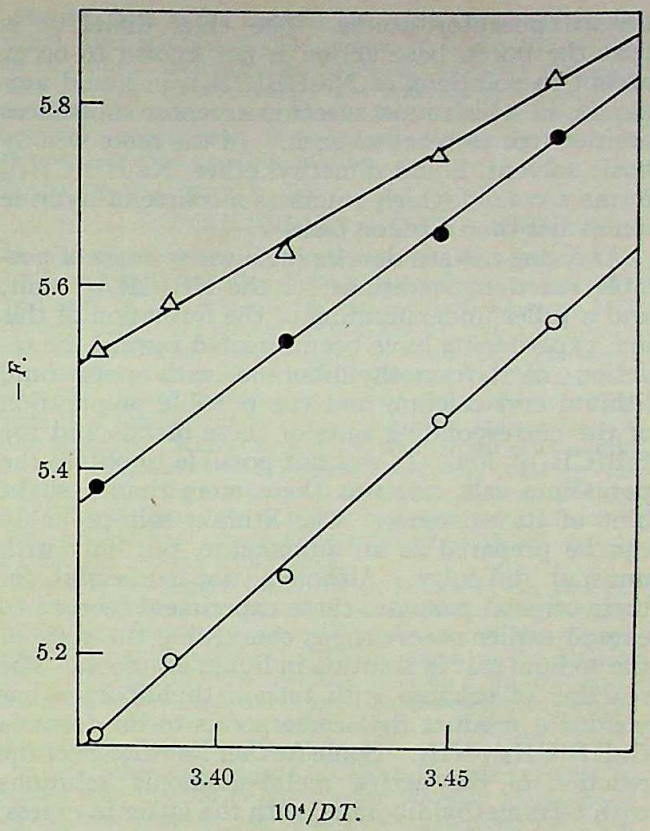

Fig. 1.—Values of the function F are plotted *vs.* $1/DT$ for the salts Et_4NPi (open circle), Pr_4NPi (closed circle, $F + 1.00$) and Bu_4NPi (triangle, $F + 1.500$) in *o*-dichlorobenzene.

Further Studies of the Boron Bases: $CaHB(CH_3)_2$[1]

BY GEORGE W. CAMPBELL, JR.[2]

RECEIVED OCTOBER 22, 1956

The reaction of tetramethyldiborane with calcium in liquid ammonia has produced the new compound $CaHB(CH_3)_2 \cdot NH_3$. The Lewis base activity of this salt is lower than that of the comparable sodium salt, as indicated by its inactivity toward $B(CH_3)_3$ in liquid ammonia. $CaHB(CH_3)_2 \cdot NH_3$ reacted with tetramethyldiborane, to produce NH_3-soluble $Ca[H_2B(CH_3)_2]_2 \cdot XNH_3$ and a second product, formulated in speculation as "$Ca[B(CH_3)_2]_2$." In methyl ether solution, $CaHB(CH_3)_2 \cdot NH_3$ reacted with SiH_3Cl to product SiH_4 in equal molal quantity. Cryoscopic and tensiometric measurements of $CaHB(CH_3)_2$ in NH_3 indicate the monomer state of the salt in solution. The identity of $CaHB(CH_3)_2 \cdot NH_3$ as a salt of the $HB(CH_3)_2^-$ anion is argued on the basis of chemical evidence. Attempts to prepare the lithium and potassium salts of the $HB(CH_3)_2^-$ have suggested that the lithium salt can be prepared, but only hinted that the potassium salt can exist. Neither salt was obtained in a state approaching purity. However, these studies have provided a possible explanation for the contamination of the sodium salt with $B(CH_3)_3$, and the formation of $B(CH_3)_3$ in the reactions of tetramethyldiborane with potassium and with sodium in liquid ammonia.

The discovery of the boron base $Na_2HB(CH_3)_2$ and its ability to establish a firm B–B bond by reacting with trimethylboron in liquid ammonia[3] implies the possibility of forming previously unknown bonds by an electron-donor action of boron

toward acceptor atoms. The chief difficulty is that the boron base action is not known to occur except in solutions of $Na_2HB(CH_3)_2$ in liquid ammonia, in which most electron-acceptor substances are not free to react as such. In the more weakly basic solvent, liquid dimethyl ether, $Na_2HB(CH_3)_2$ forms a colloid which reacts as a source of hydride ion rather than a boron base.

As a step toward developing a wider range of possible reaction conditions for the $HB(CH_3)_2^-$ unit, and a fuller understanding of the formation of this ion, experiments have been directed toward the reaction of tetramethyldiborane with potassium, lithium and calcium and the possible preparation of the corresponding salts of these metals and the $HB(CH_3)_2^-$ ion. It was not possible to obtain the potassium salt, nor was there more than a slight hint of its existence. The lithium salt probably can be prepared as an ammoniate, but only with unusual difficulty. Although not successful for their original purpose, these experiments served to extend earlier observations concerning the state of the sodium salt in solution in liquid ammonia. The reaction of calcium with tetramethyldiborane has yielded a product that corresponds to the formula $CaHB(CH_3)_2 \cdot NH_3$. Some further knowledge of the reaction of the active metal–ammonia solutions with tetramethyldiborane, with the latter in excess, also was obtained.

Experimental

Materials.—The $(CH_3)_4B_2H_2$ used in these studies was prepared by the reaction of B_2H_6 with $B(CH_3)_3$.[4] It was purified by fractional condensation at −80° until the vapor tension at 0° was 48.0 mm. (literature value 48.0 mm.) prior to each use. Hydrolysis of 0.232 mmole produced 0.452 mmole of H_2 (calculated 0.464) and 0.464 mmole of $(CH_3)_2BOH$ (calculated 0.464).

Anhydrous 99.9% NH_3, purchased from the Matheson Company, was stored *in vacuo* with dissolved Na. The NH_3 was distilled from this solution for use in these experiments.

The dimethyl ether, reported to be 99.9% pure by the manufacturer, contained considerable CO_2, and required NaOH-washing before use. The purified ether had a vapor pressure of 34.0 mm. at −78.6° (literature value 34 mm.).

The SiH_3Cl was prepared by the Al_2Cl_6 catalyzed reaction of SiH_4 with HCl.[5] It was purified by distillation in the high vacuum apparatus.

The Reaction of $(CH_3)_4B_2H_2$ with Calcium in Liquid NH_3.—The addition of approximately one-half mmole of $(CH_3)_4B_2H_2$ to a liquid ammonia solution of calcium (>20 mg.), and the subsequent steps for the isolation of the product were carried out in the same manner as described for the preparation of $Na_2HB(CH_3)_2$,[3] except that the repeated treatments with trimethylamine were found to be ineffective and of no value. Also, it was found that this preparation was far less sensitive to temperature, and the reaction occurred readily and cleanly below −65°. It was further observed that a large excess of calcium was not necessary, but that the mixture required adequate mixing to prevent a local excess of $(CH_3)_4B_2H_2$, which would react with the calcium salt first formed.

After removal of the solvent NH_3, and all volatile (at 50°) components, the non-volatile product of this process, if formulated by analogy to the sodium salt, was $CaHB(CH_3)_2 \cdot NH_3$, and all attempts to remove the remaining ammonia were unsuccessful.

The hydrolysis of the product, in acid solution, produced H_2, $(CH_3)_2BOH$ and NH_3, according to the equation

$$CaHB(CH_3)_2 \cdot NH_3 + 3H_2O \longrightarrow Ca(OH)_2 + (CH_3)_2BOH + NH_3 + 2H_2 \quad (1)$$

On fourteen samples, the ratio H_2 to $(CH_3)_2BOH$ was 1.99 (calculated 2.00), and, on nine samples, the ratio of $(CH_3)_2BOH$ to Ca (determined gravimetrically) was 1.04 (calculated 1.00). The ammonia content was not constant, but always was slightly more than corresponds to the 1-ammoniate, and averaged 1.22 ± 0.26 for six samples. The average of the analyses of two weighed samples, after correcting for ammonia content, gave 41.6% Ca (calculated 48.9); 47.1% $(CH_3)_2B$ (calculated 49.9); ratio of H_2 to $(CH_3)_2B$ was 1.94 (calculated 2.00). These analyses were made on samples of 0.28 and 0.51 mmole, representing sample weights of 23 and 43 mg., respectively. It has not been possible so far to prepare larger samples of relatively pure product apparently because of the high reactivity of $CaHB(CH_3)_2 \cdot NH_3$ toward $(CH_3)_4B_2H_2$. It should be noted, however, that in two experiments, where $(CH_3)_4B_2H_2$ was carefully added in equal molal quantity to approximately 0.5 mmole of calcium, the blue color faded out after approximately 15 minutes at −75°. After removing the volatile components at temperatures up to 50°, the NH_3-soluble residue was found to be $CaHB(CH_3)_2 \cdot NH_3$ by analysis. Due to the extreme sensitivity of the product toward air or moisture, a methyl ether solution of the sample was filtered into a tube and the tube separated from the filter apparatus[3] *in vacuo*. The methyl ether was then distilled away from the sample, and the tube evacuated, removed from the vacuum line and weighed. The tube was then returned to the vacuum line for analysis of the sample, after which the clean evacuated tube was reweighed to determine the sample weight. Since the sample weight never exceeded 50 mg., and the accuracy of measurement of gas volumes was approximately 5%, the estimated accuracy of the analyses was not better than 5%.

Attempts to Prepare the Potassium Salt.—The addition of $(CH_3)_4B_2H_2$ to a liquid ammonia solution of potassium and the subsequent steps for the isolation of the salt product were carried out in the same manner as for the sodium salt,[3] with the difference that the removal of the solvent was far less difficult in this case. However, in the product most nearly approaching the expected formula "$K_2HB(CH_3)_2$," hydrolysis yielded 15% more than the calculated amount of $(CH_3)_2BOH$, 12% too much hydrogen and $B(CH_3)_3$ amounting to 0.23 mole per K_2X unit. Thus it would appear 35% of the expected $HB(CH_3)^-$ units were bonded by the electron acceptors $B(CH_3)_3$ or $HB(CH_3)_2$. In the most deviant experiment the attached $B(CH_3)_3$ amounted to 0.58 mole per K_2X unit, while $(CH_3)_2BOH$ ran 14% low and H_2 24% high—as though some $CH_3BH_2^-$ ions were taking the place of $HB(CH_3)_2^-$ ions.

Attempts to Prepare $Li_2HB(CH_3)_2$.—For the preparation of "$Li_2HB(CH_3)_2$" it was considered necessary to choose an alkali metal solvent which would not solvate the Li^+ ion so strongly as to make it impossible to isolate the desired product. For this purpose methylamine proved to be almost suitable, and certainly far better than ammonia. In the best experiment the supposed "$Li_2HB(CH_3)_2$" was hydrolyzed to give only 56% of the expected $(CH_3)_2BOH$ (based upon a lithium-analysis which might have been somewhat high), while H_2 ran only 8% high. However, no $B(CH_3)_3$ could be found in the products. Thus the disproportionation of the $(CH_3)_2BH$ evidently was important, but it differed sharply from the reactions involving sodium and potassium where the disproportionation was accompanied by methyl group migration. In this respect it is comparable to the reaction of $(CH_3)_4B_2H_2$ with calcium, for in that reaction no $B(CH_3)_3$ was ever formed either.

The Use of Methylamine to Extract the Sodium Salt.—Some advantage was found in the use of methylamine instead of dimethyl ether as a solvent for extracting $Na_2HB(CH_3)_2$ from excess sodium after the removal of the ammonia from the original reaction mixture.[3] The yields varied from 74 to 84% (based upon half the tetramethyldiborane) and the conformity to the ideal formula $Na_2HB(CH_3)_2$ was good. However, it was not possible to remove the methylamine effectively except in very small scale experiments (0.6 mmole or less), and even then a mono-amine solvate was obtained. Hence the product could be used only for chemical studies in solution, as in liquid ammonia.

Hydridic Behavior of $Na_2HB_2(CH_3)_5$.—The salt $Na_2HB_2(CH_3)_5$ reacted with SiH_3Cl in dimethyl ether to form SiH_4 as readily as the original $Na_2HB(CH_3)_2$ had done,[3] indicating that the addition of $B(CH_3)_3$ to the $HB(CH_3)_2^-$ unit had not seriously impaired the hydridic reactivity of the B–H bond.

The experiment was done with a sample of $Na_2HB_2(CH_3)_5$ which had been formed directly from $(CH_3)_4B_2H_2$ and sodium in liquid ammonia containing $B(CH_3)_3$. The time allowed for completion of the B–B bond was 150 minutes (at −78°); then the last of the ammonia was displaced by trimethylamine and the salt was extracted with methylamine. The sample was suspended in 2 ml. of dimethyl ether and treated with excess SiH_3Cl during 14 hours at −78°. The reaction yielded 0.59 mmole of SiH_4, while the sodium analysis indicated 0.47 mmole of the original salt, $Na_2HB_2(CH_3)_5$. A low sodium analysis and some extra B–H bonds were possible sources of the discrepancy. The recovered $B(CH_3)_3$ (0.26 mmole with the SiH_4 and 0.05 mmole more by hydrolysis of the residue) and $(CH_3)BOH$ were low, for salt residue of such reactions contains boron and methyl groups in a situation which is not yet understood.

In passing, it is worthy of note that the action of C_2H_5Cl upon $Na_2HB(CH_3)_2$ in dimethyl ether (6 days at −78°) was virtually negligible. However, there was an indication of ethane: a 3% yield (0.013 mmole) of a gas having the right volatility. At least the reaction was far slower than the conversion of SiH_3Cl to SiH_4.

Tensiometric Determination of the Molecular Weight of $CaHB(CH_3)_2$ in Solution.—Samples of the calcium salt "$CaHB(CH_3)_2 \cdot NH_3$" were prepared in a suitable bulb which could be attached to a differential manometer for the comparison of the vapor tension of the pure solvent with that of the solution. The two bulbs, one containing the solution and the other the pure solvent, were then immersed in melting chlorobenzene, thus establishing a constant uniform temperature of approximately −46°. In two experiments in liquid ammonia, the results indicated a molecular weight of 87 and 89, respectively, ±10% (formula weight 81.8) at an average molality of 0.27.[6] Although the formula weight and empirical molecular weight agree within the limits of accuracy, the results suggest the possibility of a small amount of association of solute molecules.

When liquid methyl ether was the solvent, an apparent molecular weight of 213 ± 10% was found, corresponding to an average association of 2.6 "$CaHB(CH_3)_2$" units. The clear colorless solution contained 0.50 mmole of "$CaHB(CH_3)_2$" in 1.0 g. of dimethyl ether.

Cryoscopic Determination of the Molecular Weight of the Calcium Salt in NH_3.—The apparatus used in the cryoscopic determination was described in an earlier paper.[3] By comparison with pure ammonia, it was observed that 0.0286 g. of "$CaHB(CH_3)_2$"[6] in 2.73 g. of ammonia lowered the freezing point 0.129 ± 0.006°, indicating a molecular weight value of 79 ± 4 (calculated value 81.8).

The Conductance of the Calcium Salt in NH_3.—The conductance of $CaHB(CH_3)_2$ in liquid ammonia at −70 to −75° was measured by conventional methods. The detailed results are given in Table I.

TABLE I

THE ELECTROLYTIC CONDUCTANCE OF $CaHB(CH_3)_2$ IN LIQUID AMMONIA

Sample	1	2	3
Temp., °C.	−75	−75	−70
Molarity	0.0185	0.0218	0.0272
Specific conductance (ohms^{-1})	8.1×10^{-4}	8.7×10^{-4}	1.03×10^{-3}
Molar conductance (ohms^{-1})	43.0	39.9	37.9

Samples 1 and 2 were prepared by the reaction of $(CH_3)_4B_2H_2$ with calcium (present in excess), followed by a methyl ether extraction of the sample. Sample 3 was prepared by the addition of equal molal quantities of $(CH_3)_4B_2H_2$ and Ca, in liquid ammonia.

These results would compare with an estimated 10% ionization for a uni-univalent salt in this medium, since electrolytes in liquid ammonia at −33° have molar conductances around 300 at infinite dilution. However, an accurate basis for comparison is not available since most di-divalent salts do not dissolve or ionize in liquid ammonia.

(6) In these experiments the sample weight was calculated as "$CaHB(CH_3)_2$" on the basis of the analysis of the sample, since the NH_3 content of this compound is variable, and the solvent tetrahydrofuran

The Reaction of the Calcium Salt with Chlorosilane.—A methyl ether solution of 0.45 mmole of $CaHB(CH_3)_2 \cdot NH_3$ was treated with more than an equivalent quantity of chlorosilane at −78° for 48 hours. The reaction produced 0.47 mmole of silane, and the excess chlorosilane was recovered apparently unchanged. It is suggested that the reaction proceeded according to the equation

$$2CaHB(CH_3)_2 + 2SiH_3Cl \longrightarrow \text{"}Ca[B(CH_3)_2]_2\text{"} + CaCl_2 + 2SiH_4 \quad (2)$$

The non-volatile residue from this reaction was found to be 33.6% calcium (calculated 34.3 according to eq. 10). Treatment of this non-volatile residue with aqueous HCl produced only 0.076 mmole of $(CH_3)_2BOH$, but 0.38 mmole of H_2 was produced, corresponding to a ratio of 1.6 moles of H_2 per calculated mole of "$Ca[B(CH_3)_2]_2$." The production of H_2 started rapidly, but slowed down such as to indicate that equilibrium was approached but apparently not quite attained. When the non-volatile portion of this mixture was evaporated to dryness with H_2SO_4, charring was observed indicating the presence of organic carbon, and the typical green flame-test of boron was observed. Hence it seems evident that the residue retained (CH_3)–B groups in a manner not yet understood.

Attempts to Prepare $CaHB(CH_3)_2 \cdot B(CH_3)_3$.—In two experiments $B(CH_3)_3$ was added to solutions of $CaHB(CH_3)_2 \cdot NH_3$ in liquid ammonia at −75°. In one of the experiments the results indicated $B(CH_3)_3$ added to the $CaHB(CH_3)_2 \cdot NH_3$ in the mole ratio of 0.39 to 1 in two days. This could not be repeated in the second experiment, where five days were allowed for reaction, yet no $B(CH_3)_3$ was retained by the "$CaHB(CH_3)_2 \cdot NH_3$."

In two other experiments, $(CH_3)_4B_2H_2$ was brought to reaction with calcium in liquid ammonia with an excess of $B(CH_3)_3$ also present. In these two experiments only $CaHB(CH_3)_2 \cdot NH_3$ was obtained and all of the $B(CH_3)_3$ was recovered as the sublimable $B(CH_3)_3 \cdot NH_3$. Hence it appears that the apparent addition of $B(CH_3)_3$ to $CaHB(CH_3)_2 \cdot NH_3$ was due to incomplete sublimation of the $B(CH_3)_3 \cdot NH_3$, and that no addition reaction occurred with the boron base.

The Reaction of $CaHB(CH_3)_2 \cdot NH_3$ with $(CH_3)_4B_2H_2$.—The reaction of $(CH_3)_4B_2H_2$ with $CaHB(CH_2)_2 \cdot NH_3$ in liquid ammonia produced a clear solution at −75°, but a solid precipitate was formed after 14 hours. The solid residue obtained, after removal of the solvent and all components volatile at 25°, was 28.4% Ca, and released 3.26 moles of H_2 per mole of Ca by hydrolysis (calculated for $Ca(CH_3)_4B_2H_2$; Ca 32.4%; ratio $H_2/Ca = 3.0$). Hydrolysis also produced 1.6 moles of $(CH_3)_2BOH$, but some organic carbon was retained by the non-volatile residue, since evaporation with H_2SO_4 caused charring. The analysis and properties of the non-volatile product obtained in this reaction corresponds in every respect to that produced by the reaction of Ca (in NH_3) with $(CH_3)_4B_2H_2$ when the latter was in excess, as described below.

The Reaction of Calcium with $(CH_3)_4B_2H_2$, the Latter Present in Excess.—When $(CH_3)_4B_2H_2$ was added to a Ca–NH_3 solution (mole ratio = 1.5 to 2.0) at −75°, the blue color of the metal solution faded and a milky suspension was formed which finally dissolved to produce a colorless, clear solution. After standing for several hours, a permanent precipitate was formed from the solution. In one experiment, where the mole ratio of $(CH_3)_4B_2H_2$ to Ca was 2.0, after reaction all volatile components of the mixture were removed at 25°, leaving a solid residue that was 29.6% Ca (calcd. for $Ca(CH_3)_4B_2H_2$, 32.4%) correcting for NH_3 content (mole ratio $NH_3/Ca = 0.24$). Hydrolysis of this residue produced 3.35 moles of H_2 and 1.60 moles of $(CH_3)_2BOH$ per mole of calcium. A wet combustion of this non-volatile portion of the hydrolysis mixture produced CO_2 corresponding to an additional 0.273 mole of $(CH_3)_2B$-groups, to give a total ratio of $(CH_3)_2B/Ca$ of 1.87. Hence it appears that the non-volatile solid obtained from the reaction of $(CH_3)_4B_2H_2$ with Ca corresponds approximately to the speculative formula $Ca(CH_3)_4B_2H_2$.

In three other similar experiments $(CH_3)_4B_2H_2$ and calcium (mole ratio ≧ 1.5) were brought to reaction and the solvent and all volatile products were removed at 25°, but liquid ammonia was then added to the non-volatile residue and the mixture was filtered. The NH_3-soluble product had the empirical formula $Ca[(CH_3)_2BH_2]_2 \cdot XNH_3$ (X = 1.4 to 2.4). The combustion, hydrolysis analyses, corrected for NH_3

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

are as follows: Ca, 32.1% (31.8 calcd.); ratio H_2/Ca = 3.99 (4.00 calcd.); ratio R_2B/Ca = 2.04 (2.00 calcd.).

In the further experiments, where the mole ratio of $(CH_3)_4B_2H_2$ to calcium was equal to or greater than 2.5, the reaction resulted in a product that was permanently soluble in NH_3. After removal of all volatile products at 25°, the residue was readily and completely soluble in NH_3. Analysis of the product corresponded to the formula $Ca[(CH_3)_2BH_2]_2 \cdot XNH_3$.

However, when the ratio of $(CH_3)_4B_2H_2$ to calcium was 1.5, almost exactly half of the calcium was converted to $Ca[(CH_3)_2BH_2]_2$, the other half apparently forming the hypothetical $Ca[(CH_3)_2B]_2$. Thus, in one experiment, 0.622 mmole of $(CH_3)_4B_2H_2$ was added to 0.427 mmole of calcium in liquid ammonia, at −75°. The solution turned milky white, then clear within 30 minutes. After 14 hours, however, a precipitate had formed. When all volatile components were removed at 65°, it was possible to extract 0.206 mmole of $Ca[H_2B(CH_3)_2]_2$ from the residue by means of liquid NH_3. The insoluble portion produced less than 0.1 mmole of H_2 and no detectable amount of $(CH_3)_2BOH$ when treated with H_2O-HCl. Examination of the volatile components of the reaction mixture, which were removed by distillation showed that 0.26 mmole of $(CH_3)_2BNH_2$ was present. Since the total mmoles of $(CH_3)_2B$-groups added was 1.24, and 0.41 were found as Ca $[(CH_3)_2BH_2]_2$, and 0.26 as $(CH_3)_2BNH_2$, there remains 0.57 mmole to be accounted for. Due to the low volatility of polymeric $(CH_3)_2BNH_2$, especially in the presence of NH_3, it is conceivable that as much as 0.15 mmole, as an upper limit, could be lost in this analysis. Hence, it would appear that the 0.22 mmole of calcium which was not removed as $Ca[(CH_3)_2BH_2]_2$ was present as NH_3-insoluble "$Ca[(CH_3)_2B]_2$."

Discussion

The Reaction of Tetramethyldiborane with Calcium in Ammonia.—The preparation of the compound which appears to be $CaHB(CH_3)_2 \cdot NH_3$ was accomplished by condensing tetramethyldiborane on a previously prepared and frozen solution of calcium in ammonia, followed by rapid warming to −70 to −75° with thorough mixing. A second product, apparently $(CH_3)_2BHNH_3$, was decomposed thermally, *in vacuo* at 25 to 50°, and the $(CH_3)_2BNH_2$ and H_2 were removed as gases and identified. Hence, it would appear that this reaction parallels that of sodium with tetramethyldiborane,[3] and therefore it would be described by the equation

$$Ca + (CH_3)_4B_2H_2 + NH_3 \xrightarrow[NH_3(l)]{-70^\circ} CaHB(CH_3)_2 \cdot XNH_3 + (CH_3)_2BHNH_3 \quad (3)$$

This system was not as temperature sensitive as that where sodium was the active metal, nor was it necessary that there be a large excess of the active metal to avoid secondary reactions. However, the product does react with tetramethyldiborane, so the mixing of the reactants was quite critical. Based upon this equation, the calcium salt was readily obtained in 80% yield, or higher.

This new calcium salt was soluble in ammonia, dimethyl ether and diethylene-glycol dimethyl ether (diglyme). In most of the experiments dimethyl ether was used to extract this product from the excess calcium in the preparation.

Cryoscopic and tensiometric measurements on the liquid ammonia solutions of $CaHB(CH_3)_2$ clearly indicate the monomeric salt, while conductance measurements suggest some ionization, but considerably less than that indicated for the sodium salt.

In liquid methyl ether the salt formed an aggregate of approximately 2.6 "$CaHB(CH_3)_2$" units according to the vapor tension of the solution, thus apparently differing from the colloidal state of $Na_2HB(CH_3)_2$ in this medium only in the degree of aggregation.

The Chemical Properties of the Calcium Salt.—In sharp contrast to $Na_2HB(CH_3)_2$, the calcium salt did not react as a Lewis-base toward trimethylboron in liquid ammonia solution. A further attempt to cause such an addition, by bringing tetramethyldiborane to reaction with calcium in the presence of trimethylboron, in liquid ammonia, apparently produced $CaHB(CH_3)_2 \cdot NH_3$ as the only non-volatile product, yet this method did give excellent samples of $Na_2HB(CH_3)_2 \cdot B(CH_3)_3$ when sodium was the active metal.[3]

In liquid dimethyl ether chlorosilane reacted with "$CaHB(CH_3)_2$" to produce an equal molal quantity of silane.

The reaction of $CaHB(CH_3)_2$ with tetramethyldiborane (mole ratio 1:1) in liquid ammonia, produced a water clear solution which did not change visibly for 3 hours at −75°, but after 14 hours at −78° an insoluble product had formed. The analysis of the non-volatile (at 50° *in vacuo*) residue from this reaction corresponded approximately to the formula $Ca(CH_3)_4B_2H_2$, and retained a slight and probably insignificant amount of ammonia. However, a substance empirically formulated as $Ca[H_2B(CH_3)_2]_2$, could be extracted from this solid by liquid ammonia. These results suggest that the mixture consisted of nearly equal molal parts of the substance $Ca[H_2B(CH_3)_2]_2$ and the speculative, probably polymeric, salt "$Ca[B(CH_3)_2]_2$" which would compare with the substance tentatively formulated as "$NaB(CH_3)_2$" in a previous publication.[3] It should be noted further that the products of this reaction of $CaHB(CH_3)_2 \cdot NH_3$ with tetramethyldiborane appear to be identical to those obtained by the reaction of tetramethyldiborane (present in excess) with calcium in liquid ammonia.

The Nature of the Calcium Salt.—On the basis of the analyses alone, the calcium salt can reasonably be formulated as $CaHB(CH_3)_2 \cdot NH_3$ or as the amido salt $H_2NCaH_2B(CH_3)_2$. In accord with the latter postulate, the reaction of tetramethyldiborane with calcium in liquid ammonia might be written as

$$Ca + (CH_3)_4B_2H_2 + NH_3 \longrightarrow H_2NCaH_2B(CH_3)_2 + (CH_3)_2BHNH_3 \quad (4)$$

It appears also that this postulate would be in good agreement with some of the observed chemical and physical properties of this calcium salt. Hence, the failure of this compound to add trimethylboron would be expected if the $H_2B(CH_3)_2^-$ ion were present instead of the boron base, providing also that the amido ion were not available enough from the calcium salt to compete with the ammonia. Also, the moderate electrolytic conductance of the calcium salt would conform well to this interpretation.

On the other hand, the reactions of the calcium salt with tetramethyldiborane and with chlorosilane appear to favor the boron base formulation.

It should be noted that when the calcium salt was brought to reaction with an equal molal quantity of $(CH_3)_4B_2H_2$, the products of the reaction appeared to be identical to those resulting from the reaction of

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

calcium metal with $(CH_3)_4B_2H_2$, when the mole ratio was 1:2, respectively. In both cases a solid mixture was produced with nearly identical composition, and approximately corresponding to the empirical formula $Ca(CH_3)_4B_2H_2$, but from which $Ca[H_2B(CH_3)_2]_2$ could be extracted. Also, if the ratio of $(CH_3)_4B_2H_2$ to calcium metal was reduced to 1.5:1, exactly half of the calcium was converted to NH_3-soluble $Ca[H_2B(CH_3)_2]_2$, the rest of the calcium apparently forming the NH_3 insoluble, apparently polymeric, substance empirically formulated to be $Ca[(CH_3)_2B]_2$. If it is assumed that the reaction of $(CH_3)_4B_2H_2$ with calcium produces the amido-salt $H_2NCaH_2B(CH_3)_2$, according to eq. 4, the formation of $Ca[H_2B(CH_3)_2]_2$ would reasonably be written as

$$(CH_3)_4B_2H_2 + 2NH_3 \longrightarrow (CH_3)_2BNH_2 + NH_4^+H_2B(CH_3)_2^- \quad (5)^7$$

$$NH_4^+H_2B(CH_3)_2^- + NH_2CaH_2B(CH_3)_2 \longrightarrow 2NH_3 + Ca[H_2B(CH_3)_2]_2 \quad (6)$$

This interpretation, however, cannot account for the fact that this reaction produced a mixture of $Ca[H_2B(CH_3)_2]_2$ and a second calcium compound "$Ca[B(CH_3)_2]_2$." In fact any reaction of $(CH_3)_4B_2H_2$ with $NH_2CaH_2B(CH_3)_2$ to form $Ca[H_2B(CH_3)_2]_2$ and $Ca[B(CH_3)_2]_2$ would require a transfer of B–H hydrogen to N–H hydrogen, which appears quite unlikely in view of the failure of ND_3 to undergo H–D exchange with diborane.[8]

On the other hand, if it is assumed that the formula $CaHB(CH_3)_2 \cdot NH_3$ represents the correct structure for this salt, the suggested reaction sequence is as

$$2CaHB(CH_3)_2 + (CH_3)_4B_2H_2 \longleftarrow 2"CaHB(CH_3)_2 \cdot HB(CH_3)_2" \quad (7)$$

$$2"CaHB(CH_3)_2 \cdot HB(CH_3)_2" \longrightarrow Ca[H_2B(CH_3)_2]_2 + "Ca[B(CH_3)_2]_2" \quad (8)$$

In this postulate, the formation of the hypothetical "$CaHB(CH_3)_2 \cdot HB(CH_3)_2$" would represent base activity of the $CaHB(CH_3)_2$, and it would further explain the ability of $(CH_3)_4B_2H_2$ to increase the solubility of $CaHB(CH_3)_2$ in NH_3. The disproportionation of this salt according to eq. 8, and probably the polymerization of the $(CH_3)_2B^-$ anion would explain the slow formation of a precipitate in the NH_3 solution. Also, since both of the products of eq. 8 would be non-volatile, the mixture would correspond, in composition, to the formula $Ca(CH_3)_4B_2H_2$.

It was also observed that additional $(CH_3)_4B_2H_2$, beyond that required by eq. 7, produced a higher percentage of the calcium as $Ca[H_2B(CH_3)_2]_2$, with a nearly quantitative conversion of calcium to the borohydride derivative when 2.5 moles of $(CH_3)_4B_2H_2$ is added to one mole of the metal. In explanation of this, it is postulated that the disproportionation of "$CaHB(CH_3)_2 \cdot HB(CH_3)_2$" in the presence of NH_4^+ and $H_2B(CH_3)_2^-$ ions[7] would reasonably occur as

$$"CaHB(CH_3)_2 \cdot HB(CH_3)_2" + NH_4^+H_2B(CH_3)_2^- \longrightarrow Ca[H_2B(CH_3)_2]_2 + NH_3HB(CH_3)_2 \quad (9)$$

The reaction of the calcium salt with chlorosilane gives further support to the boron base interpretation, since the non-volatile product of this reaction was apparently $Ca[B(CH_3)_2]_2$. Had the calcium salt been $H_2NCaH_2B(CH_3)_2$, one mole of SiH_4 would have been produced, leaving a dimethylborine group, which would not have reacted further with the chlorosilane,[9] unless it were bonded to the NH_2^- group. However, no $(CH_3)_2B^-$ polymer could have been formed without transfer of B–H hydrogen to the NH_2-group and the presence of $(CH_3)_2BH$-groups or $(CH_3)_4B_2H_2$ in the reaction products would not have escaped detection.

On the basis of these arguments, it seems likely that the new calcium salt is best interpreted as another boron base, and an analog of $Na_2HB(CH_3)_2$. However, the chemical properties of $CaHB(CH_3)_2 \cdot NH_3$ suggest a reduced, yet definite base activity, whereas the availability of the hydride ion from this salt is comparable to that of the sodium salt.

The Preparation of Salts of the $HB(CH_3)_2^-$ Ion.—It has been reported[3] that the preparation of relatively pure $Na_2HB(CH_3)_2$, by the reaction of Na–NH_3 with $(CH_3)_4B_2H_2$, required an excess of sodium. When this requirement was not met, or when an excess of $(CH_3)_4B_2H_2$ was present, a reaction occurred which always produced some $B(CH_3)_3$. Apparently the same reaction occurred also when $(CH_3)_4B_2H_2$ was added to a solution of $Na_2HB(CH_3)_2$ in liquid NH_3. In all of the attempts to prepare $K_2HB(CH_3)_2$, even with very large excesses of potassium, it was impossible to prevent this further reaction, and considerable $B(CH_3)_3$ was produced in each experiment. In contrast to the sodium and potassium reactions, in the attempts to prepare $Li_2HB(CH_3)_2$, no $B(CH_3)_3$ was produced, although $Li_2HB(CH_3)_2$ was not obtained in a state approaching purity.

The preparation of $CaHB(CH_3)_2$ is particularly noteworthy, for it has been prepared with consistently less contamination than any of the other salts of the $HB(CH_3)_2^-$ ion, and $B(CH_3)_3$ has never been found in the reaction products. Also, a nearly pure sample of $CaHB(CH_3)_2$ was prepared when neither reactant was in excess.

It appears likely that the reaction of active metals with $(CH_3)_4B_2H_2$, in liquid ammonia, first forms salts of the $HB(CH_3)_2^-$ ion plus $(CH_3)_2BH \cdot NH_3$, as indicated in eq. 3. Further reaction of the $HB(CH_3)_2^-$ ion with $(CH_3)_4B_2H_2$ can then occur under one or more of the following conditions: if the $(CH_3)_4B_2H_2$ is present in excess; if the stirring is inadequate, leading to local excesses of $(CH_3)_4B_2H_2$; if the rate of reaction of the $HB(CH_3)_2^-$ with $(CH_3)_4B_2H_2$ is rapid relative to the reaction whereby the $HB(CH_3)_2^-$ is formed. Since the results suggest that this additional reaction cannot be prevented using potassium, but is progressively easier to prevent when the reactive metals are sodium, (lithium) and calcium, respectively, it appears that the rate of reaction of the salts of $HB(CH_3)_2^-$ with $(CH_3)_4B_2H_2$ is quite dependent upon the nature of the metal ion, and particularly upon the charge density of the cation.

If it is assumed that the potassium salt of the

(7) This represents the ammoniation of tetramethyldiborane, corresponding to the ammoniation of diborane as suggested by G. W. Schaeffer, M. D. Adams and J. J. Koenig, THIS JOURNAL, **78**, 725 (1956).

(8) A. B. Burg, *ibid.*, **69**, 747 (1947).

(9) It has been shown in this Laboratory that $Ca[H_2B(CH_3)_2]_2$ reacts with chlorosilane in methyl ether solution according to the equation

$$Ca[H_2B(CH_3)_2]_2 + 4SiH_3Cl \longrightarrow CaCl_2 + 2SiH_4 + (CH_3)_4B_2H_2.$$

boron base has some existence, then the great difficulty of avoiding contamination of the potassium salt by donor-acceptor bonding of the $HB(CH_3)_2^-$ ion to methylated borine units may be less surprising than the relative ease of making nearly pure $Na_2HB(CH_3)_2$ and $CaHB(CH_3)_2$ in the presence of the complex $(CH_3)_2BH\cdot NH_3$, for a base much stronger than ammonia as the $HB(CH_3)_2^-$ ion must be, should quickly capture methylated borine units from their ammonia complexes. Also requiring explanation is the failure of the $HB(CH_3)_2^-$ ion to react rapidly with ammonia at low temperatures removing a proton to form amide ion, as various carbon-bases do. Furthermore, it will be recalled,[3] that a relatively clean preparation of $Na_2HB(CH_3)_2$ is possible only when sodium is in large excess, as though it served in some way to block the addition of methylated borine units or ammonia to the $HB(CH_3)_2^-$ ion. Finally, it appears that the blocking of such an addition is even more effective if the metal is calcium or lithium instead of sodium.

In explanation of all these facts, it may be suggested that ammonia in the solvation sphere of a metal ion is partly replaced by the stronger boron base ion, so that one may consider the equilibrium

$$(NH_3)_xM^{+m} + HB(CH_3)_2^- \rightleftharpoons (NH_3)_yM{:}\overset{H}{B}(CH_3)_2^{(m-2)} \quad (\text{where } x > y) \quad (10)$$

to lie farthest to the right for ions of highest charge density, and at their highest concentration. Thus, the availability of the free $HB(CH_3)_2^-$ ion may be very low in the presence of much sodium ion, but considerably higher if potassium is the positive ion, or if there is no excess of sodium—conditions under which the capture of borine units by the $HB(CH_3)_2^-$ ions is hard to prevent. And with calcium or lithium as the positive ion, the electron-donor action of the $HB(CH_3)_2^-$ ion would be blocked still more effectively.

Also, it appears likely that $(CH_3)_4B_2H_2$ and possibly the partially ammoniated $(CH_3)_4B_2H_2$ are capable of providing methylated borine units for reaction with the $HB(CH_3)_2^-$ ion but that $(CH_3)_2BH\cdot NH_3$ is not able to do so, for reaction mixtures containing the boron base and $(CH_3)_2BH\cdot NH_3$ have been kept in contact as long as 36 hours at −78° without detectable reaction. This failure to react might well be attributed to the absence of a convenient mechanism, and suggests that the di-ammoniate of tetramethyldiborane is not readily converted to $(CH_3)_2BH\cdot NH_3$ and that this is not a component of the tetramethyldiborane–ammonia system.[7] This is further supported by the fact that dimethylborine ammine does not measurably react with sodium in liquid ammonia, in sharp contrast to the behavior of the diammoniate of tetramethyldiborane.

In considering the new compound, $CaHB(CH_3)_2\cdot NH_3$, it appears that the attachment of the calcium ion is quite strong, both on the basis of the chemical properties of this compound and the physical properties in solution, as indicated by the tensiometric and cryoscopic studies. It should also be noted, in this connection, that the liquid ammonia solution of $Na_2HB(CH_3)_2$ and apparently that of "$K_2HB(CH_3)_2$," (assuming by analogy that it is the product of the reaction of tetramethyldiborane with potassium in liquid ammonia) are strongly yellow and show high base activity of the $HB(CH_3)_2^-$ ion. In comparison $CaHB(CH_3)_2$ solutions are colorless and it appears that if $Li_2HB(CH_3)_2$ has existence, it is only faintly yellow in liquid ammonia, and both of the latter cases appear to have reduced base activity.

The moderate electrolytic conductance of $CaHB(CH_3)_2$ in liquid ammonia solution, however, would not appear to support the interpretation that the calcium ion is strongly bonded to the boron base. It is possible that this conductance was due to small quantities of highly conducting impurities such as calcium metal or the dimethylborohydride salt. On the other hand, it should be recognized that the solubilities of ionic di-divalent salts in liquid ammonia are generally very low, suggesting that any ionization of $CaHB(CH_3)_2$ would reasonably involve extensive solvation or association. Also, the results of the tensiometric studies suggested that some association was likely since the apparent molecular weight in solution was higher than the formula weight, although within the estimated margin of accuracy. Hence it is suggested, in speculation, that the production of ions necessary for electrolytic conductance might well have proceeded according to the equation

$$2CaHB(CH_3)_2 + xNH_3 \rightleftharpoons (CH_3)_2BHCaHB(CH_3)_2^- + Ca^{++}\cdot NH_3 \quad (11)$$

It should be noted that the $HB(CH_3)_2^-$ ion is not free on either side of this equation, thus meeting the requirement that the base activity be low. Also, this equilibrium should not affect appreciably the properties of the solution that are based upon the vapor pressure of the solvent.

The Reactions of Active Metals with Tetramethyldiborane, when the Latter Is in Excess.—In previous studies the liquid ammonia reaction of sodium with tetramethyldiborane, when the mole ratio of reactants was less than 2:1, respectively, gave results that were not readily understandable.[3] However, the similar system involving calcium instead of sodium appears to be more easily interpreted in terms of equations 3, 7, 8 and 9 above, and these results suggest a reasonable interpretation for the reactions of all of the active metals with tetramethyldiborane in liquid ammonia.

In considering the reactions observed with sodium and potassium, it is significant that the only observed difference from those involving calcium was that trimethylboron always appeared among the reaction products. In this connection it is also of interest that the reaction of lithium aluminum hydride with trimethylboron according to Wartik and Schlesinger produced dimethylaluminum hydride and lithium monomethylborohydride, but apparently none of the dimethylborohydride.[10] Therefore it appears likely that the dimethylborohydride disproportionates quite easily, and it may well be that the sodium and potassium salts of this anion are incapable of stable existence. In con-

trast, lithium appears to behave more like calcium in that no trimethylboron has been found among the reaction products, and the dimethylborohydrides of both of these metals have been isolated.

The explanation of the differences in the apparent stabilities of these salts is not obvious, although the lattice energies of the calcium and lithium salts would certainly be greater than those of the sodium and potassium salts, and the lattice energy may well serve to stabilize the dimethylborohydride ion in the solid state. In solution it could be postulated that ion aggregation, also dependent upon change density, would serve to stabilize the calcium and lithium salts.

Kinetics of Reactions Involving Neptunium(IV), Neptunium(V) and Neptunium(VI) Ions in Sulfate Media[1]

BY J. C. SULLIVAN, DONALD COHEN AND J. C. HINDMAN

RECEIVED APRIL 5, 1957

The rates of the forward and reverse reactions involved in the equilibrium Np(IV) + Np(VI) $\rightleftarrows$ 2Np(V) have been measured in sulfate solution. Both forward and reverse reactions involve multiple parallel reaction paths. The rate of the forward reaction can be expressed in the form $R = k_0'[Np^{+4}][NpO_2^{++}][H^+]^{-2} + \{k_1[NpSO_4^{++}][NpO_2^{++}] + k_2[NpSO_4^{++}][NpO_2SO_4]\}\{k_3[H^+]^{-2} + k_4[H^+]^{-3}\}$. At 25° and $\mu = 2.2$, $k_0' = 2.69$ mole l.$^{-1}$ min.$^{-1}$, $k_1 = 4.27$ mole^{-1} l. min.$^{-1}$, $k_2 = 7.12$ mole^{-1} l. min.$^{-1}$, $k_3 = 3.6$ mole^2 l.$^{-2}$ and $k_4 = 1.7$ mole^3 l.$^{-3}$. The rate of the disproportionation reaction may be represented by $R = \{k_5[NpO_2^+]^2[HSO_4^-] + k_6[NpO_2^+]^2[HSO_4^-]^2\}\{k_7 + k_8[H^+]\}$. At 25° and $\mu = 2.2$, $k_5 = 0.30$ mole^{-2} l.^{2} min.$^{-1}$, $k_6 = 0.090$ mole^{-3} l.^{3} min.$^{-1}$, $k_7 = 0.74$, and $k_8 = 0.14$ mole l.$^{-1}$. Apparent activation energies are given. Probable restrictions on the geometrical configurations for the transition state complexes and the mechanism of the electron transfer processes are considered. Relationships of the reactions in sulfate solution to similar reactions occurring in perchlorate media are discussed.

Three prior investigations of the kinetics of the neptunium(IV)–neptunium(VI) reaction have been reported.[2-4] In perchloric acid solution the mechanism of the reaction appears to involve hydrolysis products of neptunium(IV).[2] In mixed ethylene glycol–water media the mechanism is altered, ethylene glycol apparently being present in the activated complex.[3] In sulfate solution the only measurements made were in one molar sulfuric acid.[4] The present research has been carried out to see if alternate paths involving complex ion species are available. The sulfate system has been selected for further investigation for two reasons. First, data on the complexity constants of neptunium(IV) and sulfate are now available.[5] Second, measurement of the reverse reaction, the disproportionation of neptunium(V), is possible in this medium. Interest in the latter reaction is due to the apparent difference in reaction mechanism deduced from kinetic and equilibrium data in perchlorate solution[2] and the reaction which would be expected if the behavior of neptunium(V) paralleled that of uranium(V).

Experimental

The stock solutions of the neptunium ions in perchloric acid were prepared according to previously described methods. The sulfuric acid was reagent grade standardized by titration with sodium hydroxide.

The experimental technique also has been previously described.[2] The only major modification of that technique used in this investigation was the preparation of calibration curves necessary to determine the concentration of Np(IV) in the sulfuric acid–perchloric acid mixtures. The interaction between Np(IV) and bisulfate is reflected in the lowering and slight shift in wave length of the band at 724 mμ which is most useful for analytical purposes.

Results

I. The Np(IV) + Np(VI) ⟶ 2Np(V) Reaction

Effect of Metal Ion.—The stoichiometry of the reaction with respect to each of the metal ions was determined by experiments in which the concentration of Np(IV) and Np(VI) were varied in the reaction mixture. Data were obtained at total sulfuric acid concentrations of 0.0865 and 1.00 molar. At zero bisulfate the reaction is bimolecular.[2] In the bisulfate solutions the data were also found to be consistent for a bimolecular process. The rate constants, k_{obsd}, were computed from the experimental data both by graphical evaluation of the initial rate[6] and by means of the integrated equation for a bimolecular reaction

$$k_{obsd} = \frac{2.303}{([Np(IV)]^0 + [Np(VI)]^0)t} \log \frac{[Np(VI)]^0}{[Np(IV)]^0}\left(\frac{[Np(VI)]^0 - x}{[Np(IV)]^0 - x}\right) \quad (1)$$

Effect of $[HSO_4^-]$.—Table II summarizes the data on the effect of bisulfate on the apparent rate of the reaction. Examination of the data in this table shows that the rate increases to a maximum and then decreases as the bisulfate concentration is further increased. The maximum in the rate occurs when $\bar{n}_{IV}$ is close to one, that is, where the average number of sulfate groups attached to a neptunium(IV) ion is unity[5] (see Fig. 1). It would therefore appear that the rate is increased by the addition of a single sulfate ion to the Np(IV). At the point where the maximum in the rate is observed the Np(VI) is presumably largely NpO_2^{++}. Thus far successful measurements of the complex constants for the Np(VI) sulfate system have not been made.[7] The degree of complex formation was therefore estimated using the constants for the U(VI) system.[8] Calculations of the solution composition have been made using the above complexing data and a value of 0.080 for the dissociation constant of $[HSO_4^-]$ at $\mu = 2.2$.[9] These calculations have been made as

[a] $H^+ = 2.11$. [b] Reference 2.

$$[\Sigma HSO_4^-]_i = [HSO_4^-]_{free} + [SO_4^{--}]_{free} + [\Sigma \bar{n}_i Cm_i] \quad (2)$$

where

$$\bar{n} = \frac{\beta_1[HSO_4^-] + 2\beta_2[HSO_4^-]^2}{1 + \beta_1[HSO_4^-] + \beta_2[HSO_4^-]^2} \quad (3)$$

and

$$Cm_i = [\Sigma Np(IV)] \text{ or } [\Sigma Np(VI)] \quad (4)$$

combining with

$$0.080 = \frac{[H^+][SO_4^{--}]}{[HSO_4^-]} \quad (5)$$

and

$$[H^+] = [H^+]_i + [SO_4^{--}]_f + [\Sigma n_i Cm_i] \quad (6)$$

where

$$[H^+]_i = \text{initial hydrogen ion concn.} \quad (7)$$

and solving for $[HSO_4^-]_f$, we get

$$[HSO_4^-]_f^2 - [HSO_4^-]_f(2[\Sigma HSO_4^-]_i + [H^+]_i + 0.080 - [\Sigma \bar{n}_i Cm_i]) + ([H^+]_i[\Sigma HSO_4^-]_i + [\Sigma HSO_4^-]_i^2 - [H^+]_i[\bar{n}_i Cm_i] - [\Sigma HSO_4^-]_i[\bar{n}_i Cm_i]) = 0 \quad (8)$$

The quadratic is solved for $[HSO_4^-]_f$. To obtain a final value for the bisulfate concentration it is necessary to make successive approximations. This is done as follows. The $\bar{n}_i Cm_i$ terms are obtained using $\bar{n}$ values taken from a plot of $\bar{n}$ *versus* free bisulfate or by solution of equation 3. The plot is obtained using $\beta_1 = 270/[H^+]$ and $\beta_2 = 2970/[H^+]^2$ for the constants of the Np(IV) system at a given acidity and $\beta_1 = 6.25/[H^+]$ and $\beta_2 = 7.6/[H^+]^2$ for approximating the constants of the Np(VI) sulfate system. In the first approximation the free $[HSO_4^-]$ is set equal to the total sulfuric acid concentration and the $\bar{n}$ values read from the plot. $[HSO_4^-]_f$ values are then calculated from equation 8 and the process repeated.

The degree of formation of the individual complex is computed from the relation

$$a_i = \frac{[MA_i]}{Cm} = \frac{\beta_i[A_i]^i}{1 + \sum_{i=1}^{J} \beta_i[A]^i} \quad (9)$$

whence concentrations of the individual complex species are calculated readily.

The decrease in k_{obsd} (Table II) at high bisulfate concentration is coincident with the formation of the complexes $Np(SO_4)_2$ and $NpO_2(SO_4)_2^{--}$, suggesting that these complexes do not contribute appreciably to the reaction. The general rate equation that would take into account the complex de-

Digitized by Arya Samaj Foundation Chennai and eGangotri

pendence of the rate on the bisulfate concentration can be written as

$$R = [Np(IV)][Np(VI)]k_{obsd} = k_0'[Np^{+4}][NpO_2^{++}] + k_1[NpSO_4^{++}][NpO_2^{++}] + k_2[NpSO_4^{++}][NpO_2SO_4] + k_3[Np(SO_4)_2][NpO_2^{++}] + k_4[Np^{+4}][NpO_2SO_4] + \ldots \quad (10)$$

Analysis of the data shows that the rate may be reproduced within the experimental uncertainties by a rate equation involving only the first three terms on the right-hand side of equation 10. Using a value of $k_0 = 0.59$ for the 2.2 molar acid solution, the least square value for $k_1 = 4.27$ mole^{-1} l. min.$^{-1}$ and for $k_2 = 7.12$ mole^{-1} l. min.$^{-1}$. The agreement between the calculated and experimental data is shown in Fig. 1. The calculated values of the rate constant were obtained using the equation

$$k_{obsd} = k_0\left[1 - \sum_{i=1}^{J} a_i\right]_{Np(IV)}\left[1 - \sum_{i=1}^{J} a_i\right]_{Np(VI)} + k_1[a_{NpSO_4^{++}}] \times \left[1 - \sum_{i=1}^{J} a_i\right]_{Np(VI)} + k_2[a_{NpSO_4^{++}}][a_{NpO_2SO_4}] \quad (11)$$

valid for a given condition of acidity. In equation 11 and subsequent equations, the terminology

$$\left[1 - \sum_{i=1}^{J} a_i\right] = \frac{[Np^{+4}]}{[Np(IV)]}, \quad [a_{NpSO_4^{++}}] = \frac{[NpSO_4^{++}]}{[Np(IV)]}, \text{ etc.}$$

is used for simplicity.

The Effect of Hydrogen Ion Concentration.—The effect of varying the hydrogen ion concentration at constant bisulfate concentration is summarized in Table III. Two initial bisulfate concentrations were used. One corresponds approximately to the concentration at which the rate of reaction is at a maximum. The second, higher concentration is for the region in which the rate has again decreased to a relatively low value. Examination of the data shows that k_{obsd} for both regions is inversely proportional to a value between the second and third power of the hydrogen ion concentration.

TABLE III

EFFECT OF HYDROGEN ION CONCENTRATION ON THE RATE OF THE Np(IV)-Np(VI) REACTION IN SULFATE SOLUTION

The variation of the reaction rate with variation in hydrogen ion concentration can be represented as a combination of five hydrogen ion dependent paths as represented by the equation

$$k_{obsd} = k_0\frac{[a_{Np^{+4}}][a_{NpO_2^{++}}]}{[H^+]^2} + \{k_1[a_{NpSO_4^{++}}][a_{NpO_2^{++}}] + k_2[a_{NpSO_4^{++}}][a_{NpO_2SO_4}]\}\left\{\frac{k_3}{[H^+]^2} + \frac{k_4}{[H^+]^3}\right\} \quad (12)$$

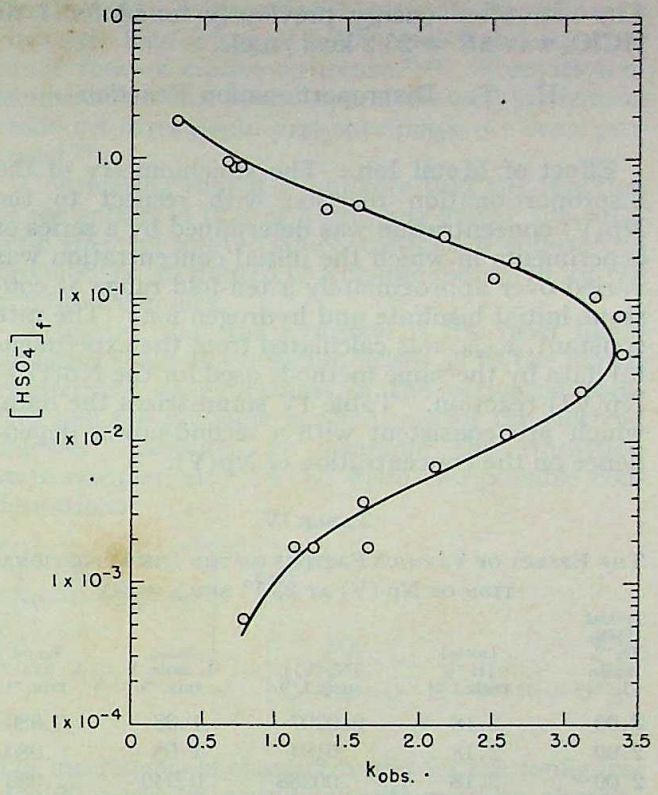

Fig. 1.—Variation of k_{obsd} with free bisulfate at constant hydrogen ion; $[H^+] = 2.2\ M$; $\mu = 2.2$; $t = 25.0°$. Solid line calculated from equation 11.

It is not possible to reproduce the data by a simpler equation involving only two sulfate dependent paths with different hydrogen ion dependencies. The four sulfate containing activated complexes implied by equation 12 are formally the same as the principal activated complexes found in sulfate solution for the disproportionation reaction of Np(V) (see later Discussion).

The least squares values of the constants are $k_3 = 3.6$ mole^2 l.$^{-2}$ and $k_4 = 1.7$ mole^3 l.$^{-3}$ for the low bisulfate region and $k_3 = 3.8$ mole^2 l.$^{-2}$ and $k_4 = 2.8$ mole^3 l.$^{-3}$ for the high bisulfate region. At the 95% confidence level the uncertainties in the precision of the constants are approximately 20%. Within the experimental uncertainties the k_3 values are the same for both sets of data. It is by no means certain that the apparent differences in k_4 values are significant. The variation in solution composition is so great that appreciable deviations in the activity coefficients of the various species would not be unexpected.

Temperature Effect.—The variation of the reaction rate with temperature was determined for solutions initially 0.084 and 0.943 M in HSO_4^-. The temperatures were 15.1, 25.0 and 35.2°. The apparent activation energies were $\Delta E = 23.1 \pm 3.3$ kcal./mole and $\Delta E = 23.3 \pm 3.2$ kcal./mole for the 0.084 and 0.943 M bisulfate solutions, respectively.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The activation energy previously found for 1 M $HClO_4$ was $\Delta E = 25.2$ kcal./mole.

II. The Disproportionation Reaction

$$2\ Np(V) \rightarrow Np(IV) + Np(VI)$$

Effect of Metal Ion.—The stoichiometry of the disproportionation reaction with respect to the Np(V) concentration was determined by a series of experiments in which the initial concentration was varied over approximately a ten-fold range at constant initial bisulfate and hydrogen ion. The rate constant, k_{obsd}, was calculated from the experimental data by the same methods used for the Np(IV)–Np(VI) reaction. Table IV summarizes the data, which are consistent with a second-power dependence on the concentration of Np(V).

TABLE IV

2.00	2.18	.00196	.890	.980
1.00	2.18	.0214	.380	.385
0.466	2.18	.0214	.154	.164
.938	1.18	.0218	.342	.327
.895	0.583	.0218	.287	.284
.823	0.184	.0218	.232	.241

The Effect of Bisulfate and Hydrogen Ion.—The rate of the disproportionation reaction is a monotonic increasing function of the bisulfate concentration. Analysis of the data in Table IV by standard methods results in a non-integral bisulfate dependence of 1.3 over the range of concentration $2.00 \leq [HSO^4{}^-] \leq 0.466$ M.

Empirical analysis of the data in Table IV also reveals that the rate of the reaction is dependent on the 0.1 power of the hydrogen ion concentration over the acid range $2.18 \leq [H^+] \leq 0.184$ M. The empirical form of the rate equation is then

$$R = [Np(V)]^2 k_{obsd} = k[Np(V)]^2[HSO_4^-]^{1.32\pm0.02} \times [H^+]^{0.092\pm0.002} \quad (13)$$

The value of $k = 0.364 \pm 0.022$ at the 95% confidence level.

As in the case of the Np(IV)–Np(VI) reaction, the non-integral bisulfate and hydrogen ion dependencies indicate that the Np(V) disproportionation reaction is complex. It is possible to express the results in the equation

$$k_{obsd} = \{k_5[HSO_4^-] + k_6[HSO_4^-]^2\}\{k_7 + k_8[H^+]\} \quad (14)$$

The least squares values for the specific constants are $k_5 = 0.300$ mole^{-2} l.^{2} min.$^{-1}$, $k_6 = 0.0877$ mole^{-3} l.^{3} min.$^{-1}$, $k_7 = 0.739$ and $k_8 = 0.135$ mole^{-1} l. Calculated values of k_{obsd} using this equation are given in Table IV, column 5. It is possible to reproduce the results if the hydrogen ion dependent terms are neglected; however, the fit to the data is not quite as good. This might be justified on the basis that the environmental conditions are altered sufficiently to give an effect of this magnitude. The resulting equation then would be

$$k_{obsd} = k_5'[HSO_4^-] + k_6'[HSO_4^-]^2 \quad (15)$$

with $k_5' = 0.26$ mole^{-2} l.^{2} min.$^{-1}$ and $k_6' = 0.14$ mole^{-3} l.^{3} min.$^{-1}$.

It should be pointed out that the four paths indicated by equation 14 yield stoichiometric formulas for the activated complexes identical with three of those obtained for the four bisulfate dependent paths of the Np(IV)–Np(VI) reaction. The principle of detailed balancing requires that all possible paths exist for the disproportionation reaction. The applicability of the simpler equation is therefore indicative of the relative rates of reaction for the several paths and the limited precision of the data.

The Effect of Temperature.—The temperature coefficient of the reaction rate was measured for solutions initially 2.18 M in $[H^+]$ and 2.00 M in $[HSO_4^-]$. Temperatures were 15.15, 25.1 and 35.15°. The apparent activation energy was $\Delta E = 14.3 \pm 3.1$ kcal./mole. The activation energy previously measured for 1 M $HClO_4$ solutions was 17.1 ± 1.6 kcal./mole.

Discussion

The stoichiometric formulas for the activated complexes derived from the rate data can be written

$$A = |NpO_2NpOOHSO_4^{+1}|^{\pm}$$
$$B = |NpO_2Np(OH)_2(SO_4)_2|^{\pm}$$
$$C = |NpO_2Np(OH)_2SO_4^{+2}|^{\pm}$$
$$D = |NpOOHNp(OH)_2(SO_4)_2^{+1}|^{\pm}$$
$$E = |NpO_2Np(OH)_3(SO_4)_2^{-1}|^{\pm}$$

Representation of the stoichiometry as above does not necessarily imply the existence of the given entities in the actual configurations of the activated complexes. Alternate representations can be given. The transition states A and B represent those for the predominant reaction paths for the Np(V) disproportionation. C and D also represent activated complexes for the disproportionation reaction. The states A, B and C are common to both the disproportionation reaction and the Np(IV)–Np(VI) reaction. Since it is a requirement of the principle of microscopic reversibility that the transition state be the same for both the forward and reverse reaction, the fact that the state D is derived only from the rate equation for the disproportionation and the state E only from the rate equation for the Np(IV)–Np(VI) reaction is therefore only indicative of the relative rates of reaction for the several paths of these two reactions.

Examination of the stoichiometric formulas for the activated complexes suggests certain conclusions as to the probable geometrical configurations of the transition states and probable restrictions on the mechanism for the electron transfer process. First, the data suggest that the neptunium ions must attain a configuration close to that of a O–Np–O$^+$ ion before the electron transfer can occur. As a corollary, it would further appear that it is unlikely that the mechanism can involve the rupture of a Np–O bond of the linear complex in the rate-determining step. That these conditions should be met is not surprising. The O–M–O structure for the ions of the penta- and hexapositive

oxidation states of the actinide elements is very stable, persisting both in solution and in the solid state as an entity.[10-13]

The principal experimental observation supporting the idea that the neptunium ions attain a configuration that readily yields NpO_2^+ before electron transfer occurs is the hydrogen ion dependencies observed for those reactions involving oxidation of Np(IV). For the Np(IV)–Np(VI) reaction in perchlorate solution the dominant reaction path yields a stoichiometry for the activated complex that may be represented as $[NpO_2Np(OH)_2^{+4}]^{\ddagger}$.[2] Similarly, the oxidation of Np(IV) to Np(V) by Fe(III) involves a hydrogen ion dependence that yields the stoichiometric formula, $[Fe(OH)Np(OH)_2^{+4}]^{\ddagger}$.[14] Analogous results have been found for the disproportionation reaction of Pu(IV), where similar species are involved.[15-17] In this case the transition state for the slow step[16] may be represented as $[Pu(OH)_2PuOH^{+5}]^{\ddagger}$. For the reactions in the present research, the importance of the hydrogen ion dependence is emphasized by the participation of sulfate in the reaction. That is, the equivalent of the reaction occurs despite the fact that this equilibrium

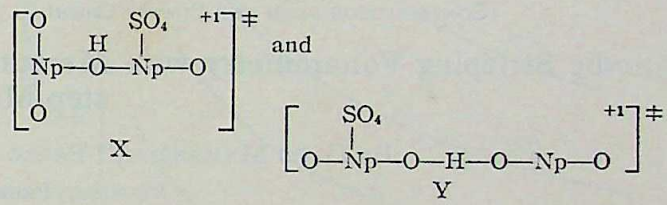
$$Np^{+4}(aq.) + 2H_2O \rightleftharpoons Np(OH)_2^{++} + 2H^+ \quad (16)$$

which lies far to the left in perchlorate solutions of equivalent acidity, will be further shifted in this direction by the presence of sulfate attached to the Np(IV). The same general argument would apply whether the hydrogen ion is split off in a preequilibrium similar to reaction 16 or in the process of formation of the activated complex. The fact that Np(IV) sulfate complexes containing more than one sulfate group do not participate in the reaction to an appreciable extent undoubtedly is partially explicable on the basis that the more sulfate groups attached, the less favorable are conditions for removal of hydrogen ions.

A second factor that may affect the number of sulfate groups involves the question of whether or not the sulfate acts as a bridging ligand in the activated complex. Considering the available data on the relative effectiveness of different bridging groups,[18,19] it appears likely that if there is a choice between bridging through sulfate or hydroxyl, the hydroxyl would be highly favored. In this connection it might be mentioned that in the solid compounds $Th(OH)_2SO_4$ and $Th(OH)_2CrO_4 \cdot H_2O$, the structure appears to consist of chains of thorium ions linked by hydroxide bridges with the sulfate or chromate ions acting to hold these chains together in the form of a layer structure.[20,21] Formation of similar structures in the hydrolysis–polymerization reactions of uranium and thorium have been proposed.[22]

Considering that it is unlikely that the function of the sulfate is that of a bridging group, the catalytic effect of limited concentrations of sulfate can probably be attributed to a charge reduction for the activated complex.

Assuming that the hydroxyl is the most likely bridging anion the question arises as to the actual geometrical configurations in the activated complex and the probable mechanisms for the electron transfer. Consider for example the transition state complex, A. We can write two possible configurations



X Y

The mechanism of charge transfer for the configuration X could be considered either as an electron transfer through a hydroxyl bridge or as a hydroxy atom transfer. If we accept our argument that the tendency is to form and maintain the O–M–O structure, then we can rule out the hydroxyl atom transfer mechanism. There is no *a priori* way of deciding whether an electron transfer or a hydrogen atom transfer mechanism, corresponding to the configuration Y, is the correct one. It might be pointed out, however, that formation of complexes corresponding to the general configuration Y involves no rearrangement of the hydration spheres of the reacting ions in the formation of the bridge. The transition state is also more symmetrical for those complexes with the Y configuration.

If we assume that the bridging is by way of either hydroxyl or hydrogen, then the fundamental mechanism for the electron transfer process is probably the same in the presence or absence of sulfate. We can then advance a reasonable explanation for the apparent anomalies previously discussed for experiments in perchlorate media.[2,23] For example, it was found that the Np(IV)–Np(VI) reaction in perchlorate solution could be adequately represented by

$$-\frac{d[Np^{+4}]}{dt} = k_0'[Np^{+4}][NpO_2^{++}][H^+]^{-2} \quad (17)$$

Combining this with the equation for the over-all equilibrium involving Np(IV), Np(V) and Np(VI), it was deduced that the Np(V) disproportionation reaction could be written as a mechanism which

$$-\frac{d[NpO_2^+]}{dt} = k_1'[NpO_2^+]^2[H^+]^2 \quad (18)$$

differed in stoichiometry with respect to hydrogen ion from the analogous U(V) reaction.[24] On the other hand, one of the paths for the Np(IV)–Np(V) exchange reaction had the stoichiometry of the U(V) disproportionation.

$$-\frac{d[NpO_2^+]}{dt} = k_1''[NpO_2^+]^2[H^+] \qquad (19)$$

It was found further that the energetics for the overall equilibrium was not in accord with the energetics for the two reactions, (19) and (17). It appears likely from the present observations that the explanation for the disparities is that multiple reaction paths are involved. With this possibility in mind the data for the Np(IV)–Np(VI) reaction were re-examined. Least squares analysis showed that the hydrogen ion dependence was $[H^+]^{-2.08 \pm 0.06}$ (95% confidence level). From this it is possible to write a kinetic expression involving two hydrogen ion dependent paths as

$$k_{obsd} = k_1[H^+]^{-2} + k_2[H^+]^{-3} \qquad (20)$$

with $k_1 = 2.59$ and $k_2 = 0.074$. Although it is clear that the predominant reaction involves only two hydrogen ions these computations lend some support to the hypothesis that more than a single reaction path is involved in perchlorate solution.

Anodic Stripping Voltammetry with Mercury Electrodes—Potential-step and Current-step Methods

BY GLEB MAMANTOV,[1a] PAOLO PAPOFF[1b] AND PAUL DELAHAY

RECEIVED FEBRUARY 25, 1957

An amalgam forming metal is deposited on a stationary mercury electrode and then is anodically oxidized. Anodic stripping is carried out either by sudden switching of potential (potential-step method) or by passing a constant current through the cell (current-step method). A theoretical analysis is developed for both methods for conditions of semi-infinite linear diffusion. The following derivations are given: equations for current–time, current–potential and potential–time curves; diffusion current and transition time for the stripping process; sensitivity gain. Detailed experimental results are discussed for the anodic stripping of cadmium from a hanging mercury drop, and theory and experiment are compared. Sensitivity gains with respect to voltammetry with stirred solution can be larger than 100. Application to concentrations as low as 10^{-7}–10^{-9} molar appears feasible. The two methods are compared with anodic stripping at continuously varying potential (Nikelly and Cooke).

Anodic stripping methods which have been known for years[2] recently have been applied again to the analysis of traces of metals.[3–5] The metal to be determined in a solution is first deposited on a solid[3,5] or amalgamated[4] electrode, and then is stripped from this electrode by anodic oxidation. The amount of metal ion in solution is determined from the quantity of electricity consumed in the stripping process. Nikelly and Cooke[6] recently modified the method and used a mercury pool electrode for deposition of the metal to be analyzed. They reoxidized the metal at continuously varying potential and obtained current–potential curves not unlike those of oscillographic polarography. These curves exhibit a peak from the height of which the concentration of metal is deduced directly. The method of Nikelly and Cooke is a voltammetric procedure whereas previous methods belong to coulometry. These authors coined the expression "anodic stripping polarography" for their method, but we prefer to call it "anodic stripping voltammetry," thus reserving the term "polarography" for methods involving the use of the dropping mercury electrode.[7]

In addition to the method of Nikelly and Cooke, two other simple methods can be conceived: (a) the "potential-step" method in which the metal is oxidized by sudden variation of potential to a more anodic value; and (b) the "current-step" method in which the stripping process is carried out at constant current. These methods are discussed and compared in this paper for the case of stationary mercury electrodes.

Potential-step Method

Diffusion Stripping Current.—A metal M is deposited at constant potential on a stationary mercury electrode in stirred solution. The conditions are such that the electrolysis current is constant; *i.e.*, the volume of solution is so large and the plating time so short that depletion of ions M^{+n} in solution can be neglected. Electrolysis is carried out at a potential corresponding to the limiting current range. Mercury is not stirred, and M is supposed to diffuse in the bulk of mercury under conditions of semi-infinite linear diffusion. After τ seconds, the potential is changed abruptly to a sufficiently anodic value at which metal M is oxidized at a rate that is solely diffusion controlled. The resulting *diffusion stripping current* will now be derived. This current is obtained by deriving the flux of metal M at the electrode surface, *e.g.*, by solving

Fick's equation for the following initial and boundary conditions.

The initial condition expresses the concentration of M in mercury at time τ, *i.e.*, at the instant of switching of potential. This concentration is[8]

$$C_M(x,0) = \frac{i_p}{nFAD_M}\left[2\left(\frac{D_M\tau}{\pi}\right)^{1/2}\exp\left(-\frac{x^2}{4D_M\tau}\right) - x\ \mathrm{erfc}\left(\frac{x}{2D_M^{1/2}\tau^{1/2}}\right)\right] \quad (1)$$

There, x is the distance from the electrode surface in the mercury, i_p the plating current during deposition of M on mercury, D_M the diffusion coefficient of M in mercury, n the number of electrons for the discharge of M^{+n}, F the faraday, A the electrode area, and "erfc" represents the error function complement. We write $C_M(x,0)$ to indicate that the origin of time in the following derivation is taken at the beginning of the stripping process.

As boundary condition we prescribe that M is immediately oxidized to M^{+n} as it reaches the electrode surface. Hence, $C_M(0,t) = 0$ for $t > 0$. Finally, $C_M(x,t) \to 0$ for $x \to \infty$ and for $t \geqslant 0$.

This boundary value problem is quite similar to the one previously studied in this Laboratory for two consecutive electrode reactions in voltammetry at constant current.[9] The result is[10]

$$-\frac{i_{s,d}}{i_p} = \frac{2}{\pi}\left(\frac{\tau}{t}\right)^{1/2} - \frac{1}{2} - \frac{1}{\pi}\sin^{-1}\frac{\tau - t}{\tau + t} \quad (2)$$

where $i_{s,d}$ is the diffusion stripping current. According to polarographic practice, the anodic current $i_{s,d}$ is negative and the cathodic current i_p is positive in (2).

Variations of $-i_{s,d}/i_p$ with t/τ are shown in Fig. 1 (solid curves). It is seen from this diagram that the ratio $-i_{s,d}/i_p$ is much larger than unity provided that t/τ is sufficiently small. One has[11] $i_{s,d}/i_p \to \infty$ for $t/\tau \to 0$, and $-i_{s,d}/i_p \to 0$ for $t/\tau \to \infty$.

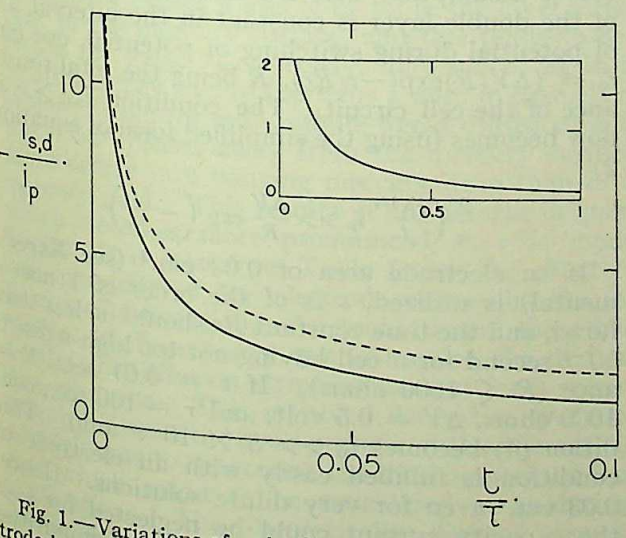

Fig. 1.—Variations of $-i_{s,d}/i_p$ with t/τ for the plane electrode in the potential-step method. Solid curve represents exact solution in equation 2; dashed curve corresponds to the approximate solution $-i_{s,d}/i_p = (2/\pi)(\tau/t)^{1/2}$.

(10) The detailed and rather involved derivation is given in Mamantov's Ph.D. dissertation, June, 1957.

(11) Note that $\sin^{-1}(-1) = -\pi/2$.

Tracings of experimental curves $i_{s,d}$ against t are shown in Fig. 2 for the anodic stripping of cadmium for different pre-electrolysis times. For reasons discussed in the Experimental part, these curves were recorded with a hanging mercury drop and not with a mercury pool. Furthermore, the mechanical stirrer was stopped at the end of pre-electrolysis and 4 seconds were allowed to elapse before the recording of the current–time stripping curves. Deformation of the drop during stripping was avoided in this fashion, and results were more reliable. These conditions do not correspond to the foregoing theoretical analysis, which should be regarded primarily as a guide for a judicious choice of experimental conditions. Note that the experimental curves have the same general shape as the theoretical curve of Fig. 1 (see also below).

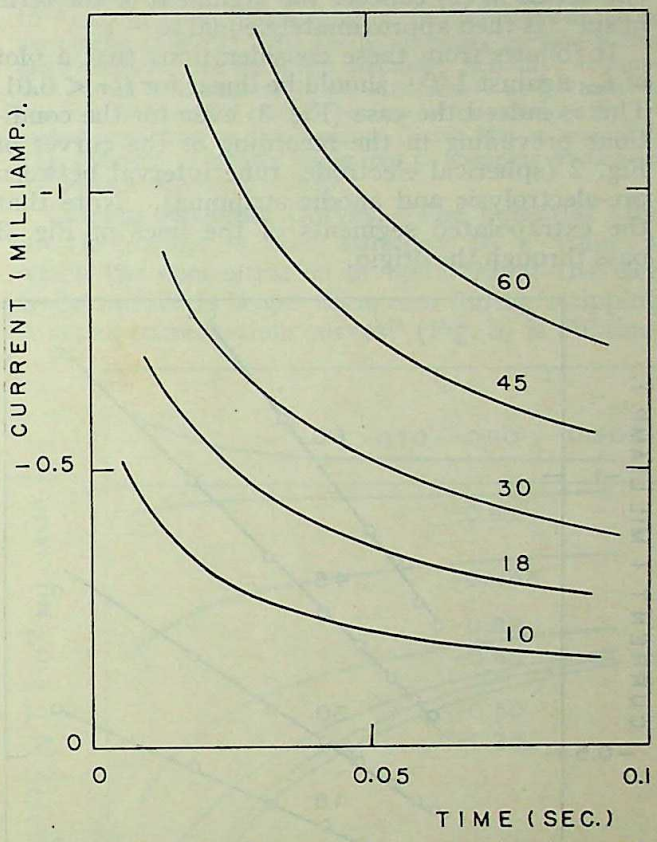

Fig. 2.—Tracings of current–time curves for the anodic stripping of cadmium in 1 *M* potassium chloride at −0.25 volt (*versus* S.C.E.). Numbers on curves are pre-electrolysis times in seconds. Time interval between pre-electrolysis and stripping, 4 seconds.

The term $(2/\pi)(\tau/t)^{1/2}$ in equation 2, which is determinative for short and very long times (dashed curve in Fig. 1), is the ratio $-i_{s,d}/i_p$ one would calculate by assuming that the concentration $C_M(x,0)$ at the instant of switching of potential is independent of x and equal to the concentration at $x = 0$. Thus, one deduces from (1) for $t = 0$ (*i.e.*, after τ seconds of pre-electrolysis)

$$C_M(0,0) = 2\left(\frac{D_M\tau}{\pi}\right)^{1/2}\frac{i_p}{nFAD_M} \quad (3)$$

By introducing this concentration in the Ilkovic equation, as written for the plane electrode, there follows the approximate relationship $-i_{s,d}/i_p = (2/\pi)(\tau/t)^{1/2}$. The resulting approximation is

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

quite satisfactory for short times, *i.e.*, for $t/\tau < 0.01$. For larger values of t/τ, the effect of the non-uniform initial concentration distribution is very pronounced (Fig. 1) at least until t/τ is much larger than unity. The term $(2/\pi)(\tau/t)^{1/2}$ is again determinative for $t/\tau >> 1$ because the last two terms in (2) cancel: the argument of the term in $\sin^{-1}$ is then approximately equal to -1.

It follows from these considerations that a plot of $i_{s,d}$ against $1/t^{1/2}$ should be linear for $t/\tau < 0.01$. This is indeed the case (Fig. 3) even for the conditions prevailing in the recording of the curves of Fig. 2 (spherical electrode, time interval between pre-electrolysis and anodic stripping). Note that the extrapolated segments of the lines of Fig. 3 pass through the origin.

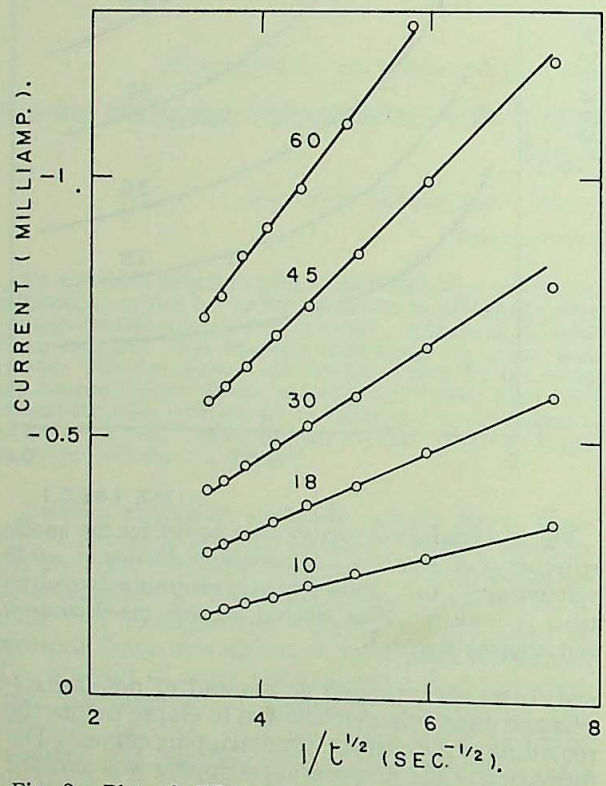

Fig. 3.—Plot of diffusion stripping against $1/t^{1/2}$. Data are from Fig. 2.

It is of interest to calculate the recovery of metal M during stripping. The recovery, which is defined as the ratio $[-\int_0^t i_{s,d}\,dt]/i_p\,\tau$, is obtained by integrating $i_{s,d}$ from 0 to t. Integration is performed by expanding $\sin^{-1}[(\tau - t)/(\tau + t)]$ in series[12] and by retaining only the first term. The resulting approximation is fairly good since the argument is practically equal to unity for $t/\tau << 1$ and the term in $\sin^{-1}$ is quite unimportant. Variations of the recovery with t/τ are shown in Fig. 4. It is seen from this diagram that the recovery is small ($< 10\%$) for $t/\tau < 0.01$. For long times, the recovery is surprisingly good; it approaches unity for $t/\tau \to \infty$.

Sensitivity Gain.—The gain in sensitivity can be expressed in two ways: (a) as the ratio $-i_{s,d}/i_p$

(12) $\sin^{-1} y = y + \frac{y^3}{6} + \frac{1 \times 3}{2 \times 4} \times \frac{y^5}{5} \ldots\ldots$

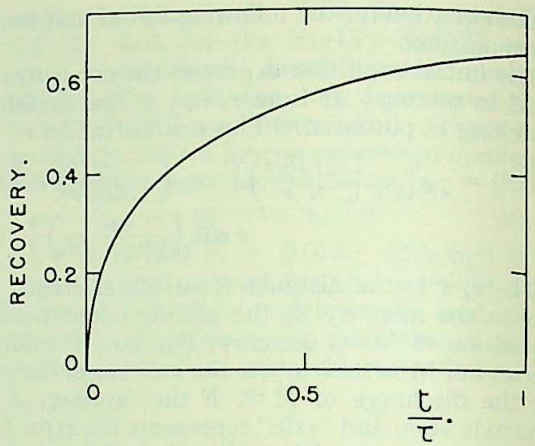

Fig. 4.—Recovery as a function of t/τ in the potential-step method.

of equation 2; or (b) as the gain $-i_{s,d}/i_d$ where i_d is the diffusion current measured directly with the analyzed solution (*e.g.*, without pre-electrolysis) and for the same time t as $i_{s,d}$. Both methods will be discussed.

The gain in sensitivity, as expressed by equation 2, corresponds to the comparison between the stripping method and voltammetry with a stationary electrode in stirred solution. It follows from the discussion of equation 2 that the gain for $t/\tau << 1$ is approximately $(2/\pi)(\tau/t)^{1/2}$. The ratio $(\tau/t)^{1/2}$ should be as large as possible, but there are two limitations: (a) convection interferes with diffusion when τ is too long thus causing unreliability; and (b) the charging (or discharging) of the double layer interferes with the stripping current when t is too short. Obviously, one should have $i_{s,d} >> i_c$ where i_c is the charging current of the double layer. If one makes the rather coarse assumption that the differential capacity c of the double layer is constant in the interval ΔV of potential during switching of potential, one has $i_c = (\Delta V/R)\exp(-t/Rc)$, R being the total resistance of the cell circuit. The condition $i_{s,d} >> i_c$ now becomes (using the simplified form of equation 2)

$$\frac{2}{\pi}\left(\frac{\tau}{t}\right)^{1/2} i_p >> \frac{\Delta V}{R} \exp\left(-\frac{t}{Rc}\right) \qquad (4)$$

If an electrode area of 0.03 cm.^{2} (see Experimental) is utilized, c is of the order of 1 microfarad, and the time constant Rc should be less than 10^{-3} second for a cell having not too high a resistance ($R \leqslant 1000$ ohms). If $t = 0.01$ sec., $R = 1000$ ohms, $\Delta V = 0.5$ volt, and $\tau = 100$ sec., condition (4) becomes $i_p >> 5 \times 10^{-10}$ amp. This condition is fulfilled easily with an electrode of 0.03 cm.^{2} even for very dilute solutions. Hence, the capacity current could be neglected for $t \geqslant 0.01$ sec. Actually, there are traces of impurities adsorbed on the electrode, and the switching of potential generally causes a variation in the surface concentration of these impurities. Variations of surface concentrations are quite slow,[13] and the capacity current may not die out for times appreciably longer that $t = 0.01$ sec. Removal of traces of adsorbable organic substances, possibly

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

by chromatography,[14] is recommended. At any rate, experimental gains of the order of 100 are possible. Since voltammetry with stirred solution is applicable to concentrations as low as 10^{-6} to 10^{-7} molar,[15,16] application of the potential-step stripping method to solutions even as dilute as 10^{-8} molar appears feasible.

Experimental gains are given in Table I for conditions similar to those of Fig. 2 (hanging mercury drop, 4 second interval between pre-electrolysis and anodic stripping). Gains of the order of 100 were obtained for the longest plating time (180 sec.). Experimental and theoretical gains which are in fairly good agreement for short pre-electrolysis times (τ = 10 sec.), are quite different for the larger values of τ. There are two main reasons for this discrepancy. Firstly, convection of metal M in mercury causes a loss of metal in the layer adjacent to the mercury surface, and this tends to decrease the gain. Conversely, diffusion of M in a small mercury sphere (perhaps 1 mm. in diameter) is slower than for semi-infinite linear diffusion, and metal M diffuses away from the mercury surface more slowly in a hanging mercury drop than in a mercury pool. This results in an increase in gain, which becomes more pronounced as τ is made larger. It is seen from Table I that the effect of the sphericity of the electrode outweighs the influence of convection. An evaluation of these two sources of discrepancy would require the derivation of the diffusion stripping current for a spherical electrode. This involved derivation was not attempted since the main purpose of this theoretical analysis was to determine the most important factors which ought to be considered in analytical applications. The theoretically derived general conclusions are confirmed by experiment.

TABLE I

EXPERIMENTAL GAIN FOR HANGING MERCURY DROP *versus* CALCULATED GAIN FOR PLANE ELECTRODE—ANODIC STRIPPING OF CADMIUM

10	8.8	.160	6.16	5.80

[a] The pre-electrolysis current was 26 microamp. except for τ = 180 sec. for which it was 34 microamp.

The second method of expressing the sensitivity gain is to compare $i_{s,d}$ with the diffusion current i_d measured at time t in direct voltammetry without pre-electrolysis. The current i_d is given by the Ilkovic equation written for the plane electrode. The gain calculated by the simplified form of equation 2 and by replacing i_p by its value, $i_p = nFADD_{M^{+n}}C^0/\delta$ (C^0 bulk concentration of M^{+n}, δ diffusion layer thickness), is $(2/\pi^{1/2})(D^{1/2}\tau^{1/2}/\delta)$.

One has $i_{s,d}/i_d \backsimeq 40$ for data of the following orders of magnitude: $D = 10^{-5}$ cm.^{2} sec.$^{-1}$, τ = 100 sec., and $\delta = 10^{-3}$ cm. (an approximate value of the conditions in the experimental study[17]). The anodic stripping method is thus more sensitive than the direct method. Actually, we found that direct voltammetry is not satisfactory at low concentrations (below 10^{-5} molar) because of interference by adsorbed impurities on the electrode (oxide film on mercury). This difficulty is greatly minimized in stripping voltammetry because of pre-electrolysis.

Current–Potential Curves.—The potential after pre-electrolysis is now switched to a value at which the concentration of metal M at the electrode surface is larger than zero during stripping. A set of current–time curves[18] (Fig. 5) is obtained for different stripping potentials. By measuring the current on each of these curves at a given time, one can construct a current–potential curve for that particular stripping time. These curves will now be discussed on the assumption that the Nernst equation is applicable. It first will be assumed that the solution is stirred during stripping and that there is no time interval between pre-electrolysis and stripping.

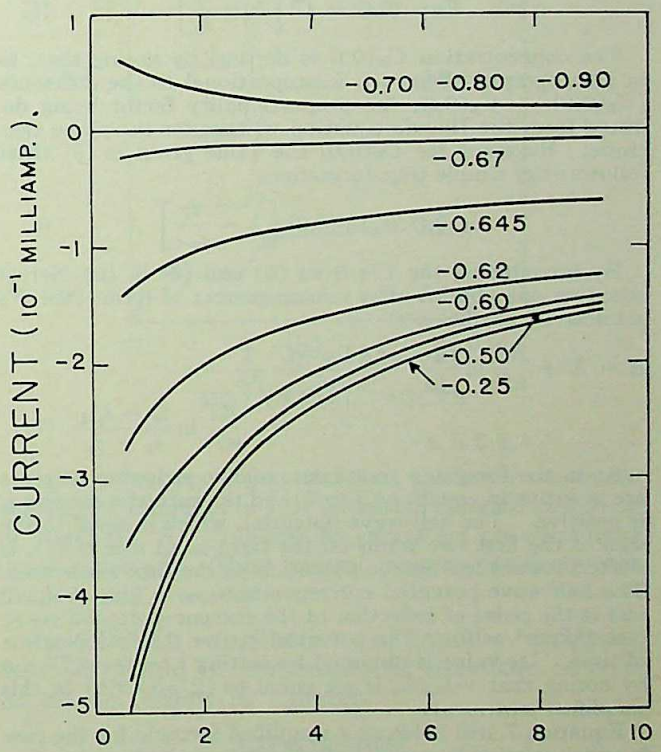

Fig. 5.—Tracings of current–time curves for the anodic stripping potentials (in volts *versus* S.C.E.). Pre-electrolysis time, 10 seconds; time interval between pre-electrolysis and stripping, 4 seconds.

(14) As far as we know, chromatography was first used in the purification of electrolytes in electrochemical studies by P. J. Hillson, *Trans. Faraday Soc.*, **50**, 385 (1954).

(15) T. S. Lee, THIS JOURNAL, **74**, 5001 (1952).

(16) J. G. Nikelly and W. D. Cooke, *Anal. Chem.*, **28**, 243 (1956).

(17) Data were: $i_p \backsimeq 3 \times 10^{-5}$ amp., n = 2, $A \backsimeq 3 \times 10^{-2}$ cm.^{2}, $D = 10^{-5}$ cm.^{2} sec.$^{-1}$, $C^0 = 5 \times 10^{-7}$ mole cm.$^{-3}$.

(18) Note that the curves for −0.90, −0.80 and −0.70 volt in Fig. 5 correspond to the limiting current range for pre-electrolysis. The current decreases progressively because of concentration polarization. Thus, the electrolysis circuit was open after pre-electrolysis and closed again after the interval of 4 seconds, the solution being not stirred after pre-electrolysis.

To derive the equation of the i_s *versus* t curves for any potential we could use again the initial condition (1) for M and prescribe that the ratio $C_{M^{+n}}/C_M$ at $x = 0$ is equal to a constant readily given by the Nernst equation. Another boundary condition would be obtained by prescribing that the sum of the fluxes of M and M^{+n} at $x = 0$ is equal to zero. The approach is the same as in the rigorous derivation of reversible polarographic waves,[19] but the algebra is far more involved—in fact, too involved for the result to be achieved. It is much easier to assume that C_M is independent of x at $t = 0$ and has the value given by equation 3. This approximation is very good for $t/\tau \leqslant 0.01$ (see above) but is poor for $t/\tau > 0.1$. The concentrations $C_{M^{+n}}(0,t)$ and $C_M(0,t)$ are calculated as follows.

The concentration $C_{M^{+n}}(0,t)$ during stripping is deduced from the condition that the sum of the fluxes of M and M^{+n} at $x = 0$ is equal to zero. On the basis of the Nernst diffusion layer treatment, the flux of M^{+n} during stripping which is equal to i_s/nFA is $D_{M^{+n}}[C_{M^{+n}}(0,t) - C^0]/\delta$, δ being the diffusion layer thickness, and C^0 the bulk concentration of M^{+n}. The thickness δ can be evaluated from $i_p = nFA \cdot D_{M^{+n}}C^0/\delta$. Hence

$$C_{M^{+n}}(0,t) = C^0\left[1 - \frac{i_s}{i_p}\right] \qquad (5)$$

The concentration $C_M(0,t)$ is derived by noting that, as in polarography theory, i_s is proportional to the difference $[C_M(0,0) - C_M(0,t)]$, the proportionality factor being deduced from the Ilkovic equation written for the plane electrode. By using for $C_M(0,0)$ the value given in (3) there follows after simple transformations

$$C_M(0,t) = C_M(0,0)\left[1 - \frac{i_s}{i_{s,d}}\right] \qquad (6)$$

By introducing the C's from (5) and (6) in the Nernst equation one obtains after rearrangement of terms (the F's are activity coefficients)

$$E = E + \frac{RT}{nF}\ln\frac{f_{M^{+n}}}{f_M}\frac{nFAD_M^{1/2}C^0}{\pi^{1/2}i_p}\frac{1}{t^{1/2}} - \frac{RT}{nF}\ln\frac{i_s - i_{s,d}}{i_p - i_s} \qquad (7)$$

As in the foregoing treatment, anodic stripping currents are negative in equations 5 to 7, and the cathodic current i_p is positive. The half-wave potential, which is equal to the sum of the first two terms on the right-hand side of (7), is shifted toward less anodic potentials as the time t increases. The half-wave potential corresponds to $i_s = (i_{s,d} + i_p)/2$ and is the point of inflection of the current–potential curve (set $d^2E/di^2 = 0$). The potential at $i = 0$ is independent of time. Its value is obtained by setting $i_s = 0$ in (7) and by noting that $-i_{s,d}/i_p$ is set equal to $(2/\pi)(\tau/t)^{1/2}$ in this simplified treatment.

Equation 7 still holds as a simplified formula for the case in which stirring is stopped after pre-electrolysis and a time interval elapses before anodic stripping, but the half-wave potential has now the value $E^0 + (RT/nF)\ln(f_{M^{+n}}/f_M)(D_M/D_{M^{+n}})^{1/2}$ and is independent of time. This is the value derived in the theory of reversible polarographic waves.

Current–potential curves deduced from the data of Fig. 5 are plotted in Fig. 6 for different values of t. The half-wave potential is independent of time and has the same value (−0.64 volt *versus* S.C.E.) as the polarographic half-wave potential. The foregoing approximate analysis is thus quite satisfactory for the stripping times involved here.

Current-step Method

Transition Time and Sensitivity Gain.—The conditions are the same as in the potential-step method except that anodic stripping is carried out at constant current. The potential of the amalgam electrode is followed during anodic stripping, and a potential–time curve is recorded. This curve exhibits a rapid variation of potential at the transition time τ_s, *i.e.*, at the time at which $C_M(0, \tau_s) = 0$ (Fig. 7). The ratio τ_s/τ, of the transition time τ_s to the pre-electrolysis time τ, was calculated in a previous paper[9]

$$\frac{\tau_s}{\tau} = \frac{1}{\left(1 - \frac{i_s}{i_p}\right)^2 - 1} \qquad (8)$$

with i_p positive and i_s negative. Experimental and calculated values of τ_s/τ are compared in Table II for the anodic stripping of cadmium from a hanging amalgam drop. The agreement is relatively good in view of the two sources of discrepancy, sphericity of the electrode and loss of metal in mercury by convection. The effect of sphericity becomes more pronounced as the electrolysis is prolonged (compare data for $\tau = 10$ sec. and $\tau = 75$ sec.).

TABLE II

EXPERIMENTAL RATIO τ_s/τ FOR HANGING MERCURY DROP *versus* CALCULATED GAIN FOR A PLANE ELECTRODE—ANODIC STRIPPING OF CADMIUM

i_s,[a] μa.	τ, sec.	τ_s, sec.	τ_s/τ Exptl.	Calcd.
9.9	10	17.5	1.75	2.18
19.6	10	8.5	0.85	1.02
49.4	10	2.4	.24	0.32
49.4	25	7.8	.31	.32
49.4	50	16.0	.32	.32
49.4	75	27.2	.36	.32

[a] Pre-electrolysis current, 48 microamperes; electrode area, 3.16×10^{-2} cm.^{2}.

The sensitivity gain can be expressed by comparing τ_s with the transition time τ_d that would be observed in direct electrolysis at current i_s without pre-electrolysis. Since $\tau_d^{1/2}$ is proportional to the bulk concentration of reducible substance, the ratio $(\tau_s/\tau_d)^{1/2}$, and not τ_s/τ_d, should be considered to express the gain in sensitivity. The gain is $(\tau/\tau_d)^{1/2}[(1 - i_s/i_p)^2 - 1]^{-1/2}$. For the data of Table II ($\tau = 10$ sec., $\tau_s = 17.5$ sec.), one evaluates a gain, $(\tau_s/\tau_d)^{1/2}$, of approximately 6 over the direct method.[20] Actually, the direct method is not applied easily at low concentrations (adsorbed impurities, capacity effect), and the stripping method is more advantageous than this simple calculation of the gain would indicate.

Potential–Time Curves.—As in the potential-step method, we consider only the case in which the Nernst equation is applicable. By introducing the value of the concentration previously derived[9]

$$C_M(0,t) = \frac{2[i_p(\tau + t)^{1/2} - (i_p - i_s)t^{1/2}]}{\pi^{1/2}nFAD_M^{1/2}} \qquad (9)$$

and $C_{M+N}(0,t)$ from equation 5 in the Nernst equation there follows after simple transformations (no time interval between pre-electrolysis and stripping)

$$E = E^0 + \frac{RT}{nF}\ln\frac{f_{M^{+n}}}{f_M}\frac{\pi^{1/2}nFAD_M^{1/2}C^0}{2i_p} - \frac{RT}{nF}\ln\left[(\tau + t)^{1/2}\frac{i_p}{i_p - i_s} - t^{1/2}\right] \qquad (10)$$

Potential–time curves do not have a point of inflection, and the potential becomes progressively more anodic as the electrolysis proceeds (Fig. 7). The potential at $t = 0$ is readily deduced from (10); it depends on pre-electrolysis time and current. It follows from (10) that a plot of log $[(\tau + t)^{1/2}[i_p/(i_p - i_s)] - t^{1/2}]$ against E should have the reciprocal slope of $0.059/n$ at 25°.

(19) See ref. 7, pp. 52–57. Note that this derivation is different from the one usually given in the polarographic literature.

(20) On the basis of the evaluated value $\tau_d \approx 0.5$ sec.

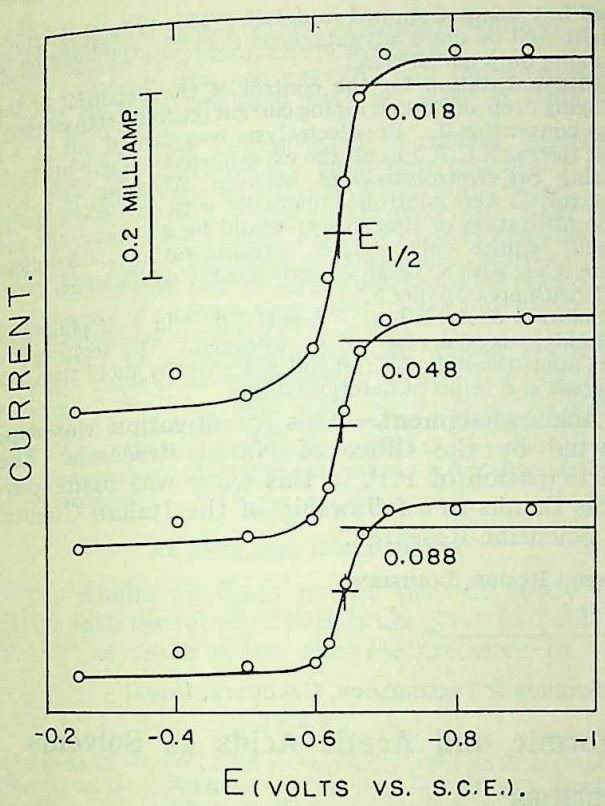

Fig. 6.—Current–potential curves from the data of Fig. 5. Numbers on curves are the times in seconds at which current was measured.

Potential–time curves for the case in which stirring is stopped after pre-electrolysis can be analyzed readily in an approximate fashion on the basis of previous results for voltammetry at constant current (g).

Application to Analysis

The two methods studied in this paper and the method of Nikelly and Cooke[6] (anodic stripping with continuously varying potential) are of interest in the analysis of traces of amalgam forming metals in the concentration range in which direct voltammetry and polarography fail. Hence, anodic stripping methods have a practical value for concentrations below 10^{-6} molar.[21] The sensitivity gain that is achieved results from concentration of the metal to be analyzed in a thin layer at the surface of the mercury electrode. Rather high gains are possible because the metal is deposited in stirred solution at a much higher rate than it diffuses into the bulk of mercury. In this respect, anodic stripping methods can be compared to extraction.[22] It should be emphasized that the gain does not result so much from an increase in current to be measured *per se* (very low currents are quite easy to measure) but rather from an enhancement of current under conditions in which the capacity current is not particularly increased.

(21) For a review of voltammetric and polarographic methods for trace analysis see P. Delahay in "Symposium on Trace Analysis," J. H. Yoe and H. J. Koch, Eds., John Wiley and Sons, New York, N. Y., in preparation, 1955.

(22) Comparison also should be made with the method of N. H. Furman, C. E. Bricker and B. McDuffie, *J. Wash. Acad. Sci.*, **38**, 159 (1948), in which the metal to be analyzed is plated on mercury and is subsequently dissolved in acid after removal of mercury by distillation. See also A. Hickling, J. Maxwell and J. V. Shennan, *Anal. Chim. Acta*, **14**, 287 (1956).

A comparison of the gains obtained by the three anodic stripping methods would require actual application to trace analysis, and only the tentative conclusion that the potential-step method is the most sensitive will be made here.[23]

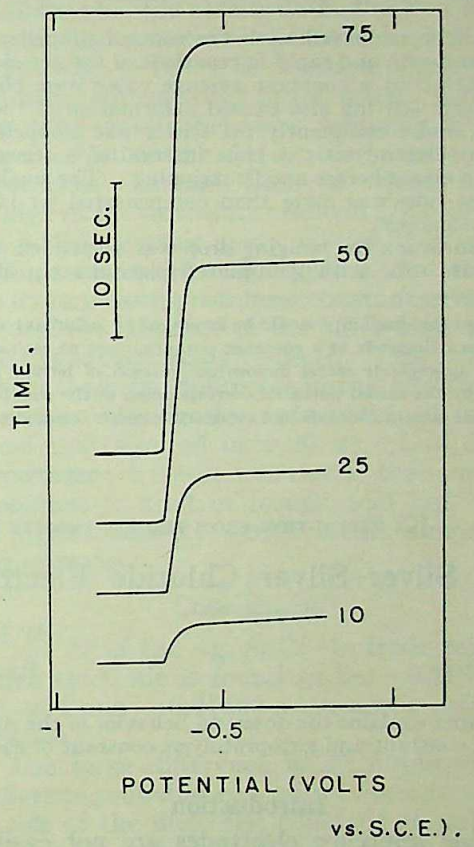

Fig. 7.—Tracings of potential–time curves for the anodic stripping of cadmium in 1 *M* potassium chloride at 1.56×10^{-3} amp.cm.$^{-2}$. Numbers on curves are pre-electrolysis times in seconds. Time interval between pre-electrolysis and stripping, 4 seconds.

An obvious application of anodic stripping methods would be amperometric titrations at concentrations below 10^{-6} molar.

Experimental

A cell with hanging mercury drop[24] of the type previously used in this Laboratory[25] was utilized. A mercury drop falling from a conventional dropping mercury electrode was caught in a small glass spoon and then hung (by rotation of the spoon) on a small gold-plated platinum wire (perhaps 0.1 mm. long) sealed in a glass tube with fine tip. The cell also was provided with a constant speed stirrer of the propeller type. The blades of the propeller were below the tip of the dropping mercury electrode and the hanging drop to avoid the projection of mercury drops on the hanging drop. The stopper was made of plastic and was carefully machined to fit the ground glass collar of the cell. Accuracy in the spacing of the electrodes and spoon was far more easily achieved with a plastic stopper than with a ground glass stopper. A saturated calomel electrode was prepared in the other arm of the cell, and the cell had the usual nitrogen inlet.

It was found that the solution could be rather vigorously

(23) The sensitivity gain of the method of Nikelly and Cooke can be evaluated by noting that the Randles–Sevcik treatment of oscillographic polarography is applicable as a first approximation when the stirrer is stopped before anodic stripping.

(24) First used, as far as we know, by H. Gerischer, *Z. physik. Chem.*, **202**, 302 (1953).

(25) (a) T. Berzins and P. Delahay, THIS JOURNAL, **77**, 6448 (1955); (b) W. Vielstich and P. Delahay, *ibid.*, in press.

stirred without the dislodging of the hanging drop, and pre-electrolysis limiting currents were relatively large (diffusion layer thickness of the order of 10^{-3} cm.). Because of vigorous stirring, the pre-electrolysis current dropped within 1–2 seconds to an average constant value upon switching on. The area of the hanging drop was reproducible with an error smaller than 1% (a conservative estimate) in a given medium.[26]

The stirring achieved with the rotated propeller stirrer was not uniform, and rapid fluctuations of the pre-electrolysis current about a constant average value were observed. Non-uniform stirring also caused deformation of the hanging drop, and consequently the stirrer was stopped at the end of pre-electrolysis. A time interval of 4 seconds was allowed to elapse before anodic stripping. The small loss in sensitivity gain was more than compensated by improvement in accuracy.

A cell in which the hanging drop was suspended on a rotating glass tube with gold-plated platinum tip also was used but was not studied in detail. This type of electrode might well be more advantageous than the combination of hanging drop and stirrer.

Instrumentation for the control of the potential of the hanging drop and the stripping current (current-step method) was conventional. Pre-electrolysis was carried out at −1 volt (*versus* S.C.E.) in all the experiments. Time intervals during pre-electrolysis and between stripping and pre-electrolysis were controlled manually with an electric timer. The utilization of time relays would be advantageous and would require only simple instrumentation. Recordings were made with a Tektronix cathode-ray oscilloscope, model 531, with preamplifier 53D.

Solution composition: 0.5 mM Cd^{++} in 1 M potassium chloride; oxygen removal by nitrogen. The temperature was approximately 25°; it did not vary by more than 1–2 degrees in a series of determinations.

Acknowledgment.—This investigation was supported by the Office of Naval Research. The participation of P.P. in this work was made possible thanks to a fellowship of the Italian Council of Scientific Research.

Baton Rouge, Louisiana

(26) The reproducibility would be improved by polarizing the dropping mercury electrode at a constant potential (not so cathodic as to cause any appreciable metal deposition) instead of letting the electrode acquire the mixed potential corresponding to the condition that the algebraic sum of faradaic and capacity currents is equal to zero.

[Contribution from the University College of Science & Technology, Calcutta, India]

The Silver–Silver Chloride Electrode in Formic and Acetic Acids as Solvents

By L. M. Mukherjee[1]

Received April 1, 1957

This paper explains the observed behavior of the Ag/AgCl electrode in formic and acetic acids, as solvents, in terms of the dielectric constant and autoprotolysis constant of each medium.

Introduction

Suitable reference electrodes are not easily obtainable for use in formic and acetic acid solutions. Cells employed in previous studies[2,3] of acids and bases in acetic acid, for instance, seem to consist essentially of an aqueous calomel reference electrode in conjunction with chloranil or glass electrode, both with and without salt bridge. To eliminate the difficulties encountered with the use of the calomel electrode, Fritz[4] and Glenn[5] recommended the Ag/AgCl electrode as a reference standard in acetic acid. Accordingly, the purpose of the present investigation is to determine the standard potential of the Ag/AgCl electrode (relative to hydrogen electrode as zero) in both formic and acetic acids with a view to test its performance as a reference electrode and also to explain the observed E^0 values in terms of the properties of the solvents themselves.

Experimental

Cells of the following type were studied in both the solvents

$$\mathrm{Pt,\ H_2;\ HCl_{non\text{-}aq};\ AgCl/Ag}$$

$$E_{obs} = E^0 - \frac{2RT}{F} \ln a^0{\pm}\mathrm{HCl}$$

The observed e.m.f.'s were extrapolated to obtain the standard potential $E°$ of the silver–silver chloride electrode by the procedure outlined by Harned,[6] taking into account the Gronwall–LaMer–Sandved extended terms. Due to incomplete ionization of HCl in formic acid and acetic acid, the extrapolation formula has been modified in each case by replacing the concentration C by α. $C\ (= \sqrt{KC})$ where α and K represent, respectively, the degree of dissociation, and the dissociation constant of HCl as obtained from the previous conductance data in the particular medium. The values of the dissociation constant of HCl in formic and acetic acids used in the present case refer, respectively, to the work of Schlesinger and Martin[7] and of Kolthoff and Willman.[8]

Of the solvents employed in the present study, acetic acid was purified as: 99–100% glacial acetic acid (E. Merck) was refluxed with a little solid $K_2Cr_2O_7$ for about 5 hours on a sand-bath and then distilled in an all-glass Pyrex apparatus provided with $CaCl_2$ guard tube directly into a clean, dry Jena bottle. The distillate so obtained was then frozen out, the liquid portion was discarded and the crystals (m.p. 16.6°) were collected and stored in Jena bottles which were kept in a closed chamber containing some dehydrated silica gel. The sample so obtained was finally characterized by ultraviolet spectrophotometry.

One hundred per cent. A.R. quality formic acid (E. Merck) was used as such without any initial treatment; the acid and the prepared solutions as well were preserved in a closed chamber kept in a refrigerator.

Solutions of HCl were obtained by absorbing in the respective solvents, in almost complete absence of air, HCl gas prepared from concd. H_2SO_4 and NaCl (E. Merck, G.R., oven-dried at 105–110°) and dried by passing through concd. H_2SO_4. Due to very low solubility of HCl in acetic acid, solutions of concentrations higher than 0.00533 N could not be studied in this solvent. Aliquots of the HCl solutions so prepared were taken in water and then estimated either by weighing as AgCl or by back titration of $AgNO_3$ added in

excess against standard KCNS in aqueous solution. The concentrations were calculated in molarity.

The hydrogen electrode assembly and the silver–silver chloride electrode employed were the same as those described before.[9]

After preparation the silver–silver chloride electrodes were kept short-circuited for some time and finally preserved in dilute aqueous solution of KCl in the dark. The electrodes were usually washed thoroughly with water and then with the desired solvent prior to use in non-aqueous solutions. Before and after the experiments, the electrodes (*viz.*, the hydrogen and the silver–silver chloride electrodes) were checked in aqueous solutions of known activities of hydrogen or halide ions as the case may be.

The e.m.f.'s were recorded at intervals of about 30 minutes for 3 to 4 hours at 35 ± 0.25° with the help of a Leeds and Northrup Type K2 potentiometer and a Hartmann Braun galvanometer till the values were constant within ±0.0001 volt. An additional thermionic amplifier was used to aid the measurements in acetic acid solutions because of their high resistance.

Results and Discussions

The results obtained in the present study together with the relevant details are given in Table I. The E^0 of silver–silver chloride (relative to hydrogen electrode as zero) is found to be −0.11995 and −0.61800 volt, respectively, in formic and acetic acids.

TABLE I

E^0 Ag/AgCl = −0.11995 v. (molar); −0.13022 v. (molal) (formic acid) = −0.61800 v. (molar); −0.62084 v. (molal) (acetic acid). $AgCl + {}^1/_2H_2 \rightleftharpoons Ag + H^+ + Cl^-$; temp. = 35°

Formic acid pK_{HCl} = 1.398, D = 58.5 (16°), a^0 = 6 Å.		Acetic acid pK_{HCl} = 9.292, D = 6.15 (20°), a^0 = 5 Å.

It follows from a consideration of the actual values of the standard reduction potentials for the silver–silver chloride electrode in the two solvents, *viz.*, formic and acetic acids, that the reaction $AgX + {}^1/_2H_2 \rightarrow Ag + H^+ + X^-$ is more likely to occur in the former solvent than in the latter. The reason for this difference in behavior probably lies in the combined effect of the dielectric constant and the autoprotolysis constant both of which are relatively high in the case of formic acid (D = 58.50 and pK_s = 6.20 for formic acid; D = 6.15 and pK_s = 14.45 for acetic acid). It appears that the effect due to its large autoprotolysis constant acts in such a way that the influence of the fairly high dielectric constant is substantially reduced. This is also evident from the large difference in the E^0 value of the silver–silver chloride electrode obtained in formic acid and that secured in a 20 wt. % of dioxane–water mixture—a medium of nearly the same dielectric constant as that of formic acid but of much lower proton activity which seems almost equal to that of water.

Conclusions

1. The E^0 of the Ag/AgCl electrode relative to hydrogen electrode is found to be −0.11995 v. in formic acid and −0.61800 v. in acetic acid in the molar scale.

2. The large difference in E^0 obtained in the two solvents probably can be ascribed to the combined role of the dielectric constant as well as the autoprotolysis constant of the solvents concerned and not simply to the influence of any one of these two factors.

Acknowledgments.—My grateful thanks are due to Dr. S. K. Mukherjee, Reader, Department of Applied Chemistry, University of Calcutta, and to Dr. A. K. Ganguly, Senior Research Officer, Department of Atomic Energy, Govt. of India, for helpful suggestions and valuable criticism of the work.

The Hydrogen Fluoride Solvent System. IV. Metallic Complexes in Liquid HF[1]

BY A. F. CLIFFORD[2] AND J. SARGENT

RECEIVED MARCH 28, 1957

Evidence is presented for the existence in liquid HF of complexes of Co(II), Co(III), Ni(II), Cu(II), Zn(II), Hg(II) and Pb(II). In particular the system Ni(II)–CH_3CN is discussed and evidence presented for the existence of the ions $NiCH_3CN^{+2}$ and $Ni(CH_3CN)_{1+x}^{+2}$. The instability constant for the former was found to be 1.4×10^{-3}.

Introduction

The existence of metallic complexes in a solvent so extremely acidic as liquid hydrogen fluoride, in which the complexing agents themselves must exist largely in cationic form, is of practical and theoretical interest.[3]

As one of the commonest types of complex ion in water is the ammono complex, such as $Cu(NH_3)_4^{+2}$, so in the search for complexes in liquid HF, one

may first think of aquo complexes, such as $Cu(H_2O)_x^{+2}$. Indeed, evidence for these does exist. Thus, it is found[4] that several metallic fluorides, whose solubility in water solution is decreased by increasing the concentration of potassium fluoride, on the other hand become more soluble as the concentration of hydrofluoric acid is increased. After a maximum is reached, however, the solubility decreases as anhydrous hydrogen fluoride is approached (*i.e.*, as the concentration of water is decreased). Thus the compounds CoF_2, NiF_2, CuF_2, ZnF_2 and MnF_2 are found to decrease in solubility in aqueous solutions of KF and NH_4F, obviating the formation of complex ions such as CuF_3^-, and yet their solubility increases in aqueous HF solutions. The solid phases in equilibrium with the HF solutions of high water concentration are found generally to be hydrated, and often contain a ratio of water molecules per metal ion that might be expected for a complex aquo ion. Examples of these are $CoF_2 \cdot 4H_2O$, $NiF_2 \cdot 4H_2O$, $CuF_2 \cdot 2H_2O$ and $ZnF_2 \cdot 4H_2O$. It is to be noted that none of these contain "HF of crystallization" in contrast to the substances which form anionic fluoro complexes. An example of the latter case is AlF_3[4] which forms $AlF_3 \cdot 3H_2O \cdot 3HF$ and $AlF_3 \cdot 6H_2O \cdot 3HF$, which are presumably $[H_3O^+]_3[AlF_6^{-3}]$ and $(H_3O^+)_3[AlF_6^{-6}] \cdot 3H_2O$.

An exact parallel is found in the case of ammono complexes. Thus, the oxides and hydroxides of most metals are quite insoluble in anhydrous ammonia.[5] With the transition metal hydroxides, however, as the concentration of water increases, the solubility increases to a maximum (*i.e.*, a solution of the "ammono complex" is produced), finally decreasing again to a minimum as pure water is approached. The available data do not permit actual calculation of constants of the aquo complexes in HF.

It might be expected, however, that more strongly complexing groups than the aquo group could form complexes of reasonable stability in liquid HF. This paper is a report on some of those which were found.

Discussion of Results

A wide variety of complexes was investigated. In most cases the complexes were not sufficiently stable to withstand isolation of solid phases, so that most of the work was confined to the observation of what complexes were capable of formation in solution. In general this was accomplished by observing simply whether a metallic fluoride could be taken into solution by addition of the complexing agent.

In Table I are listed the results of the reactions between various metal–agent pairs. As nearly as possible the metals and the agents are listed in order of increasing ability to form *covalent* or *inner* complexes.

It can be seen from this table that many complexes which form in aqueous solution apparently do not do so in HF. Moreover, those which do survive in HF are the most "covalent" in nature—*i.e.*, those of Ni, Cu, Zn, Pb, which also involve nitrogen and sulfur.

The colors of the complexes were generally close to those of their aqueous counterparts and are listed in Table II. The colors of lead complexes with thiosalicylic acid and diphenylthiocarbazone (dithizone) could not be observed because of the intensity of the red-brown solutions of the reagents themselves.

The complexes of iron were for the most part weak and ill-defined. It was found that diglycolic acid precipitated from its solution in HF on

			Pb(II)–thiosal	s	Obscured

[a] See footnote *a* of Table I.

addition of FeF_3, although no iron could be detected in the solution. The composition of the solid phase was variable and corresponded to no definite ratio of acid to iron. A typical analysis was Fe 32%, F 25% corresponding to an atom ratio of F to Fe of 2.3 (theoretical for FeF_3, Fe 49%). Apparently reaction took place on the surface of the ferric fluoride or iron metal to form an insoluble complex.

When iron pentacarbonyl was mixed with liquid HF a two phase system resulted, at the interface of which gas was evolved in a somewhat more rapid reaction than was observed with nickel tetracarbonyl. If the solution were at least as cold as 0°, and not acidified (*e.g.*, with BF_3), a clear emerald green solution resulted. If the solution were warmed to 20°, acidified with BF_3 or allowed to stand at 0°, or if the initial reaction were carried out under these conditions, a bright yellow solution resulted. Neither of these colors was extractable into CCl_4. This solution partially decomposed in a matter of hours, precipitating FeF_2 and FeF_3 (the latter probably resulting from oxidation by atmospheric oxygen). Complete decomposition to these products resulted when either solution was evaporated. Both of these solutions when treated with solid KI became deep purple. When the purple solution was shaken with CCl_4, the color was extracted into the CCl_4, giving a deep red solution which was found to contain iron tetracarbonyl iodide. This was identified by means of its pyridine complex. The fact that both of these solutions yielded $Fe(CO)_4I_2$ shows that both the green and yellow complexes must contain at least four carbonyl groups. Since both solutions were found to be electrolytic, the complexes must have been ionized.

Nickel tetracarbonyl differed from $Fe(CO)_5$ in decomposing at the liquid–liquid interface directly to NiF_2 with no evidence for the formation of an intermediate complex. For this reason it was used in some experiments as a source of pure, fresh NiF_2.

As in water, the α-nitroso-β-naphthol complex of Co(III) was insoluble. It is interesting that this could be prepared from Co(II) just as in aqueous solution, as well as directly from Co(III). The reaction also proceeded with Co(II) in 48% aqueous HF. Because of the heterogeneous nature of these reactions, however, the products were of variable composition.

Certain of the complexes were strong enough that the free metals would dissolve in solutions of the complexing agents with liberation of hydrogen. Thus in acetonitrile solution zinc dissolved vigorously; nickel, readily; and cobalt and iron, slowly, the last with subsequent precipitation of white iron(II) fluoride. This probably indicates decreasing stability of the complexes of Ni(II), Co(II) and Fe(II) in this order. The greater vigor of dissolution of zinc, on the other hand, may be related to its more electropositive character. Acetonitrile dissolved CoF_3, giving a cherry red solution which on evaporation gave a red solid which oxidized hydrochloric acid and was 46.1% Co (theoretical for CoF_3, 50%; for $CoF_3.CH_3CN$, 37.5%). The solid resulting from evaporation of the Cu(II)–acetonitrile solutions contained a white phase analyzing 0% Cu, 31% F (theoretical for CH_3CNHF, 33.7% F) and a blue phase analyzing 44.2% Cu (theoretical for $CuF_2 \cdot CH_3CN$, 45% Cu).

The gummy solid residue from the Cu(II)–ethyl acetoacetate complex analyzed Cu 10%, F 27%. (A mixture of one part CuF_2 to 3.1 parts $[C_6H_{10}O_3 \cdot H_2]F_2$ would analyze Cu 10%, F 28%.)

In the case of the acetate and trifluoroacetate complexes of lead, the fact that the residue from evaporation of solutions of the former approximated $Pb(C_2H_3O_2)F$, (75% Pb, theoretical 73% Pb) and of the latter, PbF_2 (83% Pb, theoretical 84.5%), may indicate greater stability of the former. This would accord with expectation based on the relative strengths of the free acids. That these were not oxonium fluoroplumbates was shown by the non-reaction of PbF_2 with HF solutions of water, ethanol and KF.

Since none of the metals involved is amphoteric in HF, as shown by the inability of NaF solutions to dissolve the metal fluorides, reaction can in no case be attributed to that cause. That none of the reagents acted as an acid is attested by the complete lack of reaction with the magnesium vessel.

Chromium.—In addition to the complexes already discussed, it was attempted to form an ethyl acetoacetate complex of chromium(III). It was

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

found that CrF_3 dissolved in ethyl acetoacetate solution in HF to give a deep green solution identical in appearance with that of CrF_3 in KF solutions in HF. The solid obtained on evaporation of the solution corresponded in analysis to no simple cationic complex, Cr 23%, F 29%.

Quantitative Studies.—The nickel–acetonitrile complex was made the subject of a quantitative study by observing the concentration of nickel taken into solution when introduced as metal powder into HF solutions of known acetonitrile concentration. A plot of the curve obtained is shown in Fig. 1. The numerical data are given in Table III.

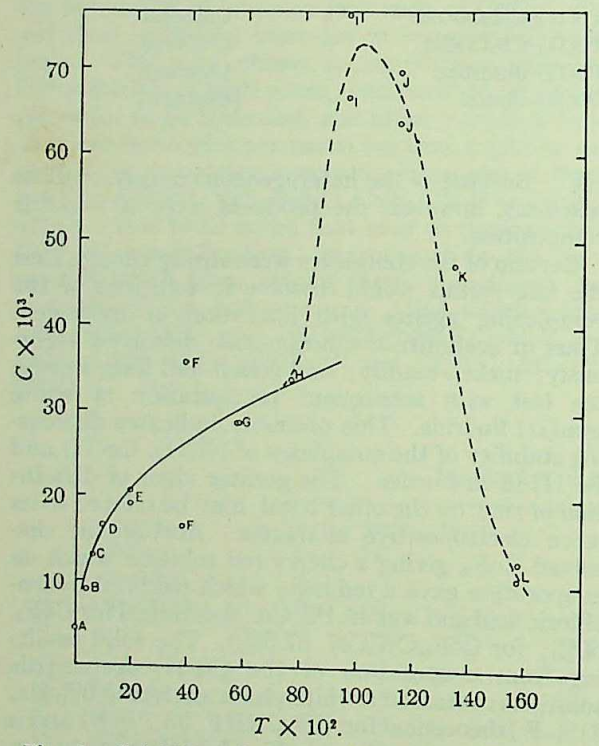

Fig. 1.—Solubility of Ni in HF *vs.* concentration of CH_3CN at −10°. Solid curve: $(T - C)/C^3 = 2.0 \times 10^4$; C = molar concentration of Ni(total); $T = [CH_3CN]_{total}$.

The reaction times quoted show that equilibrium was attained in at least one hour.

If the ionization of acetonitrile as a base ($CH_3CN + HF \rightleftarrows CH_3CNH^+ + F^-$) is ignored, the equations involved in this system are

(1) $F = 2C$ where $F = [F^-]$, C = [complex]

(2) $T = nC + A$ where $T = [CH_3CN]_{total}$, $A = [CH_3CN]$

(3) $MF^2 = s$ where $M = [Ni^{+2}]$, $s = K_{sp}(NiF_2) = 2.81 \times 10^{-7}$ at −10° (calcd. from ref. 6)

(4) $MA^n = jC$ where j = instability constant of complex, n = coördination no.

from which $(T - nC)^n/C^3 = 4j/s$ = const.

It can be seen from Table III that up to point H the value of $(T - nC)^n/C^3$ is very nearly constant for $n = 1$. Consequently, for concentrations of CH_3CN up to 0.60 M, the predominant complex in solution must be $[Ni(CH_3CN)]^{+2}$.

Eliminating point B, and points above H, an average value is found for $4j/s$ of $2.0 \pm 0.2 \times 10^4$.

		3.00	63.5			
K	133.3	3.00		47.0	1.3	15.0
L	157.5	2.00	12.7	11.4	12.0	1700
		3.00	10.6			

[a] T = total concentration of CH_3CN; C = total concentration of nickel.

From this the instability constant is found to be $j = 1.4 \times 10^{-3}$.

(If the alternative simplification is made, that the basic ionization of CH_3CN is large, the concentration of fluoride ion therefore being primarily the result of this ionization and also the concentration of free nitrile as a result being negligible in comparison to the nitrile in other forms, then the following calculations result

(5) $F = H$ where $H = [CH_3CNH^+]$

(6) $T = H + nC$

(7) $HF = bA$ where b = ionization constant of CH_3CN, which in conjunction with (3) and (4) give

$$\frac{(T - nC)^{2n-2}}{C} = \frac{b^n j}{s} = \text{const.}$$

This is constant for no integral value of n.)

The portion of the curve from H to I corresponds to the formation of a higher complex. However, the data are not sufficient to determine the nature of the complex. Since in this region the concentration of $[Ni(CH_3CN)]^{+2}$ cannot be considered negligible, the mathematical equation for the curve—even with the same simplification as before—is necessarily complicated. It takes the form

$$(8)\quad k = \frac{js(4jC^2)^{n-1}(T - nC)^{n-2}}{[4jC^3 - s(T - C)][4jC^2 - s(n - 1)]^{n-1}}$$

where k is the instability constant of the new complex. The values of this expression calculated from points H and I are not consistent for any value of n.

The portion of the curve from I to L appears to correspond to the formation of an insoluble phase, presumably $Ni(CH_3CN)_nF_2$. Since with the available data the value of n cannot be determined, however, it is not possible to treat this quantitatively.

Experimental

Apparatus.—The cell employed for these experiments was a magnesium cylinder, 6 cm. in internal diameter and 5 cm.

deep, closed at top and bottom with Teflon-gasketed Kel-F plates for visibility. The top window was removable. Connections to a reflux condenser of coiled polyethylene tubing, to drainage and to an inlet for liquid HF were provided through magnesium fittings in the walls. These were protected from atmospheric moisture with anhydrous $CaSO_4$ and could be closed by means of magnesium bodied stopcocks with Teflon plugs held in place by spring tension. The drainage outlet was used for obtaining samples of supernate. The HF (General Chemical Company, sulfur-free) was led through a copper coil condenser to a cooled calibrated magnesium reservoir with a Kel-F window from which measured quantities of HF could be delivered to the cell. The cell itself was provided with a cooling coil which maintained the temperature close to −10°.

Thorough mixing of the solutions was ensured by use of a magnetic stirrer. The internal magnet was sealed in a polyethylene capsule for protection.

The Nickel–Acetonitrile Complex.—A portion of pure nickel powder weighed with the magnet, and known volume of acetonitrile, measured by pipet, were placed in the dry cell through the top window, which was then closed tightly. One hundred ml. of HF was now delivered to the cell and stirring begun. In most cases the evolution of hydrogen, brisk at first, was no longer observable after 30 minutes. Stirring was maintained for a longer period (Table III) to ensure attainment of equilibrium. When equilibrium was deemed to have been reached, the cell was drained and washed out with HF until the washes were colorless. The magnet with the unreacted nickel clinging to it was then removed quickly to an anhydrous potassium fluoride desiccator and subsequently weighed. From the loss in weight of the nickel the concentration of nickel in solution was calculated. In two blank runs in the absence of acetonitrile and with different weights of nickel, it was found that complete transfer of the nickel could be accomplished by this method. Because of the formation of a fluoride coating on the metal, the weight increased each time exactly 3.62%, agreeing within the accuracy of the analytical balance. All weights of nickel found during the course of the investigation were corrected by this amount before calculation of the concentration of nickel in solution. The data so obtained are those appearing in Fig. 1 and Table III.

Reagents.—The complexing agents used were of reagent grade in all cases except that of the diglycolic acid, which was of technical grade.

The metal powders were of reagent grade. The metal fluorides were commercial materials obtained from Penn Salt. The $Ni(CO)_4$ was obtained from the International Nickel Company, and the $Fe(CO)_5$ from Chemical Commerce.

Analytical.—All analyses were done by the analytical laboratories of the Central Research Department of Minnesota Mining and Manufacturing Company.

In all cases where analyses were carried out on solutions, the solution of complexing agent was treated with an excess of the solid metallic fluoride.

Heats of Formation of Potassium Chromate, Potassium Dichromate, Chromate and Dichromate Aqueous Ions. Entropy of Dichromate Ion

By C. N. Muldrow, Jr., and L. G. Hepler

Received February 28, 1957

We have determined the heats of solution of K_2CrO_4(c), $K_2Cr_2O_7$(c) and $(NH_4)_2Cr_2O_7$(c) and the heats of reaction of $K_2Cr_2O_7$(c) and CrO_3(c) with aqueous alkali and of K_2CrO_4(c) with aqueous acid. From the results of these determinations we have calculated the heats of formation of K_2CrO_4(c), $K_2Cr_2O_7$(c), $(NH_4)_2Cr_2O_7$(c), $CrO_4^=$(aq) and $Cr_2O_7^=$(aq) to be, respectively, −331.9, −486.4, −425.0, −207.6 and −345.2 kcal./mole. From our heats of formation and reaction, equilibrium constants and entropy data from the literature, we have calculated the entropies of $Cr_2O_7^=$(aq) and $HCrO_4^-$(aq) to be 70.5 and 47.8 cal./deg. mole, respectively. The standard free energies of $CrO_4^=$(aq), $Cr_2O_7^=$(aq) and $HCrO_4^-$(aq) have also been calculated to be −170.1, −303.4 and −179.0 kcal./mole, respectively.

Investigation of the experimental data on which the thermodynamic properties of $CrO_4^=$(aq) and $Cr_2O_7^=$(aq) as given by the Bureau of Standards,[1] Bichowsky and Rossini[2] and Latimer[3] are based showed that these values were not reliably known. Especially, it became apparent that the heats of formation of these ions and of various chromates and dichromates (*e.g.*, K_2CrO_4, $K_2Cr_2O_7$, etc.) were based on questionable heats of reaction of CrO_3 and heats of solution of chromates and dichromates. Calculation of standard heats of formation at 298°K. from the results of many of the pertinent earlier investigations is difficult because most of that work was carried out under such conditions that heats of dilution and heat changes in correcting observed heats of reaction to 298°K. are both large and uncertain. Therefore we have undertaken an investigation of the thermochemistry of $K_2Cr_2O_7$(c), $Cr_2O_7^=$(aq), K_2CrO_4(c) and $CrO_4^=$(aq) by means of solution calorimetry. This work also has involved the study of CrO_3(c) and $(NH_4)_2Cr_2O_7$(c).

(3) W. M. Latimer, "Oxidation Potentials," Second Ed., Prentice–Hall, Inc., New York, N. Y., 1952.

Experimental

Our high-precision solution calorimeter used in previous investigations[4,5] has been improved by several changes. The rate of stirring has been increased and more efficient stirrers have been used. This improved stirring has markedly lessened the time required to attain thermal and reaction equilibrium in the calorimeter, without significantly changing the calorimetric drifts, and has therefore reduced extrapolation uncertainties. A second improvement has been more accurate timing of the heating periods. The calibrated stopwatch has been replaced by a Standard electrical timer read to 0.01 second. The timer is wired through a triple pole-double throw switch that is used to switch the electrical power from the dummy heater to the calorimeter heater. We estimate that the total uncertainty in elapsed time for the heating periods due to variation in the frequency of the local 60 cycle a.c. current, etc., is no more than 0.05 second.

All of the reactions investigated have been rapid. In every experiment the reaction was completed and steady after-period drifts were obtained less than five minutes after breaking the sample bulbs. The heating periods varied from 55–200 seconds.

All of the heats have been determined at 25.0 ± 0.3°.

Materials.—The potassium dichromate ($K_2Cr_2O_7$) used was Mallinckrodt primary standard analytical reagent and the potassium chromate (K_2CrO_4) was Mallinckrodt A.C.S. Reagent. The ammonium dichromate [$(NH_4)_2Cr_2O_7$] was Mallinckrodt analytical reagent. All of these reagents were thoroughly dried before use.

Two brands of CrO_3 were used: Coleman and Bell C.P. and Baker and Adamson Reagent. Samples of both were analyzed by reaction of CrO_3 with standardized ferrous ammonium sulfate solution and titration of the excess ferrous ions with standardized potassium dichromate solution. The titrations were carried out in sulfuric acid–phosphoric acid solution with sodium diphenylaminesulfonate indicator. The two samples of CrO_3 were found to be 99.7 and 99.6% pure, respectively. By making use of a dry box, we were able to load CrO_3 into a weighed calorimeter bulb, weigh the bulb plus CrO_3 and fasten the bulb to the calorimeter stirrer without exposing the CrO_3 to the atmosphere.

The perchloric acid and potassium hydroxide solutions used in the calorimetric runs were prepared by dilution of previously standardized stock acid and alkali solutions.

Results

The difference in the heats of formation of $Cr_2O_7^=$(aq) and $CrO_4^=$(aq) was determined in two different ways, each of which involved the calorimetric determination of two different heats of reaction. We have expressed the difference in these heats of formation in terms of the standard heat of reaction 1 at infinite dilution. This has been done for two purposes: (a) for the calculation of several heats of formation, (b) for the calculation of ΔS_1° from ΔH_1° and ΔF_1°. Because the entropy of every species in (1) except $Cr_2O_7^=$(aq) is known, a value for ΔS_1° makes possible the calculation of the partial molal entropy of $Cr_2O_7^=$(aq).

$$2CrO_4^=(aq) + 2H^+(aq) = Cr_2O_7^=(aq) + H_2O \quad \Delta H_1^\circ \quad (1)$$

The first method for the experimental investigation of the heat of reaction 1 involved determination of the heat of solution of potassium chromate to give potassium and chromate ions and determination of the heat of reaction of potassium chromate with aqueous perchloric acid to give potassium and dichromate ions. The calorimetric reactions are given by eq. 2 and 3, respectively. In the case of reaction 3, the solutions were in every experiment so dilute that no potassium perchlorate was precipitated.

$$K_2CrO_4(c) = 2K^+(aq) + CrO_4^=(aq) \quad \Delta H_2 \quad (2)$$

$$K_2CrO_4(c) + H^+(aq) = 2K^+(aq) + {}^1/_2Cr_2O_7^=(aq) + {}^1/_2H_2O \quad \Delta H_3 \quad (3)$$

The results of these experiments are given in Table I. The starred heats for reaction 2 indicate solution in 7.5×10^{-4} M potassium hydroxide and the others refer to solution in pure water.

Table I

Heat of Solution (2)				Heat of Reaction (3)

.02064	4.33*			10.427	14.34	3.97
				11.463	14.34	3.89
				14.481	19.11	3.76
				15.604	19.11	3.77

We have extrapolated the heats of (2) and (3) to infinite dilution in order to obtain ΔH_2° and ΔH_3°, which are, respectively, 4.2 and 4.6 kcal./mole K_2CrO_4. We have also calculated $\Delta H_1^\circ = 2\,\Delta H_3^\circ - 2\,\Delta H_2^\circ = +0.8$ kcal. The estimated uncertainty in the measured heats ΔH_2 and ΔH_3 is 0.05 kcal./mole and the uncertainties in the extrapolated values for ΔH_2° and ΔH_3° are 0.1 and 0.2 kcal., respectively.

The second method for the experimental investigation of the heat of reaction 1 involved the heat of solution of potassium dichromate to give potassium and dichromate ions and determination of the heat of reaction of potassium dichromate with aqueous potassium hydroxide to give potassium and chromate ions. The calorimetric reactions are given by eq. 4 and 5, respectively.

$$K_2Cr_2O_7(c) = 2K^+(aq) + Cr_2O_7^=(aq) \quad \Delta H_4 \quad (4)$$

$$K_2Cr_2O_7(c) + 2OH^-(aq) = 2K^+(aq) + 2CrO_4^=(aq) + H_2O \quad \Delta H_5 \quad (5)$$

The results of these experiments are given in Table II. All of the heats of solution of potassium dichromate to give $Cr_2O_7^=$(aq), except one, were carried out in very dilute perchloric acid (10^{-3} to 10^{-4} M). The starred run indicates solution in pure water. No potassium perchlorate was precipitated in any of these runs.

Table II

2.610	19.86	5.806	18.60*	8.747	24.34	−7.39
3.445	19.18	5.829	18.76	10.100	48.72	−7.36
5.199	18.80	6.870	18.59	15.320	48.72	−7.45
				19.999	48.72	−7.40

We have extrapolated the heats of reactions 4 and 5 to infinite dilution in order to obtain ΔH_4° and ΔH_5°, which are, respectively, 20.0 and −7.3 kcal./mole $K_2Cr_2O_7$. We estimate the uncertainties in the measured heats ΔH_4 and ΔH_5 to be 0.1 and 0.05 kcal./mole. The estimated uncertainties in the extrapolated values for ΔH_4° and ΔH_5° are 0.2 and 0.1 kcal. In order to calculate ΔH_1° from our values for ΔH_4° and ΔH_5° we need to know the standard heat of reaction 6 and have therefore

$$H^+(aq) + OH^-(aq) = H_2O(l) \quad \Delta H_6^\circ \quad (6)$$

calculated $\Delta H_6^\circ = -13.36$ kcal. from Bureau of Standards[1] heats of formation. From the relation $\Delta H_1^\circ = \Delta H_4^\circ + 2\,\Delta H_6^\circ - \Delta H_5^\circ$ we have calculated $\Delta H_1^\circ = 0.6$ kcal. This heat is in satisfactory accord with the value obtained by our first method and we take as a best value $\Delta H_1^\circ = +0.7$ kcal. It is difficult to estimate the uncertainty in this heat because so much of the uncertainty arises from the various extrapolations to infinite dilution rather than from calorimetric or reaction difficulties. However, we believe that the uncertainty in the average ΔH_1° given above is less than 0.3 kcal.

A large number of workers have investigated the various equilibria between $CrO_4^=$(aq), $Cr_2O_7^=$(aq) and intermediate species. In particular,

Digitized by Arya Samaj Foundation Chennai and eGangotri

Neuss and Rieman,[6] Tong and King,[7] and Davies and Prue[8] have investigated the equilibrium constant for reaction 7 and have obtained values in

$$Cr_2O_7^=(aq) + H_2O = 2HCrO_4^-(aq) \quad K_7 \quad (7)$$

satisfactory agreement. On the basis of these investigations we take $K_7 = 0.029$ and $\Delta F_8^\circ = +2.10$ kcal. Neuss and Rieman[6] also have investigated the acid dissociation of hydrogen chromate ion ($HCrO_4^-$) as in eq. 8. They report K_8

$$HCrO_4^-(aq) = CrO_4^=(aq) + H^+(aq) \quad K_8 \quad (8)$$

$= 3.2 \times 10^{-7}$ and we calculate $\Delta F_8^\circ = +8.86$ kcal.

We have used these equilibrium constants and free energies to calculate $K_1 = 3.37 \times 10^{14}$ and $\Delta F_1^\circ = -19.82$ kcal. We further calculate $\Delta S_1^\circ = (\Delta H_1^\circ - \Delta F_1^\circ)/T = 68.8$ cal./deg.mole. We take entropies of H_2O, H^+ and $CrO_4^=$ from the Bureau of Standards and calculate from ΔS_1° that the partial molal entropy of $Cr_2O_7^=(aq)$ is 70.5 cal./deg. mole.

The heats of solution and reaction reported above are sufficient to determine the heat of hydrolysis of $Cr_2O_7^=(aq)$ to $CrO_4^=(aq)$ and thence the entropy of $Cr_2O_7^=(aq)$. However, in order to obtain heats of formation of $CrO_4^=(aq)$, $Cr_2O_7^=(aq)$ and the potassium salts, it is necessary to carry out at least one additional calorimetric investigation. Accordingly, we have measured the heat of reaction of CrO_3 with aqueous potassium hydroxide to give chromate ions. This heat of reaction, with the heat of formation of CrO_3 and the Bureau of Standards heats of formation of the other substances involved, suffices to give us the heat of formation of $CrO_4^=(aq)$. The calorimetric reaction is given by eq. 9 and the results are given in Table

$$CrO_3(c) + 2OH^-(aq) = CrO_4^=(aq) + H_2O \quad \Delta H_9 \quad (9)$$

III. We have extrapolated these heats to infinite dilution and take $\Delta H_9^\circ = -28.0$ kcal./mole CrO_3. The estimated uncertainty in ΔH due to extrapolation to infinite dilution and the small amount of impurity in the CrO_3 is 0.2 kcal.

TABLE III

REACTION OF $CrO_3(c)$ WITH $OH^-(aq)$

Moles $CrO_3(c) \times 10^3$/ 950 ml. soln.	Moles $OH^- \times 10^3$/ 950 ml. soln.	ΔH_9 kcal./ mole CrO_3
4.881	12.11	−28.01
5.692	14.60	−28.09
7.447	17.04	−28.10

The largest error involved in this procedure comes from the uncertainty in the heat of formation of CrO_3. This heat of formation depends upon the heat of oxidation of Cr_2O_5 to CrO_3 as determined by Roth and Becker[9] and on the heat of formation of Cr_2O_3. The heat of formation of Cr_2O_3 has been investigated recently by Mah[10] (combustion calorimetry) and by Ramsey and co-workers[11] (temperature coefficient of dissociation pressure), who have discussed the earlier work on Cr_2O_3. On the basis of the results of these investigations we have chosen −270.0 kcal./mole as the standard heat of formation of $Cr_2O_3(c)$.

This is identical with the heat of formation chosen earlier by Brewer[12] and close to that adopted by the Bureau of Standards[1] (−269.7). We calculate from this heat of formation and Roth and Becker's heat of oxidation that the heat of formation of $CrO_3(c)$ is −138.0 kcal./mole.

We have used the above values of ΔH_9° and the heat of formation of CrO_3 with the Bureau of Standards[1] heats of formation of H_2O and $OH^-(aq)$ to calculate the standard heat of formation of $CrO_4^=(aq)$ to be −207.6 kcal./mole. By combining this heat of formation with heats of formation of $K^+(aq)$, H_2O and $OH^-(aq)$ as given by the Bureau of Standards[1] and our ΔH_1°, ΔH_2°, ΔH_3°, ΔH_4° and ΔH_5° we have calculated the heats of formation of $Cr_2O_7^=(aq)$, $K_2CrO_4(c)$ and $K_2Cr_2O_7(c)$ to be, respectively, −346.2, −331.9 and −486.4 kcal./mole.

We have also determined the heat of solution of $(NH_4)_2Cr_2O_7$ in very dilute perchloric acid (10^{-3} to 10^{-4} M). The calorimetric reaction is given by eq. 10 and the results are given in Table IV.

$$(NH_4)_2Cr_2O_7(c) = 2NH_4^+(aq) + Cr_2O_7^=(aq) \quad \Delta H_{10} \quad (10)$$

We have extrapolated the observed heats to infinite dilution to obtain $\Delta H_{10}^\circ = 15.3 \pm 0.2$ kcal./mole. This heat was used with our heat of formation of $Cr_2O_7^=(aq)$ and the Bureau of Standards[1] value for $NH_4^+(aq)$ to calculate the heat of formation of $(NH_4)_2Cr_2O_7(c)$ to be −425.0 kcal./mole. Kapustinskii and Shidlovskii[13] investigated the heat of combustion of $(NH_4)_2Cr_2O_7$ to give N_2, H_2O and Cr_2O_3 and reported the heat of formation of $(NH_4)_2Cr_2O_7$ to be −430 ± 6 kcal./mole. This is seen to be in satisfactory agreement with our heat of formation. In so far as our work is concerned, the only likely large source of error is the appreciable uncertainty in the heat of formation of CrO_3. The combustion work avoids this difficulty and therefore it would be desirable to have a better heat of combustion of $(NH_4)_2Cr_2O_7$.

TABLE IV

HEAT OF SOLUTION OF $(NH_4)_2Cr_2O_7(c)$

Moles $(NH_4)_2Cr_2O_7(c) \times 10^3$/ 950 ml. soln.	ΔH_{10} (kcal./mole $(NH_4)_2Cr_2O_7$)
4.256	15.21
4.976	15.02
8.426	14.59
9.610	14.55

We have calculated the standard free energies of formation of $CrO_4^=(aq)$ and $Cr_2O_7^=(aq)$ from our heats of formation and entropies to be, respectively, −170.1 and −303.4 kcal./mole. It would also be desirable to calculate the standard oxidation potential of the $Cr^{+++}/Cr_2O_7^=$ couple. There are several possible ways to carry out this calculation. The heat of formation of $Cr^{+++}(aq)$ can be used with an estimated entropy to calculate the

free energy of formation of Cr^{+++}(aq) which can then be combined with our free energy of formation of $Cr_2O_7^{=}$(aq) to give $\Delta F°$ and $E°$ for the Cr^{+++}/$Cr_2O_7^{=}$ couple. Or the heat of reduction of $Cr_2O_7^{=}$(aq) to Cr^{+++}(aq) can be combined with an estimated entropy of Cr^{+++}(aq), and our entropy of $Cr_2O_7^{=}$(aq) to give $\Delta F°$ and $E°$ for the Cr^{+++}/$Cr_2O_7^{=}$ couple. Data from the literature for the pertinent heats[3,14] are so unreliable as to make these calculations virtually meaningless.

From the results of the investigation by Davies and Prue[8] of the temperature dependence of the equilibrium constant for reaction 7 we calculate $\Delta S_7° = 8.5$ cal./deg. mole $Cr_2O_7^{=}$ and $\Delta H_7° = 4.64$ kcal./mole $Cr_2O_7^{=}$. These data have been combined with our heat of formation and entropy of $Cr_2O_7^{=}$(aq) and the National Bureau of Standards values for water to give the heat of formation of $HCrO_4^{-}$(aq) as -205.0 kcal./mole and the entropy as 47.8 cal. deg./mole. We also have calculated the standard free energy of formation of $HCrO_4^{-}$ to be -179.0 kcal./mole.

Discussion

Latimer[3] and the National Bureau of Standards[1] have taken the entropy of $HCrO_4^{-}$(aq) to be 16.5 cal./deg.mole. Our value (47.8) is much more nearly in accord with what one should expect from comparison with MnO_4^{-} (45.4),[3] ReO_4^{-} (48.3),[15] and ClO_4^{-} (43.2).[3] We also see that the entropy of ionization of $HCrO_4^{-}$ (-38.6) as calculated from our entropy is in accord with the entropies of ionization of HSO_4^{-} (-26.2), HSO_3^{-} (-33), $H_2PO_4^{-}$ (-29.9), HCO_3^{-} (-35.4) as taken from Latimer.[3]

Our heat of solution of K_2CrO_4(c) ($\Delta H_2°$) is in good agreement with the results obtained by earlier workers.[1] Our heat of solution of $K_2Cr_2O_7$(c) ($\Delta H_4°$) is about 3 kcal./mole more positive than heats reported by earlier investigators.[1] It is impossible to compare our heats of reaction of K_2CrO_4(c) with H^{+}(aq) ($\Delta H_3°$) and of $K_2Cr_2O_7$(c) with OH^{-}(aq) ($\Delta H_5°$) with the older heats[1,2] because the older work was carried out in relatively concentrated solutions and at temperatures lower than 25°. Our heat of reaction of CrO_3(c) with OH^{-}(aq) ($\Delta H_9°$) is several kcal./mole more exothermic than earlier heats. We attribute this to the fact that the older work was carried out in more concentrated solutions at temperatures lower than 25° and possibly with less pure CrO_3.

Acknowledgments.—We are pleased to express our gratitude to Mr. Robert L. Graham for help with some of the calorimetric work and to the Research Corporation for financial assistance.

A Copper Analog of the Alkali Tungsten Bronzes

BY LAWRENCE E. CONROY AND M. J. SIENKO[1]

RECEIVED FEBRUARY 5, 1957

Non-stoichiometric solids of the form Cu_xWO_3 have been prepared by electrolytic reduction at 800° of molten mixtures of $CuWO_4$ and WO_3. Copper content has been varied from $x = 0.26$ to $x = 0.77$. Two kinds of crystals have been found—orthorhombic with $a = 3.88$ Å., $b = 3.73$ Å., and $c = 7.74$ Å., taken from the preparation for which $x = 0.26$, and triclinic with $a = 5.85$ Å., $b = 6.65$ Å., $c = 4.88$ Å., $\alpha = 134°45'$, $\beta = 91°40'$, and $\gamma = 93°37'$, taken from the preparation for which $x = 0.77$. The molar magnetic susceptibility at 26° of the powder for which $x = 0.26$ was observed to be $+34 \pm 1 \times 10^{-6}$. Conductivity measurements from $-160°$ to $+80°$ made on single triclinic crystals taken from the preparation for which $x = 0.77$ showed typical semi-conductor behavior. At 26° the specific resistance was 12.6 ohm-cm. perpendicular to the c-axis and 17.2 ohm-cm. parallel to the c-axis. Energies of activation for the conduction process were found to be 0.147 and 0.149 electron volt, respectively. Attempts to measure the Hall voltage of a single crystal indicated 13 cc. per coulomb as an upper limit for the Hall constant, from which it is deduced that the minimum concentration of current carriers is 5×10^{17} particles per cc. It is proposed that these materials are analogous to the tungsten bronzes.

The alkali tungsten bronzes are non-stoichiometric solids of composition M_xWO_3, where M is an alkali metal and x can vary from 0 to 1. Although known since their discovery by Wöhler[2] in 1824, it is only recently that these bronzes have been well characterized.[3] The sodium tungsten bronzes, for which the data are most extensive, have been shown to have a cubic perovskite structure[4] if x is greater than about 0.35, a high electronic[5] conductivity which passes through a maximum[6] at $x = 0.75$, and a feeble paramagnetism[7,8] which is independent of temperature.[8] The Hall coefficient is negative, and its magnitude indicates that there is approximately one free electron per sodium atom.[5] Chemically, all the alkali tungsten bronzes are quite inert, being attacked only by strong alkalies.

As discussed in a previous paper,[9] the tungsten

bronzes can best be considered as solutions of M in WO_3, in which each M atom is dissociated into M^+ and an electron. The cubic bronzes can then be visualized as consisting of a simple cubic arrangement of tungsten atoms with shared oxygen atoms on the cube edges and with vacancies in the cube centers more or less occupied by alkali metal cations. Each alkali metal atom has thus effectively contributed one free electron to the electron gas which permeates the whole lattice. Since Cu(I) has approximately the same ionic radius as the sodium ion, it might be possible to substitute copper cations for sodium cations in the above structure and thereby obtain a Cu_xWO_3 analogous to Na_xWO_3. In the following, the preparation and properties of Cu_xWO_3 are described.

Experimental Procedure and Results

Preparation.—Cu_xWO_3 was prepared by electrolytic reduction of fused mixtures of $CuWO_4$ and WO_3. The $CuWO_4$ was made by mixing tungstic acid, H_2WO_4, and basic copper carbonate, $CuCO_3 \cdot Cu(OH)_2$, in a 2:1 molar ratio and adding enough water to make a thin slurry. The mixture was heated at about 70° for 3 to 4 hr. and the remaining water was then evaporated off at 130° in a drying oven. The product was a green-brown powder melting at about 680°. The WO_3 was made as previously described.[9]

To produce Cu_xWO_3, mixtures of various proportions of $CuWO_4$ and WO_3 were electrolyzed at 800° using platinum electrodes. The applied potential was six volts at the electrodes with a cathode current density of 0.06 to 0.08 amp. per cm.^{2}. Electrolysis was continued for four hours. The cooled melt, on being heated with 5% NaOH solution at 80° overnight, disintegrated into a mixture of black crystals and red Cu_2O. After the Cu_2O was removed with concentrated HCl, the remaining crystals were further leached with 5% NaOH for one hour, washed alternately with aqueous HF and NH_4OH, and finally rinsed with water. Chemically, the Cu_xWO_3 was found to be as inert as the alkali tungsten bronzes.

Three different preparations of Cu_xWO_3 were produced, having values of x of 0.26, 0.34 and 0.77. These materials were prepared from melts containing one, two and six moles of $CuWO_4$, respectively, per one mole of WO_3.

Chemical Analysis.—The products were brought into solution by fusion with a mixture consisting of three parts of $NaNO_3$ to one part of Na_2CO_3 by weight. The cooled melt was then dissolved in water. Tungsten was determined as the trioxide by the nitric acid–cinchonine precipitation.[10] Copper was determined (1) electrolytically[11] in ammoniacal solution and (2) polarographically using a dropping mercury electrode. For the latter method, the copper diffusion current of the analysis solution was compared with the copper diffusion current of a standard copper solution containing all other ions in the same concentrations as in the analysis solution. The two methods agreed within 4% of the copper content. Oxygen content, calculated by difference, amounted to 2.9 ± 0.3 gram-atoms per gram-atom of tungsten.

X-Ray Studies.—Powder X-ray patterns of the three products prepared were very similar. The lines in all cases were quite diffuse in the high angle region and could not be measured more accurately than 0.1 mm. Indexing the powder pattern lines proved to be a formidable task, so single crystal photographs were taken of two crystals. Crystal I was taken from the preparation having the composition $Cu_{0.26}WO_3$ and crystal II, $Cu_{0.77}WO_3$.

Crystal I was a needle about 0.7 mm. long and 0.08 mm. in diameter. It was mounted for oscillation about the direction of elongation. Fifteen-degree oscillation photographs and zero and first layer Weissenberg photographs were taken using copper Kα radiation. The zero layer Weissenberg photograph showed the axes to be orthogonal within 0.2°. This photograph also showed the systematic absence of any spots with indices l odd. The lattice parameters were calculated to be: $a = 3.88$ Å., $b = 3.73$ Å., and $c = 7.74$ Å. The zero and first layer Weissenberg photographs about the b-axis showed no other special extinctions. Since photographs were not taken about the other axes, the crystal symmetry could be classified only as far as orthorhombic.

Crystal II was a needle about 0.9 mm. in length and 0.07 mm. in diameter. This crystal was mounted for oscillation about the elongation direction, and 15° oscillation photographs were taken. The layer line spacings indicated an interplanar spacing of 4.90 Å. Zero layer and first layer equi-inclination Weissenberg photographs were taken about the same axis. It was found that two series of spots could be indexed on these photographs, indicating that the crystal was twinned. The apparent presence of a symmetry plane led us at first to the erroneous assumption that the symmetry was monoclinic. Further studies[12] on other crystals of this preparation, however, have shown that the symmetry is actually triclinic. The lattice parameters of the "best" primitive cell have been taken as: $a = 5.85$ Å., $b = 6.65$ Å., and $c = 4.88$ Å. with $\alpha = 134°45'$, $\beta = 91°40'$, and $\gamma = 93°37'$. The needle axis is always in the direction of c, and the crystals are twinned about a. (The proximity of β to 90° was responsible for our original assumption of monoclinic symmetry.) The space group is either P1 or $P\bar{1}$.

Magnetic Susceptibility.—The molar magnetic susceptibility of a powder sample having the composition $Cu_{0.26}WO_3$ was determined by the Gouy method using the apparatus and the procedure previously described.[9] The observed susceptibility at 26° for a mole of $Cu_{0.26}WO_3$ was found to be $+34 \pm 1 \times 10^{-6}$ c.g.s. units. Furthermore, using 3 cm. radiation, there was no detectable paramagnetic resonance absorption in magnetic fields ranging from zero to 9000 oersted, either at 26° or at liquid nitrogen temperature.

Electrical Conductivity.—The electrical conductivity of some apparently single crystals of $Cu_{0.77}WO_3$ was measured as a function of temperature over the range 110 to 350°K. The crystals used were of the triclinic form and were 2 to 3 mm. long and 0.5 to 1 mm. in diameter. They were cleaved approximately perpendicular to the long axis and were mounted in a brass crystal holder between indium-faced pressure contacts by means of a micromanipulator. The potential drop across the crystal was measured with a Leeds and Northrup type K-2 potentiometer. The current flowing through the crystal was measured by noting the potential drop across a standard resistor in series with the crystal. The crystal holder itself was mounted on a Plexiglas rod support and enclosed in a silvered Dewar flask by a Plexiglas cover sealed with a rubber O-ring. The gas pressure in the Dewar jacket could be varied through a side-arm and stopcock. The temperature of the crystal was measured by a copper–constantan thermocouple mounted on the brass crystal holder with the junction in contact with one of the pressure contacts which held the crystal.

Before each set of conductivity measurements, the Dewar containing the crystal was flushed for 30 min. with dried argon or oil-pumped nitrogen. For the low temperature measurements, dry air was let into the Dewar jacket and the Dewar and contents immersed in liquid nitrogen. The Dewar jacket was then pumped out and the liquid nitrogen-bath removed. Readings were then taken as the crystal slowly warmed to room temperature. For temperatures above room temperature the Dewar was immersed in a heated water-bath.

A typical crystal had a resistance of 2 to 3 thousand ohms, so that the current through the crystal from a 6-volt dry cell source was a few milliamperes. Using this apparatus, the conductivity curve for a given crystal could be reproduced to within the precision of the thermocouple reading (*ca.* 0.5%). Reversal of the polarity of the imposed potential produced no detectable change in the conductivity. For specific resistivity values the crystal dimensions were measured with a microscope, using a micrometer eyepiece. The data obtained for several crystals are represented in Fig. 1 as a plot of the logarithm of the specific resistivity against the reciprocal of the absolute temperature. At 26° a typical crystal showed a specific resistivity of 12.6 ohm-cm. perpendicular to the crystal elongation axis (c-axis) and 17.2 ohm-cm. parallel to the same axis. Assuming an exponential form of the dependence of resistivity on the reciprocal of the absolute temperature, we obtain for

the energy of activation of the process 0.147 electron volt for conductance perpendicular to the c-axis and 0.149 e.v. for conductance parallel to the c-axis. Measurements using sputtered contacts in place of the pressure plates give essentially the same values.

Measurement of the Hall Coefficient.—A three-probe method was used. One probe was mounted on one side of the crystal; the other two were connected through a 100,000 ohm helipot and were in contact with the opposite side of the crystal. With the center tap of the helipot connected to the voltage-measuring apparatus, the IR drop between the probes in the direction of the current in the crystal could be balanced out by obtaining a minimum voltage reading with current flowing in the crystal in the absence of a magnetic field. Any change in the voltage when the magnetic field was applied must then be due solely to the magnetic field. The probes were 10 mil diameter tungsten wires, sharpened by dipping repeatedly in molten potassium nitrite. The magnetic field was supplied by a small magnetron magnet with half-inch diameter pole faces rated at 7500 gauss.

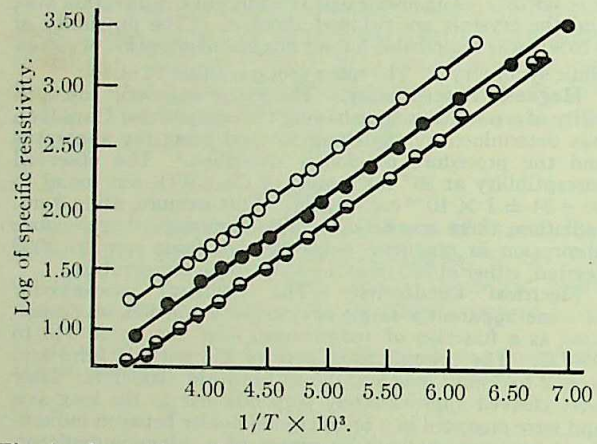

Fig. 1.—Logarithm of the specific resistivity *vs.* reciprocal temperature of three different crystals of $Cu_{0.77}WO_3$.

Attempts to measure the Hall voltage using direct current through the crystal did not give reproducible results. An alternating current method, using a 50-cycle square wave of 10 milliamperes through the crystal and a narrow-band amplifier tuned to 50 cycles at the output of the Hall probes, indicated that there was no Hall voltage measurable above the noise level of the equipment. Thus, it was possible to set only an upper limit on the Hall voltage of 0.25 millivolt, which was the limit of sensitivity of the apparatus.

Discussion

Compared to the sodium tungsten bronzes, in which the magnetic susceptibility and conductivity behavior are typically metallic, the substances Cu_xWO_3 offer a contradiction in these properties. Their low magnetic susceptibility can be interpreted in terms of an electron gas, but such an electron gas structure would suggest fairly high conductivity. In fact, the conductivity of Cu_xWO_3 is low and increases with temperature, a behavior more representative of a typical semi-conductor. It is true that many semi-conductors show also a low magnetic susceptibility but this in general is due to the low concentration of impurity centers. In Cu_xWO_3, which may be considered as solutions of impurity copper in WO_3, the concentration of impurity centers is large enough to be expected to produce an easily detected paramagnetism.

If we assume that the copper atoms in Cu_xWO_3 are dissociated into Cu^+ ions and free electrons, then we would have in $Cu_{0.26}WO_3$ 0.26 mole of free electrons. Using the free electron model described in a previous paper,[9] we would calculate -12×10^{-6} for the molar susceptibility of $Cu_{0.26}WO_3$. If the electrons are not free but are bound singly, as for example to tungsten atoms so that formally some of the W(VI) of WO_3 is converted to W(V), then we would calculate a value of $+218 \times 10^{-6}$ for one mole of $Cu_{0.26}WO_3$. These values are to be compared with the experimentally observed susceptibility of $+34 \times 10^{-6}$. Evidently, the experimental value is closer to the electron gas model than to the W(V) model. The discrepancy between -12×10^{-6} and $+34 \times 10^{-6}$ could be accounted for qualitatively by assuming that the electrons are not absolutely free as in an ideal electron gas but are feebly bound to some centers in the lattice. Even feeble binding would tend to make the spin paramagnetism of the electrons start to appear.

However, feeble binding of the electrons implies that the electrons are rather free to move through the lattice, a prediction contradicted by the observed low conductivity. Therefore, in spite of the support offered by the low magnetic susceptibility, the free electron gas model does not seem applicable to Cu_xWO_3 as it is to the sodium tungsten bronzes.

What is the alternative? To account simultaneously for the low conductivity and the low susceptibility, it is necessary to assume that the odd electron of each copper atom is bound in the lattice not singly but is paired with another electron. There are several mechanisms by which this pairing could occur. An electron could be physically transferred from one copper atom to another, so that the material might consist of a solution of Cu^+ and Cu^- ions in a WO_3 lattice. Alternatively, the odd electron could be localized on a copper atom but coupled by an exchange interaction with an electron on a neighboring copper atom. There might even be coupling by superexchange through the intermediacy of an intervening oxygen atom. A third possibility would be for the electron of each copper atom to be transferred to the WO_3 network with subsequent coupling of neighboring W(V) states by superexchange through intervening oxygen atoms. In any case, the spin paramagnetism of the odd electron of the copper would have to be cancelled to agree with experimental observations. Localization of the electrons would have to be assumed, to agree with the low conductance observed.

Although the measurement of the Hall effect described above is inconclusive, there are some inferences which can be drawn from it. If we set the upper limit of the Hall voltage at 0.25 millivolt, then by using the relation

$$R_H = \frac{10^8 V_H t}{IH}$$

where V_H is the Hall voltage in volts, t is the thickness of the crystal in cm., I is the current in amperes, and H is the magnetic field in gauss, we calculate 13 cc. per coulomb as an upper limit for the Hall constant, R_H. According to theory,[13] if conduction is by electrons, the Hall constant is in-

versely proportional to the density of conducting electrons. Using

$$R_H = -\frac{1}{ne}$$

where n is the number of conduction electrons per cc. and e is the electronic charge in coulombs, we find 5×10^{17} as a lower limit for the number of free electrons per cc. This figure is in substantial agreement with the number 10^{18} absorbing centers per cc. deduced from very crude measurements of the intensity of infrared absorption by powdered Cu_xWO_3.

In view of the crudity of our Hall voltage measurement, only qualitative significance can be given to the numerical comparison offered above. We are now in the process of refining our measurements to make the comparison more meaningful. In addition, we are extending our investigations to newly prepared $Pb_{0.4}WO_3$, which seems to be typically metallic, and to $Ag_{0.4}WO_3$, which is apparently semi-conducting.

Free Energy Change and the Electron Electrode in Liquid Ammonia

BY JOHN B. RUSSELL AND M. J. SIENKO[1]

RECEIVED FEBRUARY 12, 1957

The standard free energy change for the reaction $Na_{(s)} \rightarrow Na^+_{(NH_3)} + e^-_{(NH_3)}$ has been determined experimentally by combining measurements on two types of galvanic cells: Na|NaI in liquid ethylamine|Na amalgam, for which the standard e.m.f. was found to be 0.828 ± 0.000 and 0.835 ± 0.001 volt at -50 and $-70°$, respectively, and Na amalgam|NaI in liquid ammonia‖Na in liquid ammonia|inert metal, for which the standard e.m.f. was found to be -0.933 ± 0.020 volt at $-50°$ and -0.947 ± 0.020 volt at $-70°$. These results have been used to obtain directly an experimental value for the solvation free energy of sodium ion in ammonia. Measurements are also reported for the distribution of sodium between mercury and liquid ammonia.

The existence of ion-like electrons in sodium–liquid ammonia solutions[2] suggests the possibility of constructing a galvanic cell which would give directly the free energy change for the reaction

$$Na_{(s)} \longrightarrow Na^+_{(NH_3)} + e^-_{(NH_3)}$$

The most obvious design—solid sodium as one electrode and an inert metal as the other, both immersed in the same solution of sodium in liquid ammonia—gives no useful information because the over-all cell reaction shown above comes to equilibrium as a dissolution equilibrium at the solid sodium–liquid ammonia interface. To bypass this difficulty, we have constructed two cells—in one of which the dissolution equilibrium was completely suppressed by amalgamation of the sodium and in the other of which the effect of such amalgamation on the voltage was determined. The two types of cells and their designations in this paper are

Cell I $\quad Na_{(s)}|NaI \text{ in } EtNH_2|Na_{(Hg)}$

Cell II $\quad Na_{(Hg)}|NaI \text{ in } NH_3‖Na \text{ in } NH_3|\text{inert metal}$

Before describing the structure and operation of these cells, we note two problems that arose in the course of this research. In order to choose an amalgam concentration that would be sufficient to repress the sodium dissolution equilibrium, it was necessary that we investigate the distribution of sodium between mercury and liquid ammonia. The second problem dealt with the choice of metal to use as an inert "electron electrode" in liquid ammonia. Kraus[3] in his work on transference numbers and Laitinen and Nyman[4] in their polarographic work with the "electron electrode" used platinum as the inert conductor. For ease in constructing the complicated closed systems of glass required to keep the sodium–ammonia solutions away from air, we used tungsten. However, since tungsten does not give reproducible results when used as an electrode in aqueous solutions, it was necessary that we show for ammonia solutions that platinum and tungsten electrodes give substantially equivalent results.

Experimental Procedure

Preparation of Materials.—All procedures were carried out in a high vacuum chain capable of producing pressures less than 1×10^{-6} mm. Degassing and baking out were carried out where needed. Ammonia, obtained from Matheson as anhydrous 99.9% pure, was triply distilled from its solutions with sodium before use. Sodium, obtained from Mallinckrodt, was purified by the method of Watt and Sowards.[5] Ethylamine, obtained from Eastman Kodak as a 33% solution in water, was first concentrated by distilling it off from a slurry of calcium oxide and then purified by redistilling it from its solution of lithium metal. Sodium iodide, Baker and Adamson reagent grade, was used directly without further purification except for drying. Mercury for the amalgams was scrubbed in a mercury oxifier, washed with nitric acid and triply distilled before use.

Distribution Experiments.—The distribution of sodium between mercury and liquid ammonia was determined in an all-glass system with a built-in pipet which served both to introduce gas for stirring the liquid ammonia solutions and to take samples of the solutions for analysis. In operation, a sodium–ammonia solution was formed in an outer jacket and a weighed amount of mercury dropped in through a ball-and-socket valve manipulated from the outside. Prepurified hydrogen bubbled through the pipet tip served to mix the solution. A pair of tungsten electrodes sealed through the outer jacket wall enabled concentration changes in the solution to be followed from measurements of the a.c. electrical resistance. After distribution equilibrium had been established, hydrogen pressure could be applied to force a sample of the ammonia solution into the pipet. Distribution experiments were also performed in which

equilibrium was approached from the other side—that is, ammonia was added to a sodium amalgam.

After a sample of the ammonia phase had been taken, the apparatus was quenched in liquid nitrogen, the outside tube was detached, and the ammonia in the outside jacket and in the pipet separately evaporated off into measured volumes of standard sulfuric acid. Sodium in the pipet was determined by washing it out with ethanol and water and titrating the wash solution with standard acid. Total sodium in the jacket was determined similarly after washing out the sodium and the sodium amalgam, boiling with water until all reaction between amalgam and water had ceased, and titrating.

Cell I.—The "sodium–sodium amalgam" cell consisted essentially of an inverted "Y" tube with a tungsten electrode sealed into each arm of the "Y." The sodium electrode was formed by melting sodium around the tungsten in one arm; the sodium amalgam electrode, by breaking a sodium-containing ampule into a mercury pool in the other arm. Ethylamine could then be condensed into the cell on sodium iodide which had been added previously. For reproducible voltages, it was found necessary that the leads from the tungsten wires to the outside of the thermostat bath be insulated from the bath by lengths of glass tubing sealed to the cell. Furthermore, it was found that the observed cell voltage could vary as much as 10 to 20 millivolts from one run to the next unless the amalgam electrodes were annealed for at least an hour just below their eutectic temperature of −47°.

Cell II.—The "sodium amalgam–electron electrode" cell consisted essentially of an "H," with a tungsten electrode sealed in each leg of the "H" and a fritted glass disk in the cross-bar. The disk was originally of medium porosity but for our purposes it had been almost completely fused closed by careful heating around the edge. By trial and error it was possible to produce a disk which effectively prevented liquid transfer between the two compartments but still gave a reasonably low electrical resistance. For filling cell II, a weighed quantity of mercury, a weighed ampule of sodium, and a weighed quantity of sodium iodide were placed in one compartment and a weighed ampule of sodium in the other. Ammonia could then be distilled into the cell after evacuation and degassing of the fritted disk. Usually the voltage settled down in a matter of minutes but data were not considered reliable unless the voltage remained constant within two millivolts for at least an hour. In contrast to cells of type I, which essentially lasted indefinitely, the lifetime of cells of type II was only four or five hours, after which time the e.m.f. became somewhat erratic. This onset of erratic behavior was attributed to autocatalytic decomposition of the sodium–ammonia solution at the fritted disk. For analysis, ammonia was boiled off into measured volumes of standard sulfuric acid. With the pressures involved, only a negligible amount of ammonia could have been forced through the fritted disk.

Temperature Control and Measurement.—The distribution apparatus was thermostated by immersion in a large test-tube of boiling liquid ammonia, the temperature of which was −33.2 ± 0.2°. Cells I and II, which were run at both −50 and −70°, were immersed in a large Dewar flask filled with cold acetone. The bath was stirred mechanically, and the temperature was regulated manually by the addition of small pieces of Dry Ice. The temperature could be kept constant to ±0.2° by this method. More precise control was not necessary because it was observed that the thermal coefficients of the cells were low. Temperatures were measured by means of a copper–constantan thermocouple and a Leeds and Northrup Portable Precision Potentiometer. The junctions were immersed in tubes of paraffin oil with the reference junction kept at the ice point. The thermocouple was calibrated at the ice point, the freezing point of mercury and the CO_2 point.[6]

Test for Reversibility.—The thermodynamic reversibility of a galvanic cell can be determined by applying an external voltage to the cell just sufficient to balance its e.m.f. and then changing the external voltage infinitesimally so as to pass current in opposite directions through the cell.[7] If the electrode reactions are reversible, there should be no discontinuity in the voltage–current proportionality at the null point. In this research, we measured the voltages in the external circuit which were required to produce small galvanometer deflections on either side of the null point. Since the galvanometer was in series with the cell under investigation, its deflection was a measure of the current through the cell. For each of the cells studied, such a plot of external voltage *vs.* current produced a straight line.

Platinum–Tungsten Equivalence Test.—To test platinum and tungsten as equivalent electron electrodes, cell I was modified by the insertion of a piece of copper wire on the end of which was soldered a strip of platinum wire. With sodium–ammonia solution in the cell the voltage between the platinum and each of the tungsten electrodes was observed to be 0.00006 ± 0.00001 volt; it did not change from one tungsten electrode to the other. It may be that even this voltage was due not to any real difference between tungsten and platinum but rather to a small temperature gradient at the copper-to-platinum junction, which was only a few cm. below the level of the surrounding external thermostat bath.

Results

Distribution Experiments.—The distribution experiments were performed (1) by adding mercury to a solution of sodium in liquid ammonia and (2) by adding ammonia to a concentrated sodium amalgam. In every experiment of the first set, all of the sodium was extracted from the ammonia by the mercury. This by itself is not significant since geometrical considerations limited us to quantities of reagents such as to preclude formation of a sodium amalgam richer than 6.0 atomic % sodium. In the second set of experiments, four quite concentrated amalgams were equilibrated with liquid ammonia. The distribution results are shown in Table I. It is evident that the most dilute of these concentrated amalgams, even though it already contains 36.4 atomic % sodium, is still too dilute to allow any detectable sodium in the ammonia phase. Since in the following cells we did not exceed 2.5 atomic % sodium for the composition of the amalgam electrode, we can be reasonably sure that the dissolution equilibrium of sodium in ammonia has been completely repressed.

Table I

Distribution of Sodium between Mercury and Liquid Ammonia at −33.2°

Amalgam	Equilibrium mole fraction of sodium: Ammonia phase	Mercury phase
1	Not measurable	0.364
2	2.10×10^{-4}	.503
3	6.15×10^{-3}	.582
4	1.12×10^{-2}	.603

Cell I.—Of the two "sodium–sodium amalgam" cells that were prepared, the first showed 0.8277 ± 0.0005 volt at −50° and 0.8331 ± 0.0003 volt at −70° and the second, 0.8284 ± 0.0002 volt at −50° and 0.8364 ± 0.0009 volt at −70°. As an average, we have taken the values

at −50° $E = 0.828 \pm 0.000$ v.

at −70° $E = 0.835 \pm 0.001$ v.

Cell II.—For the "sodium amalgam–electron electrode" cells, the observed voltages at −50° and at −70° are shown in Table II. The column headed "Sodium, m" indicates the concentration of sodium in the liquid ammonia adjacent to the "electron electrode" and the column headed

"NaI, m" indicates the concentration of sodium iodide in the liquid ammonia adjacent to the "sodium amalgam" electrode. The error limits quoted for E are the observed voltage fluctuations at a given temperature. In addition, there may be an uncertainty of 0.020 volt in each value of E because of possible strains in the sodium amalgam electrode—strains which could not in practice be annealed because of the limited lifetime of the cells.

TABLE II

OBSERVED E.M.F. OF "SODIUM AMALGAM–ELECTRON ELECTRODE" CELLS

Cell	Sodium, m	NaI, m	$-E$ at $-50°$	$-E$ at $-70°$
1	0.209	0.0445	0.6961 ± 0.0004	0.7250 ± 0.0005

5	.752	.0763	.6889 ± .0018	.7132 ± .0005

Discussion

For a cell of the type II, the over-all cell reaction can be written

$$Na_{(Hg)} \longrightarrow Na^{+}_{(NH_3)} + e^{-}_{(NH_3)}$$

Because the cell contains a liquid junction, the observed voltage, E, includes a liquid junction potential, E_L. Using the Nernst relation, we may write

$$E = E^\circ - \frac{RT}{F} \ln \frac{a_{Na^+(NH_3)}\, a_{e^-(NH_3)}}{a_{Na(Hg)}} + E_L \qquad (1)$$

where E° is the standard voltage, $a_{Na^+(NH_3)}$ and $a_{e^-(NH_3)}$ are the activities of sodium ion and of the electron in liquid ammonia, and $a_{Na(Hg)}$ is the activity of the sodium in the amalgam. Actually, this last quantity is a constant. The sodium–mercury system[8] shows at 2.5 atomic % sodium an eutectic between pure mercury and the compound $NaHg_4$ and an eutectic temperature of about $-47°$. Thus, any sodium amalgam having less than 2.5 atomic % sodium, as in our work, when cooled either to -50 or $-70°$, separates into pure mercury and an eutectic mixture of mercury and $NaHg_4$. Since all the sodium is present only as the compound $NaHg_4$, we can consider $a_{Na(Hg)}$ as a constant in eq. 1. If this constant is absorbed into E°, eq. 1 becomes

$$E = E^{\circ\prime} - \frac{RT}{F} \ln a_{Na^+} a_{e^-} + E_L \qquad (2)$$

where $E^{\circ\prime}$ indicates the standard e.m.f. referred to the new standard state and the NH_3 subscripts have been omitted for simplicity. Assuming that the activity of the sodium ion and of the electron in ammonia can be represented by the product of a molality m and an activity coefficient γ, we write

$$E = E^{\circ\prime} - \frac{RT}{F} \ln m_{Na^+} m_{e^-} - \frac{RT}{F} \ln \gamma_{Na^+}\gamma_{e^-} + E_L \qquad (3)$$

The first and third terms of the equation are known from these experiments; the fourth and fifth need to be estimated in order to find $E^{\circ\prime}$.

For the fourth term, because of the scarcity of data on activity coefficients in liquid ammonia, we have had to assume that the single ionic activity coefficients needed are approximately the same (at corresponding concentrations) as those found by Sedlet and DeVries[9] for the mean ionic activity coefficients of sodium chloride in ammonia. Table III shows the numerical values assumed in the different cells and the magnitude of the activity coefficient term that would then appear in eq. 3. The error limits quoted correspond approximately to a 100% error in choice of activity coefficient.

TABLE III

ACTIVITY COEFFICIENTS ASSUMED FOR e^- AND Na^+

Cell	γ_{e^-}	γ_{Na^+}	$-(RT/F) \ln \gamma_{Na^+}\gamma_{e^-}$ At $-50°$	At $-70°$
1	0.1	0.3	0.067 ± 0.02	0.061 ± 0.02
2	.1	.1	.089 ± .02	.081 ± .02
3	.07	.2	.082 ± .02	.075 ± .02
4	.06	.2	.085 ± .02	.077 ± .02
5	.04	.2	.093 ± .02	.085 ± .02

The liquid junction potential has been estimated by using the Henderson equation.[10] For a boundary between two solutions of uni-univalent electrolytes, this equation takes the form

$$E_L = \frac{RT}{F} \frac{(U_1 - V_1) - (U_2 - V_2)}{(U_1 + V_1) - (U_2 + V_2)} \ln \frac{U_1 + V_1}{U_2 + V_2}$$

where U_1 is the product of the molality and the ionic mobility of the cation on one side of the boundary and U_2 is the product of the molality and ionic mobility of the cation on the other side of the boundary. V_1 and V_2 are the corresponding quantities for anions. According to Kraus and Bray[11] the ionic mobilities of sodium ions and iodide ions are 1.35×10^{-3} and 1.77×10^{-3} cm. per second, respectively, over a wide range of concentration. The ionic mobilities of electrons in liquid ammonia, as calculated from the transport numbers obtained by Kraus for sodium in liquid ammonia solutions, vary between 4.12×10^{-2} and 8.31×10^{-2} cm. per second over the range of concentrations we used. Columns two and three of Table IV give the results we have calculated for the liquid junction potentials of the various cells. The error limits indicated are those obtained by applying the Henderson equation to aqueous solutions.

The last two columns of Table IV give the results finally calculated from eq. 3 for $E^{0\prime}$ of each cell. As most probable values for the "sodium amalgam–electron electrode" cell,

TABLE IV

ESTIMATED LIQUID JUNCTION POTENTIALS AND CALCULATED STANDARD E.M.F.'s

Cell	E_L ± 0.005 at $-50°$	E_L ± 0.005 at $-70°$	$-E^{0\prime}$ ± 0.05 at $-50°$	$-E^{0\prime}$ ± 0.05 at $-70°$
1	0.0771	0.0704	0.930	0.938
2	.0544	.0497	.928	.950

For cells of type I, the net reaction is

$$Na_{(s)} \longrightarrow Na_{(Hg)}$$

and the observed e.m.f. is given by

$$E = E^0 - \frac{RT}{F} \ln a_{Na(Hg)}$$

Again, since the concentration of sodium in the amalgam is kept below 2.5 atomic %, the sodium is in the electrode only as $NaHg_4$ and its activity is a constant. The observed voltage is invariant except with temperature, a prediction that agrees with our experiments, and, if the constant activity term is again absorbed into $E°$, the observed voltage is just the $E°'$ of the cell.

Combining the $E°'$ of the two cells, I and II, gives an $E°$ for the reaction

$$Na_{(s)} \longrightarrow Na^+_{(NH_3)} + e^-_{(NH_3)}$$

(In so doing it might be noted that a true $E°$ referred to pure sodium as standard state is obtained and not an $E°'$. The term depending on the activity of sodium in the amalgam cancels out because it comes in negatively in the $E°'$ of cell I and positively in the $E°'$ of cell II.) The results are

at $-50°$ $E° = -0.10 \pm 0.02$ v. $\Delta F° = 2.4$ kcal./mole

at $-70°$ $E° = -0.11 \pm 0.02$ v. $\Delta F° = 2.6$ kcal./mole

Corresponding to these values of the standard free energy change is a standard entropy change of approximately 10 cal. per degree per mole.

These results are in remarkable agreement with those expected on the basis of the thermodynamic functions in liquid ammonia suggested by Jolly.[12] For 25° Jolly suggests

$$Na_{(s)} \longrightarrow Na^+_{(NH_3)} + e^-_{(ext)} \qquad E° = 1.89 \text{ v.}$$

$$e^-_{(NH_3)} \longrightarrow e^-_{(ext)} \qquad E° = 1.93 \text{ v.}$$

Using standard heats of formation (−38.1 kcal./mole for sodium ion and 40.5 kcal./mole for the electron) to change these values from 25 to −50° and −70° we would have predicted the following

$$Na_{(s)} \longrightarrow Na^+_{(NH_3)} + e^-_{(ext)} \qquad E°_{-50} = 1.82 \text{ v.}; \quad E°_{-70} = 1.80 \text{ v.}$$

$$e^-_{(NH_3)} \longrightarrow e^-_{(ext)} \qquad E°_{-50} = 1.88 \text{ v.}; \quad E°_{-70} = 1.87 \text{ v.}$$

$$Na_{(s)} \longrightarrow Na^+_{(NH_3)} + e^-_{(NH_3)} \qquad E°_{-50} = -0.06 \text{ v.}; \quad E°_{-70} = -0.07 \text{ v.}$$

An experimentally determined value for the standard free energy change of

$$Na_{(s)} \longrightarrow Na^+_{(NH_3)} + e^-_{(NH_3)}$$

makes possible an experimental evaluation of single ion solvation free energies. The over-all process above can be represented by the following cycle: (1) sublimation of solid sodium, (2) ionization of sodium gas, (3) ammoniation of sodium ions, (4) ammoniation of electrons. The free energy change of step (1) is well known and is equal to 18.7 kcal./mole at 25°. The free energy change of step (2) can be estimated from the first ionization potential of sodium as equal to 118.9 kcal./mole. For step 4 the free energy change can be rather reasonably estimated to be −11.9 kcal./mole. This value we have obtained by considering the reverse process, the desolvation of electrons from liquid ammonia. Its free energy change is 18.4 kcal., the energy required to expel electrons from liquid ammonia, less 6.5 kcal., the energy released when the cavities left behind collapse. The number 18.4 kcal. comes from 0.8 electron volt, the observed photoelectric work function of sodium–ammonia solutions reported by Ogg.[13] The number 6.5 kcal. is the calculated surface energy of a mole of cavities in liquid ammonia. For the surface tension, we have used 35.4 ergs per cm.^{2} from the work of Stairs and Sienko.[14] For the radius of the cavity, we have used 3.2 Å. as suggested by Lipscomb[2] on the basis of the density measurements of Kraus, Carney and Johnson.[15]

Using 2.5 kcal. for the free energy change of the over-all reaction, we calculate the free energy change of step 3 by difference to be −123.2 kcal./mole. There is probably a large uncertainty in this figure, perhaps as much as 10 kcal., because in several of the steps we have had to use data at different temperatures and to assume, in the absence of information on the entropy changes, that the free energy change is the same as the energy change. However, the result is of more than qualitative interest because it indicates that, at least in principle, it is possible experimentally to get a single ion solvation free energy, one which does not depend on any arbitrary apportionment of solvation effects between cations and anions.

Mechanism of Substitution Reactions of Complex Ions. XII.[1] Reactions of Some Platinum(II) Complexes with Various Reactants[2]

BY DEBABRATA BANERJEA, FRED BASOLO AND RALPH G. PEARSON

RECEIVED FEBRUARY 1, 1957

Kinetic studies are reported for the reactions of some platinum(II) complexes in aqueous solution with a variety of nucleophilic reagents. The reactions studied fall into two categories: (1) those that are first order in complex but zero order in reactant and all of nearly the same rate; (2) those that are first order in both the complex and the reactant and faster than those of the first category. In general the reactants of category (1) are low in the *trans*-effect series whereas reactants of category (2) have a high *trans*-effect. The significance of the role played by the reactant in reactions of platinum(II) complexes is not involved in the current *trans*-effect theories of Chatt and Orgel. However these theories can be extended to explain the marked correlation between the reactivity of different reactants and their *trans*-directing properties. A "dissociation" mechanism is proposed for substitution reactions of "square" complexes.

The *trans*-effect in platinum(II) complexes, first recognized by Werner[3] and so designated somewhat later by Chernyaev,[4] has received considerable attention in recent years. In a review Quagliano and Schubert[5] have described the qualitative aspects of the *trans*-effect and its practical utility in the preparation of the geometrical isomers of platinum(II) complexes, as well as in some structural investigations. Several theories have been advanced by different authors, *e.g.*, Grinberg,[6] Syrkin,[7] Cardwell,[8] Chatt[9] and Orgel,[10] to account for the *trans*-effect. The theories of Chatt and of Orgel are very similar and are based on quantum mechanical (π-bonding) considerations which can satisfactorily account for the high *trans*-labilizing influence of unsaturated molecules such as C_2H_4, CO, NO, etc.

Quantitative rate data on the subject are lacking in the literature except for a recent publication by Zvyagintsev and Karandasheva[11] who have investigated the kinetics of substitution by pyridine of a halide group in some platinum(II) complexes of the type $Pt(NH_3)XYZ$, where Y and Z are negative groups (Cl^-, Br^- or NO_2^-) and X is the halide group displaced under the *trans*-influence of Z. The reactions were found to be second order as expected for an S_N2 mechanism as postulated by Cardwell,[8] Chatt[9] and Orgel.[10] Furthermore the rates decreased in the order $NO_2^- > Br^- > Cl^-$ for the ligand Z in agreement with decreasing *trans*-effects for these groups. The Russian workers also observed that $Pt(C_2H_4)Cl_3^-$ reacts with pyridine too fast to be measurable. This is expected because of the strong *trans*-effect of the olefin.[12] Grantham, Elleman and Martin[13] have studied the rate of acid hydrolysis of $PtCl_4^{2-}$ and its rate of exchange with radioactive chloride ion and found that exchange proceeded by way of the acid hydrolysis step and its reverse.

Except for some further exchange studies on symmetrical complexes which will be referred to later, nothing appears to have been done by way of studying the effect on the rate of the nature of the entering group. This present work furnishes the results of a fairly wide sampling of the kinetics of a variety of nucleophilic reagents and several platinum(II) complexes.

The compounds studied were *cis*- and *trans*-dichlorodiammineplatinum(II), dichloroethylenediamineplatinum(II), chlorotriammineplatinum(II) chloride and potassium tetrachloroplatinate(II). The rates of substitution of chlorine in one or more of these complexes by pyridine, ammonia, glycine, aniline, thiourea, allyl alcohol, water hydroxide ion, nitrite ion, oxalate ion and chloride ion itself have been investigated. In case of the chloride ion the rate of exchange has been followed kinetically by the radio-isotopic tracer method using chloride ion tagged with $^{36}Cl^-$. In the case of the other substituting groups, the progress of the reaction was estimated at intervals by physico-chemical methods such as the change in electrical conductance or change in optical density at a suitable wave length of the reacting solution in question, or by titrating the released chloride ion potentiometrically with standard silver nitrate solution using a glass–Ag/AgCl electrode assembly in acidified acetone–water medium (*cf.* Brown and Ingold[14]).

Experimental

A. Preparation of Materials.—*cis*-Dichlorodiammineplatinum(II) was prepared, from K_2PtCl_4 and ammonia in aqueous solution, following the method of Ramberg.[15] The product was purified by recrystallization from hot water acidified with hydrochloric acid.

trans-Dichlorodiammineplatinum(II) was prepared from tetrammineplatinum(II) chloride by heating the solid salt to 250° for about ½ hr., extracting with hot water acidified with hydrochloric acid and cooling. The product which separated was purified by recrystallization from acidified hot water.[16]

Dichloroethylenediamineplatinum(II) was prepared in a pure state from aqueous solution of K_2PtCl_4 and ethylene-

diamine following the method of Drew[16] as modified by Basolo, Bailar and Tarr.[17]

Chlorotriammineplatinum(II) chloride was prepared from *cis*-dichlorodiammineplatinum(II) according to the procedure described by Tschugaev.[18] The purity of the sample was checked by analysis.

Anal. Calcd. for $[Pt(NH_3)_3Cl_2]Cl$: Pt, 61.51; N, 13.24; H, 2.84. Found: Pt, 60.98; N, 13.50; H, 2.90.

B. Determination of the Rate of Exchange of Radiochloride Ion.—This has been determined in case of both *trans*-dichlorodiammineplatinum(II) and the chlorotriammineplatinum(II) cation in aqueous solutions 0.2 *M* in potassium nitrate. To an aqueous solution of the desired complex were added the requisite amounts of solid potassium nitrate and hydrochloric acid containing $^{36}Cl^-$ of known concentration; the solutions were then diluted to the requisite volume and thermostated at 25°. Aliquots of 0.50 cc. were removed at known intervals and to the aliquots were added a constant amount of a solution of potassium chloride (to form a sufficient precipitate of AgCl). The free chloride ion was then precipitated by adding 10% excess of the requisite quantity of silver nitrate solution. The mixture was centrifuged for 10 min. and then an aliquot of the clear supernatant liquid was withdrawn and evaporated on a disc of filter paper in an aluminum tray under strong infrared light. The activity of all these samples were then counted in a Scaling Unit, Model 162, Nuclear Instruments and Chemical Corporation, Inc. Since in $Pt(NH_3)_2Cl_2$ there are two equivalent chlorine atoms, it can be shown that the rate constant, k, for the constant rate of exchange of chlorine in the complex with the chloride ions in solution will be given by

$$k = \frac{2[Cl^-] \times 2.303}{\{2[Pt(NH_3)_2Cl_2] + [Cl^-]\}t} \log \frac{(C_\infty - C_0)}{(C_\infty - C_t)} \quad (1)$$

where C_0, C_t and C_∞ represent the counts per minute of the evaporated samples corresponding to the aliquots of reacting solution treated at zero time, t minutes and ∞, respectively. The latter has been calculated assuming complete exchange of both the chlorine atoms in the complex so that the radioactive isotope is distributed equally between the covalent and ionic chlorine in the system. This value was checked experimentally on one sample which was allowed to stand for several days before being treated. From the slopes of the curves obtained by plotting $\log (C_\infty - C_0)/(C_\infty - C_t)$ *vs.* t, k was calculated using eq. 1. The results are given in Table I.

The experimental procedure in the case of $Pt(NH_3)_3Cl^+$ was identical. Since, however, there is only one chlorine in the complex, k was evaluated graphically from eq. (2)

$$k = \frac{2.303}{t} \log \frac{(C_\infty - C_0)}{(C_\infty - C_t)} \quad (2)$$

by plotting $\log (C_\infty - C_0)/(C_\infty - C_t)$ *vs.* t at two different concentrations of chloride ion. The results are recorded in Table I.

C. Determination of the Rates of Release of Chloride Ion from the Chloro Complexes of Platinum(II) under the Influence of Water, Ammonia, Aniline, Pyridine, Glycine, Thiourea, Allyl Alcohol, Hydroxide Ion, Nitrite Ion and Oxalate Ion.—These reactions have been followed by one or more of the several physico-chemical methods described below.

(1) Change in Conductance.—The reactions of non-ionic and cationic complexes with neutral molecules like aniline, pyridine, glycine, thiourea and allyl alcohol (freshly prepared solutions were used) were followed by measuring the change in conductance of the solution under investigation, thermostated at 25°, using a Conductivity Bridge (Model RC 16, Industrial Instruments, Inc.). Relatively large excess of the reagent was used to follow the reaction as one of pseudo first-order type, in case it is not truly first order. Rate constants have been evaluated graphically from the equation

$$k = \frac{2.303}{t} \log \left(\frac{R_0 - R_\infty}{R_0}\right)\left(\frac{R_t}{R_t - R_\infty}\right) \quad (3)$$

where R's stand for resistances in ohms of the reacting solution measured at different times in the same cell. In the case of $Pt(NH_3)_3Cl^+$ the experimental value of R_∞ which agreed closely with the value expected for a compound of the type $[PtA_4]X_2$, was used in the calculations. This is also true for the reaction of *trans*-$Pt(NH_3)_2Cl_2$ with allyl alcohol, where only one chloride ion is released giving $[PtA_3Cl]Cl$, even after a week. But in the reaction of *trans*-$Pt(NH_3)_2Cl_2$ with pyridine, aniline and glycine both chloride ions are ionized successively. Hence, in this case the value of R_∞ used in the calculations was taken as double the observed value of the resistance after three weeks. Determination of the chloride ion at this stage by potentiometric titration (*vide infra*) indicated that both the chlorines were displaced. Results of these determinations are given in Table I. Interestingly enough $Pt(NH_3)_3Cl^+$ did not react at all with allyl alcohol, even at 50°. The reaction of *trans*-$Pt(NH_3)_2Cl_2$ with thiourea was so fast that the conductivity of the solution reached a value expected for an ionic compound of the type $[PtA_4]X_2$ within a few minutes of mixing of the constituents, and hence the rate of the reaction could not be measured.

A conductivity method was utilized in studying the reaction of hydroxide ion with $PtCl_4^{2-}$. Equimolecular amounts of the reactants were mixed and the change in conductance, due to replacement of OH^- in solution by Cl^- was followed

$$PtCl_4^{2-} + OH^- \longrightarrow Pt(OH)Cl_3^{2-} + Cl^- \quad (4)$$

The value of R_∞ could not be determined experimentally, as the solution on standing overnight became turbid due to separation of a bluish-black precipitate. R_∞ was calculated assuming that $PtCl_4^{2-}$ and $Pt(OH)Cl_3^{2-}$ have the same value of the equivalent conductance and using the known values of the equivalent conductance of $PtCl_4^{2-}$, OH^- and Cl^- ions. Since a first-order plot was obtained for this equimolecular mixture it was concluded that the reaction is independent of the OH^- ion concentration. The value of the rate constant was also checked by following the reaction by titrating the unreacted OH^- ion at different stages potentiometrically as described below.

To check the influence of ionic strength of the medium on the rate constants some of these determinations were repeated in 0.2 *M* potassium nitrate solution using the potentiometric titration technique (*vide infra*) to follow the rate of release of the chlorine ligand from the complex as chloride ion into the solution. These data are also recorded in Table I.

(2) Potentiometric Titration.—The rates of displacement of coördinated chloride ion from chloroammineplatinum(II) complexes by ammonia in ammonium nitrate buffer medium (to suppress the basic dissociation of ammonia), water, hydroxide ion, oxalate ion and nitrite ion have been investigated by potentiometric titration of the released chloride ion. Aliquots of 25 cc. of the reacting solution under investigation, thermostated at the desired temperature, were removed at intervals and immediately run into 150 cc. of acidified acetone (25 cc. of concd. nitric acid per 1 kg. of acetone) cooled in ice. The glass–Ag/AgCl electrode assembly was dipped into the solution which was kept cooled in ice and well stirred by a mechanical stirrer during the titration. Titration was carried out by gradually adding from a microburet (5 cc./0.01) a standard solution of silver nitrate (strength 10 times the molar concentration of the total chlorine in the reacting solution) and following the change in potential with a *p*H millivoltmeter (Beckman, model G). The end-point was marked by a very sharp change (decrease) in potential per 0.01 cc. of the titrant. The rate constant was calculated graphically from the usual first-order equation. The value of V_∞ used was calculated from the known concentration of the complex in solution. This calculated value always was checked experimentally and good agreement found in most cases. The results are recorded in Table I.

It is interesting to note that the reaction of the *trans*-dichloro compound with nitrite ion was so fast at 25° that it could not be conveniently followed experimentally. But from the data presented below it appears that the rate is also dependent on the concentration of nitrite ion, as in the case of the corresponding *cis*-compound, or the chlorotriammineplatinum(II) complex cation:

trans-$Pt(NH_3)_2Cl_2$, 0.0005 *M*, and NO_2^- (KNO_2), 0.02 *M*; 25°

Time, min.	0 (immediately after mixing)	12	Total Cl equiv. to 2.5 cc. of 0.01 *M* $AgNO_3$
Titer/25 cc. (cc. $AgNO_3$, 0.01 *M*)	1.92	2.44	

trans-$Pt(NH_3)_2Cl_2$, 0.0005 *M*, and NO_2^-, 0.001 *M*; 25°

Time, min.	0	15	Total Cl equiv. to 2.5 cc. of 0.01 *M* $AgNO_3$
Titer/25 cc. (cc. $AgNO_3$, 0.01 *M*)	0.76	1.90	

The reaction of OH^- ion with $PtCl_4^{2-}$ has been followed by titration of the free alkali at different stages of progress of the reaction in a solution 0.002 *M* in both K_2PtCl_4 and KOH. An alkali-glass electrode (Beckman E) with a saturated calomel reference electrode was used in conjunction with a Beckman *p*H meter (Model G) to follow the change in *p*H during the course of the titration with 0.01 *M* $HClO_4$. Titration was carried out to a *p*H of 8.0 ± 0.05 to determine the amount of free OH^-. V_∞ was taken as zero, as is expected for the equimolecular mixture. A first-order plot was obtained and the rate constant thus calculated was identical to that obtained by the conductance method.

(3) **Spectrophotometric Method.**—This was applied in studying the reaction of $Pt(NH_3)_3Cl^+$ with nitrite ion. The rate of reaction was followed spectrophotometrically at 260 mμ, where the chloro and nitro compounds have different absorbancy, the latter absorbing more strongly. The selection of wave length was made by first plotting the spectra using a Cary recording spectrophotometer, Model 11, in the region 400–220 mμ. Final measurements at the selected region were made in a Beckman DU quartz spectrophotometer, with thermostated cell compartment. The absorbancy of the nitro compound was obtained by mixing a solution of the chloro compound with excess of potassium nitrite, keeping it overnight and measuring the absorption against a blank of potassium nitrite solution of the same concentration as in the solution under investigation. This was checked daily until a reasonably constant value was obtained. It can be shown that the rate constant, *k*, is given by

$$k = \frac{2.303}{t} \log \frac{(O.D.)_\infty - (O.D.)_0}{(O.D.)_\infty - (O.D.)_t} \qquad (5)$$

where all the optical densities are measured against a blank of potassium nitrite solution of the same concentration as in the reacting solution. The value for $(O.D.)_\infty$ was obtained as described above. The same procedure has been employed in studying the reaction of $PtCl_4^{2-}$ with allyl alcohol. Measurements were carried out at the selected wave length of 300 mμ where the allyl alcohol has practically no absorption while the product of the reaction, presumably $[Pt(CH_2H_6O)Cl_3]^-$, absorbs much more than $PtCl_4^=$. The results of some determinations are also presented in Table I.

D. **Temperature Dependence.**—The effect of temperature on some of these reactions has been studied and the activation energy, E_a has been calculated from the usual Arrhenius equation. These are presented in Table II.

Discussion

The reactions studied fall into two categories. (1) Those that are first order in the complex and zero order in the attacking reagent and (2) those that are first order in both the complex and the reagent. Furthermore, those reactions which are totally first order for a given complex have very nearly identical rates for several reagents. Thus some step other than the reaction with the reagent is rate determining in these cases. This may be a slow SN2 reaction of the complex with water to form the aqua complex

$$PtA_3Cl + H_2O \xrightarrow{\text{slow}} PtA_3H_2O^+ + Cl^- \qquad (6)$$

followed by a rapid reaction of the aqua complex with the reagent Y

$$PtA_3H_2O^+ + Y \xrightarrow{\text{fast}} PtA_3Y^+ + H_2O \qquad (7)$$

Or it may be an SN1 dissociation of the complex followed by rapid reaction of a three-coördinated intermediate with Y and/or water.

$$PtA_3Cl \xrightarrow{\text{slow}} PtA_3^+ + Cl^- \qquad (8)$$

$$PtA_3^+ + Y \xrightarrow{\text{fast}} PtA_3Y^+ \qquad (9)$$

It is possible in a favorable case to distinguish between these two paths by studying the rate of reaction of the aqua complex with Y to see if it is rapid enough to be consistent. In the present studies some experiments were done to check the reactivity of the aqua complexes. If the chloro complexes are dissolved in water and allowed to stand for some time it is found that *cis*-$Pt(NH_3)_2Cl_2$ comes to an equilibrium within a few days in which 45% of the original coördinated chlorine is ionic. The product is assumed to be 90% *cis*-$[Pt(NH_3)_2(H_2O)Cl]Cl$ and 10% unreacted dichloro, since $Pt(NH_3)_3Cl^+$ was found not to release any ionic chloride after several days standing. If alkali is added to a solution of *cis*-$Pt(NH_3)_2Cl_2$, both chlorines are replaced. Upon acidifying with perchloric acid, a little over one-half of the chlorine very rapidly re-enters the complex, giving the same equilibrium mixture as before.

The *trans*-isomer of $Pt(NH_3)_2Cl_2$, on standing in solution for several weeks does not form any ionic chloride as judged by titration of the chloride ion and by conductivity. This is in disagreement with the conductivity data reported by others[19] who claimed that the *trans*-complex over a period of several hours attained an appreciable conductivity. However, our results were checked several times on different preparations of the complex obtained by heating $[Pt(NH_3)_4]Cl_2$ to 250°. An attempt to make *trans*-$Pt(NH_3)_2Cl_2$ by the method used by Drew gave a material with quite different properties from that obtained by thermal decomposition. Furthermore the analysis of this material did not agree with a dichlorodiammine of platinum(II). If the *trans* complex is treated with alkali, all of the chlorine is replaced. Upon acidifying, 75% of the chlorine rapidly returns to the coördinated form. That this is not due to a mixture of *cis*-$[Pt(NH_3)_2(H_2O)Cl]Cl$ and *trans*-$Pt(NH_3)_2Cl_2$ being formed has been proven by measuring the optical density of the solution at three different wave lengths (220, 230 and 240 mμ) where the *cis*- with *trans*-compounds absorb differently, the *trans* isomer having the greater optical density. It has been found that the solution under investigation had an optical density even higher than that expected for the pure *trans*-compound. This indicates the existence of a different species, presumably a polynuclear one, in solution, which is formed from the aqua complexes reacting with Cl^- ion. The nature of this polynuclear species is not known but it cannot be the dimer, $[Pt(NH_3)(NH_2)Cl]_2$, said to be isolated from the reactions of *cis* and of *trans*-$Pt(NH_3)_2Cl_2$ individually with sodium hydroxide followed by hydro-

The reagents which give second-order rates follow the reactivity sequence $SC(NH_2)_2 > NO_2^- > NH_3 > CH_2{=}CHCH_2OH > C_2O_4^{2-}$. Ammonia is second order with *trans*-$Pt(NH_3)_2Cl_2$ but not with $Pt(NH_3)_3Cl^+$. Also $Pt(NH_3)_3Cl^+$ does not appear to react at all with allyl alcohol. This is not surprising since the product would be of a cationic type that is known not to be stable, $Pt(NH_3)_3olefin^+$. Thus, it may be an unfavorable equilibrium constant and not an unfavorable rate which is responsible. The following approximate sequence of ligands in order of decreasing *trans* effect has been given[12]: $CN^- \sim C_2H_4 \sim CO \sim NO > SC(NH_2)_2 \sim R_2S \sim R_3P \sim NO_2^- \sim I^- \sim CNS^- > Br^- Cl^- >$ pyridine $> NH_3 > OH^- > H_2O$. It is striking that it is just the ligands which have a large activating influence when in a *trans* position to a replaceable group, which react rapidly and bimolecularly when taking the role of external reagents. Furthermore, the poor reagents, H_2O, OH^-, pyridine and Cl^- are down near the bottom in *trans* activating influence. It is indeed remarkable that OH^-, which is such a powerful reagent for organic halides and for the complexes of cobalt(III) and chromium(III), is so *ineffective* as a reagent for the planar complexes of platinum(II). On the other hand, the relatively great reactivity of allyl alcohol (reacting as an olefin) is unusual since the nucleophilic and basic properties of the double bond are very small. It is also known from the work of Jensen[20] and of Chatt and Wilkins[21] that trialkyl phosphines, arsines and stibines react very rapidly with the corresponding dichloroplatinum(II) complexes.

The picture given by Chatt[9] and by Orgel[10] for the mode of reaction of systems containing *trans* activating groups can be extended to accommodate these new observations on the effect of the nature of the reagent. It has been postulated by them that π-bonding occurs in which electrons from a filled d orbital of platinum are donated in part to a π-orbital in unsaturated ligands such as C_2H_4, CO, NO_2^-, etc., or to a ligand with empty d orbitals such as R_2S and R_3P. This is shown schematically in Fig. 1 in which the four groups attached to platinum lie in the *xy*-plane and the filled d_{xz} orbital forms a π-bond to the ligand. The resulting decrease in electron density allows a nucleophilic reagent to approach the opposite side from above or below the plane. The transition state will then approximate a trigonal bipyramid with the entering group, the departing group and the group *trans* to it all in the trigonal plane. Also in the trigonal plane will be two d orbitals belonging to platinum and filled with two electrons each. These will be the d_{xz} and $d_{x^2-z^2}$ as shown in Fig. 2 where the three groups and the two orbitals lie in the *xz*-plane. It is clear that π-bonds can be formed from either of the two d orbitals with any of the three groups in the plane. If the entering group can form a π-bond, this will be a factor stabilizing the transition state and hence causing an increase in the rate of reaction as observed. As in the theories of Chatt[9] and Orgel,[10] a group in the *trans* position to the leaving group stabilizes the transition state by removing electrons from the regions in which the entering and departing groups are placed. It also may be argued that π-bonding by the group being

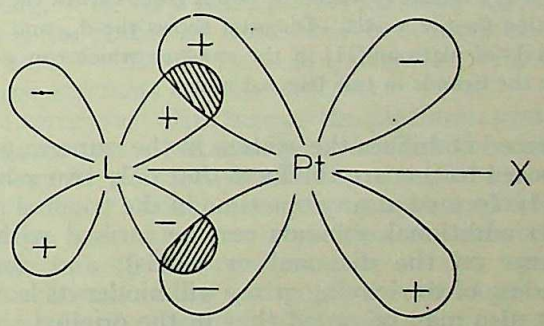

Fig. 1.—d-d-π-Bonding in platinum(II) complexes. If ligands L and X lie in the *xy*-plane than the d orbitals shown are either d_{xz} or d_{yz}.

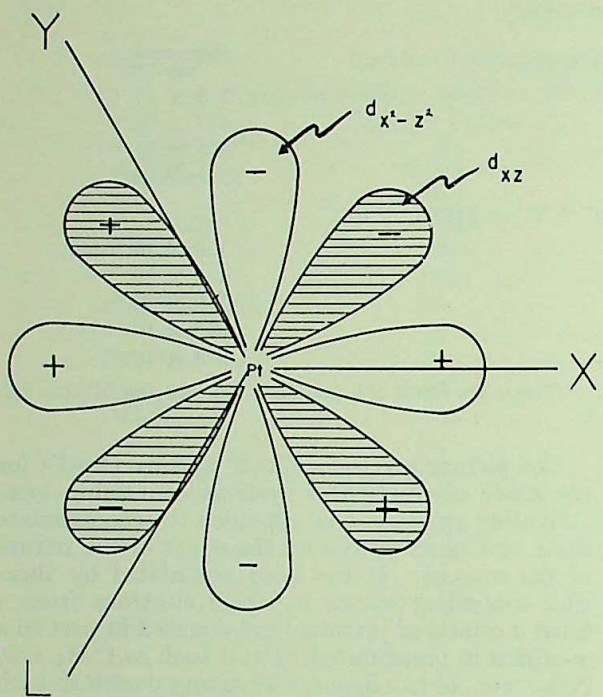

Fig. 2.—Trigonal xz-plane of trigonal bipyramid intermediate, PtA_2LXY, where the two A groups are at the apical position on the y-axis. Diagram shows the d_{xz} and $d_{x^2-z^2}$ orbitals of platinum(II) in the xz-plane which can π-bond with the ligands in this trigonal plane.

replaced stabilizes the system in the same way, but opposed to this are the facts that only two π-bonds can be formed at any one time in the trigonal plane (two additional π-bonds can be formed with the groups on the diagonal or y-axis), and double-bonding of the leaving group will hinder its leaving.

It also may be noted that in the original square planar form only three π-bonds involving metal d orbitals[22] can be formed, with d_{xz}, d_{yz} and d_{xy}. Hence if platinum is coördinated to four potential π-bonding groups, there will be an extra driving force to add a fifth group and become a trigonal bipyramid, since now four π-bonds can be formed. This explains the puzzling phenomenon observed by Grinberg and Nikolśkaya.[23]

These workers, in studying the rate of exchange of PtX_4^{2-} with labeled X^-, found the rates to increase in the order $Cl^- < Br^- < I^- < CN^-$. Since this is the order of increasing stability of the complexes as well, it implies that the most stable complex is also the most labile. The order given is also that of increasing *trans*-effect, which explains the rates. Thus in spite of the strength of the Pt–CN bond, the transition state is sufficiently stabilized by four cyano groups which can form π-bonds.

Another factor which should be considered in evaluating the stability of various transition states for platinum(II) is the change in crystal field stabilization energy in going from the original square planar configuration. The crystal field stabilization energy (CFSE) is a property of a complex ion resulting from the preferential occupation by d electrons of the central atom of the orbitals which point away from the ligands.[24]

The energies of the various d orbitals for square planar and trigonal bipyramid complexes have been calculated by Ballhausen and Klixbüll Jørgensen.[25] There are some approximations that must be made in applying these calculations to any real system but a result good enough for the present purposes can be obtained. Thus for a symmetrical, square planar complex containing eight d electrons, the CFSE is about 25 Dq, less the energy required to couple two electrons in one orbit. The parameter Dq can be obtained from spectral data and is about Dq = 4.5 kcal. in order of magnitude for a divalent, third transition series element.[26] For a symmetrical trigonal bipyramid structure, the corresponding stabilization energy is only 14 Dq and if the complex remains diamagnetic the electron coupling energy remains constant. Hence there is a loss of about 11 Dq or 50 kcal. in CFSE in a reaction going by the SN2 mechanism postulated above. Although a calculation cannot be made easily, it is certain that π-bonding by any of the groups in the trigonal plane will appreciably reduce the loss in CFSE by the process already discussed.

As opposed to this path, an SN1 mechanism in which one group leaves and the remaining three groups maintain their original positions, leads to only a small decrease in CFSE, of the order of 2 Dq. Such a reaction path might be favored by a reagent which cannot form π-bonds, *e.g.*, H_2O, NH_3 and oxalate ion. In such a case, however, it is difficult to account for the second-order kinetics observed with the last two reagents and *trans*-$Pt(NH_3)_2Cl_2$. Also an inspection of Table I shows that the reactions which are independent of the concentration of entering reagent are remarkably insensitive to the net charge on the platinum complex. Thus the ions *cis* and *trans*-$Pt(NH_3)_2Cl_2$, $PtenCl_2$, $Pt(NH_3)_3Cl^+$, *cis*-$Ptpy(NH_3)_2Cl^+$ and $PtCl_4^{2-}$ all react at the same rate within a factor of about three. By comparison $Co(NH_3)_5Cl^{2+}$ reacts slower than *trans*-$Co(NH_3)_4Cl_2^+$ by a factor of about 1000.

Such an insensitivity to coulombic effects is quite incompatible with an SN1 mechanism which goes predominantly by bond breaking. It is instead what one would expect if both bond making and bond breaking were of comparable importance. Furthermore both mechanisms described above for a square planar complex ignore a fact which has become quite apparent from recent experimental work and from elementary energetic considerations. This fact is that a square planar complex invariably will have two further groups coördinated above and below the plane at a greater distance than the four primary ligands.[27] These groups may be solvent, or solute, molecules in solution, and anions, solvent of crystallization or even

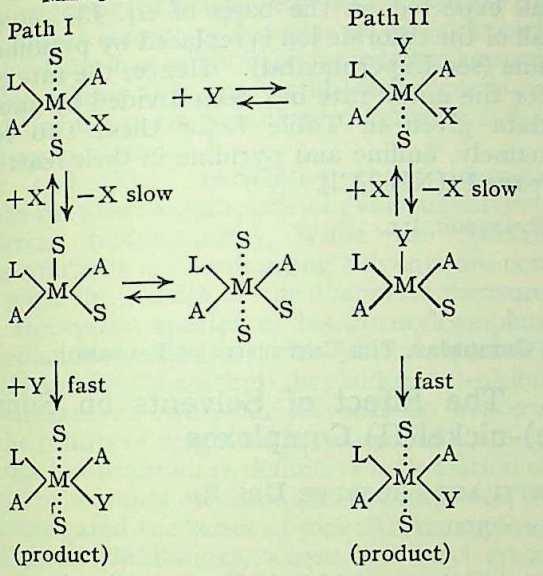
metal atoms from another complex in the solid state.

Accordingly the following mechanism is proposed for reactions of "square planar" complexes in solution

$$MLA_2X + Y \longrightarrow MLA_2Y + X \qquad (10)$$



Thus the reaction goes by a dissociation mechanism of a tetragonal complex in which two groups above and below the plane move in to help displace the group X. The five-coördinated intermediate will probably rearrange to a trigonal bipyramid, particularly if L or Y is a π-bonding group. In path II, Y can directly enter the square plane. Otherwise the aqua (or corresponding) complex will be an intermediate in a further sequence of dissociations until Y is picked up.

Such a reaction scheme accounts for (1) the over-all stereospecificity of such reactions (2) the activating influence of a π-bonding group on the ligand *trans* to it, (3) the reactivity and second-order kinetics of π-bonding reagents, (4) the small influence of electrostatic factors on the rates and (5) the second-order kinetics observed for some non π-bonding reagents such as NH_3 and oxalate ion. Furthermore it is in agreement with the almost certainly tetragonal structure of the complexes.

The mechanism also can be correlated with those postulated for the reactions of cobalt(III) complexes. These are SN1 dissociations for acid hydrolyses with usually a square pyramid structure for the five-coördinated intermediate, and SN1CB dissociations for base hydrolyses with rearrangement to a trigonal bipyramid intermediate.[28] There are two differences between the platinum(II) and cobalt(III) systems and each leads to important differences in the observed kinetics of their reactions. One difference is that platinum(II) is a d^8-system whereas cobalt(III) is a d^6-system. The extra pair of electrons in the case of platinum (originally in the d_{z^2} orbital) would lie in the trigonal plane, if a trigonal, pyramid is formed, occupying the $d_{x^2-z^2}$ orbital. In the case of cobalt(III), this orbital would be empty. This means that only ligands that are unsaturated, or have empty d or p orbitals, can stabilize the trigonal form in the case of platinum, whereas only ligands with unshared pairs of electrons (OH^- and NH^-) can stabilize the cobalt system. This is in agreement with the observed rates of reaction of these systems. Thus in platinum(II) the electron donation in π-bonding is from metal to ligand and in cobalt(III) it is from ligand to metal. Because of the original position of the extra pair of electrons on platinum, only the *trans* ligand can enter the trigonal plane and stabilize it. A *cis* ligand, even if a potential π-bonder such as $P(C_2H_5)_3$, would form a higher energy system if it became part of an *xy* trigonal plane because the extra pair of electrons would no longer be in this plane. This restriction does not hold for cobalt and in fact *cis* electron donors are more effective than *trans*.

The second difference is that all six groups in the case of cobalt are firmly held, their identity is fixed and the remaining bond distances remain nearly constant during the dissociation of one of the groups. In platinum, two of the groups are labile and can be replaced by other ligands in the solution. Further these two labile groups are believed to move in closer to platinum during the dissociation of the leaving group. This means that an external reagent, Y, can easily influence the rate of reaction of platinum complexes but not of cobalt complexes. Also cobalt complexes will react primarily by bond breaking, with very little help from bond making, whereas in platinum there will be contributions from both.[29] All of this is in agreement with the experimental facts on these systems.

The tetragonal structure of the platinum system also guarantees stereospecificity in that the entering group Y will always take up the position vacated by X. This is because the two groups labeled A always maintain a *trans* position to each other and hence hold the configuration in the square plane. A *trans* configuration for the two A groups does not fix the stereochemistry in an octahedral complex. Hence rearrangement is possible for cobalt(III) reactions.[28]

The rates of reaction for platinum complexes studied in this work are about as expected for varying *trans* ligands. Table I shows that for complexes of the same electrical charge the rates run $Cl^- > NH_3 > OH^-$, the same order as in the *trans* effect series listed above.

The reactions of *trans*-$Pt(NH_3)_2Cl_2$ with aniline and pyridine require special considerations. The experimentally observed rate of release of Cl^- was found to be approximately twice that of the hydroxide ion or glycine reactions. This can be accounted for on the basis of the mechanism

$$Pt(NH_3)Cl_2 + H_2O \underset{k_2}{\overset{k_1}{\rightleftharpoons}} Pt(NH_3)_2(H_2O)Cl^+ + Cl^- \qquad (11)$$

$$Pt(NH_3)_2(H_2O)Cl^+ + Y \xrightarrow{k_3} Pt(NH_3)_2YCl^+ + H_2O \qquad (12)$$

$$Pt(NH_3)_2YCl^+ + H_2O \underset{k_5}{\overset{k_4}{\rightleftharpoons}} Pt(NH_3)_2Y(H_2O)^{++} + Cl^- \qquad (13)$$

(28) R. G. Pearson and F. Basolo, THIS JOURNAL, 78, 4878 (1956).

(29) It is also possible that, in some cases, reaction of square planar complexes may be completely determined by bond making. That is, addition of Y to the platinum atom even in a weakly held position may be sufficient to ensure that the reaction will go to completion.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

$$Pt(NH_3)_2Y(H_2O)^{++} + Y \xrightarrow{k_6} Pt(NH_3)_2Y_2^{++} + H_2O \quad (14)$$

By using the steady-state assumption for the concentration of the intermediates $Pt(NH_3)_2(H_2O)Cl^-$, $Pt(NH_3)_2YCl^+$ and $Pt(NH_3)_2Y(H_2O)^{++}$, the rate equation reduces to

$$\frac{d[Cl^-]}{dt} = 2k_1\left(1 - \frac{k_2[Cl^-]}{k_2[Cl^-] + k_3[Y]}\right)[Pt(NH_3)_2Cl_2] \quad (15)$$

It actually has been observed that the initial, rather rapid, rate of liberation of Cl^- drops to a much lower value even before half of the total chlorine has been liberated, and that the smaller the concentration of the incoming group, Y, in the solution, the earlier this drop off occurs. Furthermore, if chloride ion is added to the solution to begin with, then for the same concentration of Y, the slowing down takes place earlier. Addition of more Y at this stage again speeds up the reaction. These are all expected on the basis of eq. 15. Eventually all of the chloride ion is replaced by pyridine or aniline (see Experimental). Hence, the rate constant for the initial rate has been divided by two for the data given in Table I for these two reagents, namely, aniline and pyridine in their reaction with *trans*-$Pt(NH_3)_2Cl_2$.

Studies in Coördination Chemistry. I. The Effect of Solvents on Some Bis-(N-alkylsalicylaldimine)-nickel(II) Complexes

BY LUIGI SACCONI, PIERO PAOLETTI AND GIUSEPPE DEL RE

RECEIVED FEBRUARY 5, 1957

A series of bis-(N-alkylsalicylaldimine)-nickel(II) complexes in the solid state and in solution of organic solvents was submitted to magnetic, spectrophotometric and electric moment measurements. The results of dipole moment determination afford evidence against the hypothesis of a tetrahedral structure of such complexes when dissolved in "non-coördinating" solvents. The paramagnetism developed in such solutions and some characteristic features of the absorption spectra can be understood with the hypothesis of an equilibrium involving an "outer orbital" $4s4p^24d$ planar configuration. The magnetic behavior and the absorption spectral data of these complexes in the solid state are discussed in terms of this concept. Observations on the influence of the length of the *n*-alkyl chains attached to the nitrogen atoms on these properties are reported. The zigzag shape of the curves of magnetic moments, atomic polarizations and melting points for this series of complexes are correlated with changes of base strength and coördination power of the parent amines. The smaller the coördination power of the amine, the greater the polarity and thus the "outer orbital" character of the coördinate bonds of the complex. This is also accompanied by a greater ease of bending vibrations of the chelate rings and a greater tendency for interactions between the polarizable molecules in the crystals.

The magnetic behavior of nickel complexes has proved of considerable value in obtaining useful information concerning the bond type and the stereochemistry of such compounds.

Generally magnetic measurements have been carried out on metal complexes in the solid state. However, some measurements also have been made on complexes dissolved in organic solvents. French, Magee and Sheffield,[1] postulate that the weak paramagnetism (1.9 B.M.) exhibited by a methanol solution of diamagnetic bis-(formylcamphor)-ethylenediaminenickel(II) is caused by a partial conversion of the planar complex to a tetrahedral form. Subsequently Willis and Mellor[2] found that a number of tetracovalent nickel(II) complexes, diamagnetic in the solid state, exhibit paramagnetism in various solvents such as pyridine, alcohols, dioxane, chloroform and benzene. The paramagnetism observed in pyridine solutions, corresponding to two unpaired electrons, was attributed to an expansion of the coördination number to six. This solvation reaction was confirmed by Basolo and Matoush[3] through the isolation of the corresponding paramagnetic complexes containing two molecules of pyridine.

Some complexes such as bis-(formylcamphor)-ethylenediaminenickel(II), bis-(salicylaldoxime)-nickel(II) and bis-(N-methylsalicylaldimine)-nickel-(II), diamagnetic in the solid state, exhibit paramagnetism even in "non-coördinating" solvents such as benzene and chloroform.[2] In such cases, where the magnetic moment is intermediate between 0 and 3.2 B.M., it was suggested that a proportion of the molecules of the complex is converted from a planar to a tetrahedral configuration.[2]

In this connection Basolo and Matoush[3] found that no direct correlation exists between the magnetic moment of bis-(formylcamphor)-ethylenediaminenickel(II) in methylbenzenes and the base strength of these solvents. They concluded that the paramagnetism must therefore not be due to solvation but rather to formation of tetrahedral nickel(II) compounds.

Nyholm[4] recently suggested that the intermolecular crystalline forces in solids may sometimes favor the square configuration, whereas in solution, the tetrahedral arrangement of lowest potential energy may be adopted by the isolated molecule.

The magnetic measurements by Fujii and Sumitani[5] and by Clark and Odell[6] on solutions of such complexes in non-coördinating solvents over a

temperature range of 100°, confirmed the occurrence of temperature-dependent equilibria between dia- and paramagnetic forms. Calculation of the thermodynamic quantities associated with the equilibria were retained as supporting Nyholm's suggestion that for certain complexes in solution the paramagnetic, probably tetrahedral, form is the state of lowest energy. However no direct experimental evidence has as yet been reported in support of the hypothesis that the tetrahedral form is responsible for the paramagnetism in benzene and in chloroform solutions.

Clark and Odell[7] correlated their magnetic data with the absorption spectra in various solvents at different temperatures. While the spectral data for solutions in coördinating solvents are consistent with the results of the magnetic measurements, absorption spectra of bis-(formylcamphorethylenediamine)-nickel(II), bis-(salicylaldoxime)-nickel(II) and bis-(N-methylsalicylaldimine)-nickel-(II) complexes in non-polar solvents do not correlate the results of magnetic measurements.

In order to obtain more definitive information on the effect of solvents on these nickel complexes, we have investigated the series of nickel(II) complexes of N-alkylsalicylaldimines, where the alkyl group increase from methyl through *n*-amyl. Chloroform, benzene and dioxane solutions of these complexes were submitted to dipole moment, magnetic and spectrophotometric measurements. Magnetic and spectrophotometric measurements also were made on the solid compounds. Relatively few spectral investigations of complexes in the crystalline state are reported in the literature.[8]

Experimental

Preparation of Compounds.—The following general method was used: bis-salicylaldehydenickel(II) dihydrate was suspended in excess of an aqueous alcoholic solution of *n*-alkylamine and heated on the water-bath under reflux for several minutes. The crystalline products obtained were then recrystallized from alcohol or from chloroform and petroleum ether. The olive-green complexes are soluble in alcohol, ether, benzene and chloroform. The solubility in non-polar solvents increases with increasing *n*-alkyl chain length.

Bis-(N-methylsalicylaldimine)-nickel(II) was prepared according to Klemm and Raddatz.[9] This compound melts between 192 and 202°.

Bis-(N-ethylsalicylaldimine)-nickel(II): m.p. 173–174°. *Anal.* Calcd. for $C_{18}H_{20}O_2N_2Ni$: N, 7.89; Ni, 16.53. Found: N, 8.05; Ni, 16.31.

Bis-(N-propylsalicylaldimine)-nickel(II): m.p. 160–161°. *Anal.* Calcd. for $C_{20}H_{24}O_2N_2Ni$: N, 7.32; Ni, 15.33. Found: N, 7.55; Ni, 15.22.

Bis-(N-butylsalicylaldimine)-nickel(II): m.p. 140–141°. *Anal.* Calcd. for $C_{22}H_{28}O_2N_2Ni$: N, 6.82; Ni, 14.27. Found: N, 6.97; Ni, 14.05.

Bis-(N-amylsalicylaldimine)-nickel(II): m.p. 142–143°. *Anal.* Calcd. for $C_{24}H_{32}O_2N_2Ni$: N, 6.38; Ni, 13.36. Found: N, 6.37; Ni, 13.24.

Magnetic Susceptibility Measurements.—Susceptibility measurements on the solids were made with the modified Bhatnagar balance described previously.[10] Magnetic measurements on the complexes dissolved in the different solvents were executed using a Gouy-type magnetic balance. The susceptibilities of the complexes were determined according to the formula

$$\chi_{g(complex)} = [\chi_{g(solution)} - \chi_{g(solvent)}(1-x)]/x$$

where x = fraction by weight of complex in solution. After calculation of the molar susceptibilities, diamagnetic corrections for the organic ligands were computed from Pascal's constants.[11] The solutions employed were of equivalent concentration. The only exception to this was the chloroform solution of the first complex, which is very sparingly soluble in this solvent.

Spectrophotometric Measurements.—Absorption spectra were obtained with a Beckman DU spectrophotometer. The silica absorption cells had a 1-cm. light path. The concentrations of the complexes in solutions were between 1.7×10^{-4} and 2.07×10^{-2} mole per liter depending upon the degree of absorption. Measurements in the solid state were made by the potassium bromide method.[12] Extinction coefficients for the ultraviolet spectra by the disk method were calculated from the familiar equation $E = 1/cd \log_{10}(I_0/I)$ in which c is reported in moles per liter of potassium bromide, and d is the length of the light path (0.080–0.085 cm.).

Dipole Moment Measurements.[13]—The dielectric constants of the solutions relative to those of the solvents were determined with a heterodyne oscillator and a cell as previously described.[14] The solvents (benzene and dioxane) were purified by the standard procedures. In each case 4 or 5 solutions were measured. The refractive indices were determined with a Pulfrich refractometer. Densities were measured with a pycnometer. The main source of error in the determinations was the low solubility of the compounds investigated, especially for the benzene solution of the first member of the series.

The molar polarizations of the solutes at infinite dilution ($P_{2\infty}$) were determined by the method of Halverstadt and Kumler.[15] The plots of dielectric constants ϵ_{12} and densities d_{12} *vs.* molar fractions were found to be straight lines with slopes α and β, respectively. The extrapolated values (ϵ_1 and d_1) for $f_2 = 0$ were always close to the experimental values for the pure solvents. The P_E values were determined experimentally, and varied according to the additivity rule of molar refractions.

Results and Discussion

The diamagnetism exhibited by these complexes in the solid state (*cf.* Table I) is indicative of a covalent dsp^2 planar configuration. Table I and Fig. 1 report the values of magnetic moments of the complexes dissolved in dioxane, benzene and chloroform.

The values of the magnetic moments found for bis-(N-methylsalicylaldimine)-nickel, ranging from 1.9 to 2.3 B.M. depending on the solvent used, are in good agreement with the results of Willis and Mellor[2] and with those of Clark and Odell.[6,7] The susceptibilities of the successive members of the series are much lower. In benzene and dioxane solutions they vary between 0.3 and 0.8 B.M. In chloroform the values are higher, ranging from 0.9 to 1.2 B.M. It may be remarked that the plot of $\mu_{eff.}$ *vs.* the number of carbon atoms in the *n*-alkyl chain has the shape of a zigzag. In this plot the lower points correspond to alkyl chains with an even number, the upper points to alkyl chains with an odd number of carbon atoms.

The values of magnetic moments, which vary between zero and that required for two unpaired

range from 0.63 to 0.88 *D* for the benzene solutions and from 0.83 to 1.29 *D* for the dioxane solutions. These data were obtained by assuming $P_A = 10\% P_E$, *i.e.*, by using P_A values ranging from 10 to 14 cc., both for benzene and dioxane solutions. In this connection it may be remembered that Sutton and co-workers[16] showed that the P_A values for several metal acetylacetonates greatly exceed the 10% P_E, being *ca.* 30 cc. For a series of copper(II) and nickel(II) chelates of analogs of bis-(acetylacetone)-ethylenediimine, where the metal is joined to two oxygen and two nitrogen atoms at the center of three ortho condensed chelate rings, McCarty and Martell[17] made the allowance for P_A of 36–41 cc. = 35–50% P_E. Besides MacQueen and J. W. Smith[18] computed P_A values ranging from 21 to 31 cc. for a number of *trans*-planar complexes of copper(II) and nickel(II) in benzene and

dioxane solutions. In our measurements if allowance is made for P_A = 17–26% P_E in benzene and 21–44% P_E in dioxane, the values of μ (D) become equal to zero. If, according to the treatment of MacQueen and Smith,[18] we interpret the difference between P_2 and R_D as atom polarizations, values of P_A ranging from 19 to 27 cc. for benzene solutions are found. This fact leads to the conclusion that the dipole moments are practically zero when correct allowance for the atom polarization is made. On the basis of these data both the *cis*-planar and the tetrahedral structure are to be rejected and therefore a *trans*-planar configuration can be ascribed to all the nickel chelates in Table II. This conclusion is corroborated by the results of dipole moment measurements on some analogous copper(II) chelates. For bis-(N-methylsalicylaldimine)-copper(II), where a *trans*-planar configuration is generally accepted, if allowance is made[19] for P_A = 20% P_E, then the same value of $\mu_{app.}$ = 1.21 D (solvent dioxane) is found. Besides the value of P_A of *ca.* 50 cc., computed from the difference between $P_{2\infty}$ and R_D agrees with the value of 54 cc. calculated by MacQueen and Smith from the data of Charles and Freiser[19] for this copper chelate. The complex bis-(N-ethylsalicylaldimine)-copper(II) in dioxane exhibits a still higher moment of 1.50 D (P_A = 20% P_E)(*cf.* Table II).

The spectra of the complexes in chloroform solutions (see Table III and Figs. 2 and 3) show three bands in the 326, 414–418 and 610–620 mμ regions. The absorption curves of the chelate groups in dioxane and benzene solutions are quite similar, excepting a shift of 2–20 and 3–25 mμ toward the red in dioxane and benzene solutions, respectively.

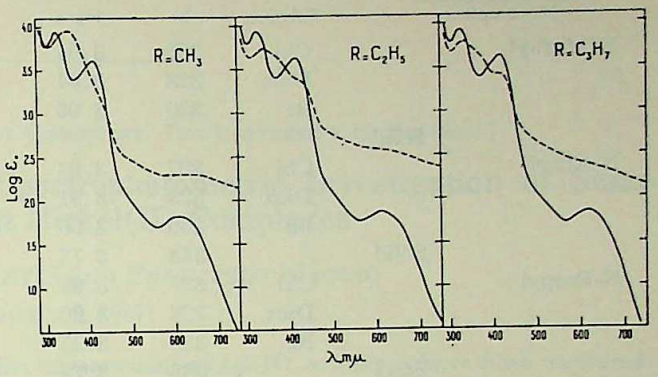

Fig. 2.—Absorption curves of bis-N-alkylsalic.-Ni complexes in chloroform (———) and in the solid state (– – – –). The spectra of bis-N-butyl and bis-N-amyl complexes are very similar to that of the bis-N-propyl complex and therefore are not shown.

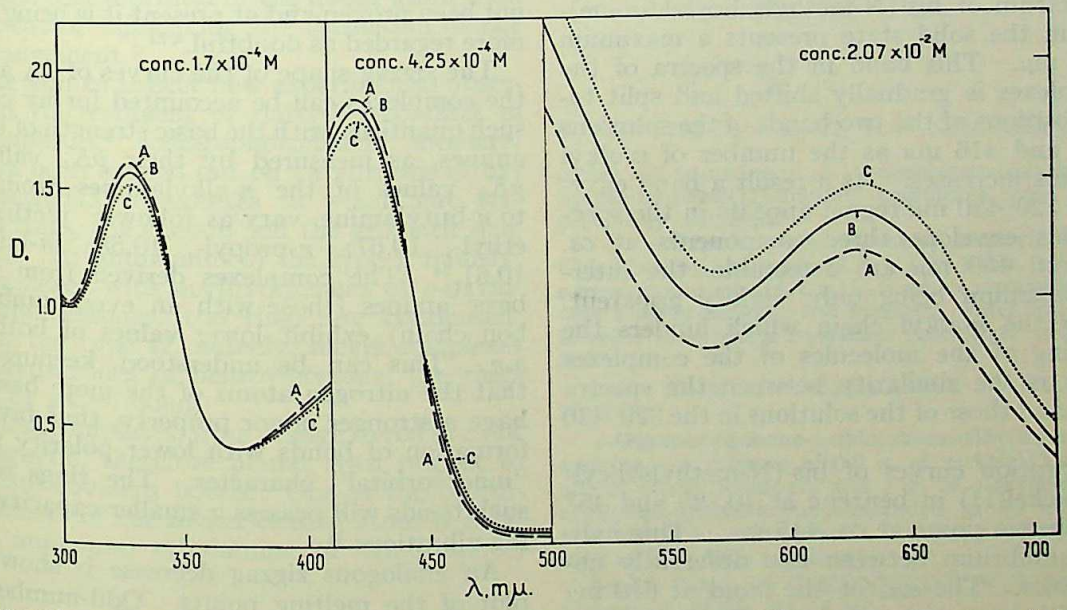

Fig. 3.—Absorption curves of bis-N-methylsalic.-Ni(II) complex in benzene at different temperatures: A (- - - -), 10°; B (———), 25°; C (. . . . .), 45°. At *ca.* 445 mμ the isosbestic point.

Furthermore it is remarkable that the values of $P_{2\infty}$ and $P_{2\infty} - R_D$ found for all the complexes investigated in solution of dioxane are slightly higher than those in benzene, in accordance with the results of both Sutton and MacQueen and Smith. In accordance with the conclusions of these authors, the high P_A values found for the square complexes of the series of N-alkyl-salicylaldimine can be explained as principally due to bending vibrations of the rings as units relative to the remainder of the molecule. These vibrations of the six-membered rings would involve a folding or twisting of the molecule as a whole.

This shift increases gradually with increasing λ_{max} of the bands. The very strong absorption band at *ca.* 420 mμ (log $\epsilon > 3.5$) may be identified as the band characteristic of covalent nickel chelates.[20] The weak band at 610–640 mμ can be considered as due to the central metallic cation.[21] The intensity of this band (log $\epsilon < 2$) is that typical of a forbidden transition, probably 3d-3d.[22] This fact leads to the assumption of the existence of unoccupied 3d levels in these complexes when dis-

[a] The values of the wave lengths of the inflections are enclosed in parentheses.

solved in the above solvents, in accordance with the results of magnetic measurements.

The spectrum of bis-(N-methylsalicylaldimine)-nickel(II) in the solid state presents a maximum at *ca.* 354 mμ. This band in the spectra of the other complexes is gradually shifted and split toward the positions of the two bands of the solutions at *ca.* 326 and 416 mμ as the number of *n*-alkyl carbon atoms increases. As a result a band envelope in the 320–430 mμ region appears in the spectra. In this envelope three components at *ca.* 340, 360 and 430 mμ are detectable, the intermediate maximum being only slightly apparent. The longer the *n*-alkyl chain which hinders the close packing of the molecules of the complexes the greater is the similarity between the spectra of the solid and those of the solutions in the 320–430 mμ region.

The absorption curves of bis-(N-methylsalicylaldimine)-nickel(II) in benzene at 10, 25 and 45° have a isosbestic point at *ca.* 445 mμ. This indicates an equilibrium between two differently absorbing species. The ϵ_{max} of the band at 610 mμ increases with increasing temperature, an increase which takes place also by dilution at constant temperature. The two forms in equilibrium correspond, evidently, to the diamagnetic and the paramagnetic one revealed by the magnetic measurements of Clark and Odell.[6]

Our observation that the paramagnetic form possesses a non-polar, planar structure can be explained by assuming that the four bonds from the nickel atom in this form are of the "outer orbital" $4s4p^24d$ type. This signifies that the equilibrium existing in such solutions is not between a planar and a tetrahedral form but probably between an "inner" and an "outer orbital" one. In the solid, only the "inner orbital" $3d4s4p^2$ form probably exists, owing to the influence of the crystalline field which forces a complete spin coupling.

In this connection it should be remembered that the existence of tetrahedral Ni(II) complexes has not been proven and at present it is being more and more regarded as doubtful.[4,23]

The zigzag shape of the curves of P_A and $\mu_{eff.}$ of the complexes can be accounted for by correlating such quantities with the basic strength of the parent amines, as measured by their pK_a values. The pK_a values of the *n*-alkylamines from methyl- to *n*-butylamine, vary as follows: methyl-, 10.64; ethyl-, 10.67; *n*-propyl-, 10.58; *n*-butylamine, 10.61.[24] The complexes derived from the more basic amines (those with an even-numbered carbon chain) exhibit lower values of both P_A and $\mu_{eff.}$. This can be understood, keeping in mind that the nitrogen atoms of the more basic amines have a stronger donor property, thus favoring the formation of bonds with lower polarity and more "inner orbital" character. The rings containing such bonds will possess a smaller capacity of bending vibrations.[18]

An analogous zigzag decrease is shown by the plot of the melting points. Odd-numbered complexes which have more polar bonds, exhibit relatively higher melting points, presumably as a consequence of a stronger interaction between the molecules. It is probable, however, that steric factors of the type which are operative in melting of normal alkanes,[25] expressed in terms of different orientation of the carbon chain within the unit

Studies in Coördination Chemistry. II. Spectrophotometric Investigation of Some Hydrazidic Tetracovalent Nickel(II) Complexes

BY LUIGI SACCONI, PIERO PAOLETTI AND FRANCESCO MAGGIO

RECEIVED FEBRUARY 5, 1957

The ultraviolet absorption spectra of a number of hydrazidic tetracovalent nickel(II) complexes have been measured. The effect of certain atomic grouping adjacent to the chelate ring has been studied and discussed in terms of the hypothesis of dative π-bond in metal complexes.

The concept of double bond formation between metals and donor atoms is now regarded as of great importance in many complexes.[1]

Pauling was the first to explain the unusual strength and shortening of some metal–ligand bonds in certain coördination compounds by the hypothesis of double bonding.[2] In the case of nickel complexes it was suggested that the formation of double bond using d_π electron pairs of the metal and a vacant p or d orbital of the donor atom is an important factor influencing the formation of the square arrangement.[3]

With the aim to collect new experimental observations on the problem of dative π-bonding in metal complexes,[4] spectrophotometric measurements have been carried out on two groups of hydrazidic nickel(II) complexes in which two six-membered rings, the chelate and the aromatic one, are present. In compounds of the type I, namely, nickel complexes with acylhydrazones of *o*-oxyaldehydes and ketones, the rings are condensed; in those of the type II, namely, nickel complexes with acylhydrazones of benzoylacetone, the rings are joined by a C–C bond.

All of these complexes, from orange to red in color are diamagnetic, therefore planar with respect to the four dsp^2 covalent bonds. One of the coördinative valences of the nickel central atom is saturated by ammonia, ethylamine or triethylphosphine.

amine.—Nickel(II) acetate (1 g.) in 20 ml. of alcohol and 10 ml. of 33% ethylamine was mixed with 1 g. of *o*-oxyacetophenonebenzoylhydrazone in 30 ml. of alcohol. The mixture was heated on a water-bath for few minutes to yield red prisms of m.p. 141–142° dec.

Anal. Calcd. for $C_{17}H_{19}O_2N_3Ni$: N, 11.80; Ni, 14.49. *Found:* N, 11.84; Ni, 14.43.

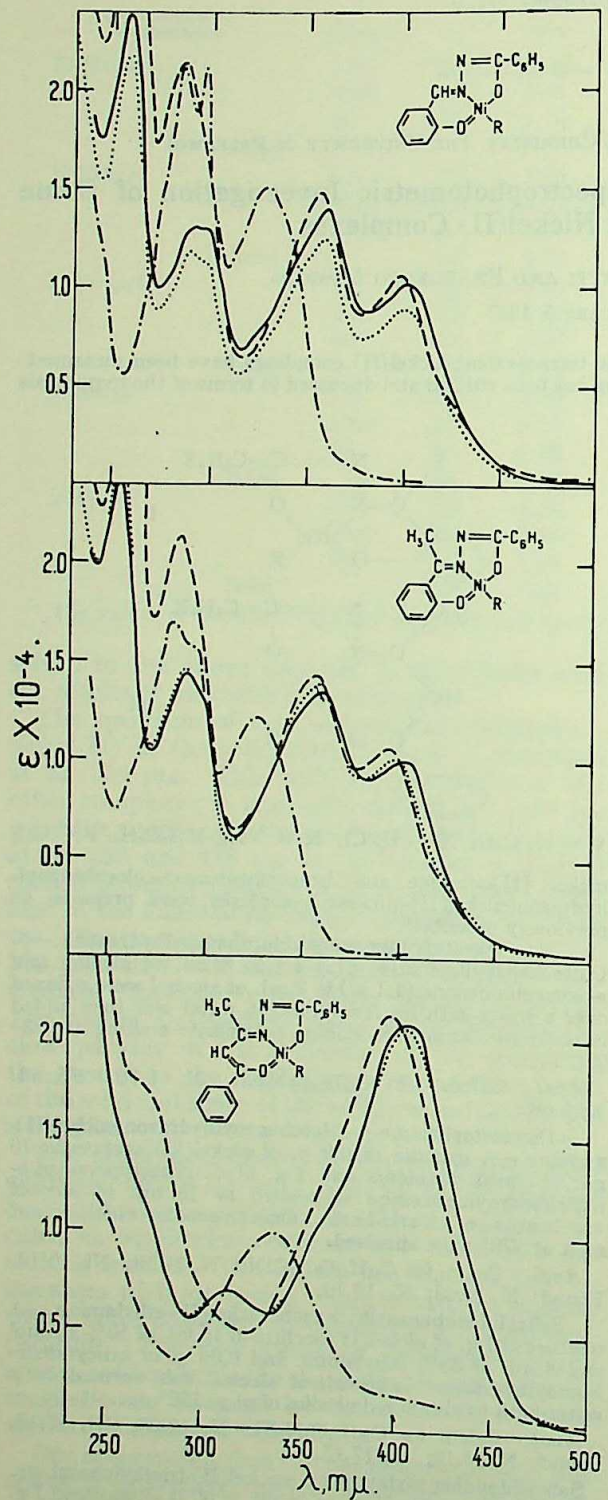

Fig. 1.—Absorption spectra of the ligands with X = H (-·-·-·-) and related complexes with R = NH_3 (———), R = $NH_2C_2H_5$ (.....) and R = $P(C_2H_5)_3$ (--------).

o-Oxyacetophenonebenzoylhydrazonenickel(II)-triethylphosphine.—A solution of 1 g. of nickel(II) acetate in 6 ml. of water, 12 ml. of alcohol and 1 g. of triethylphosphine was mixed with 1 g. of *o*-oxyacetophenonebenzoylhydrazone suspended in 30 ml. of alcohol. The mixture was warmed on a water-bath under reflux for a few minutes. Orange-red prisms were obtained which melt, with decomposition, at 98–99°.

Anal. Calcd. for $C_{21}H_{27}O_2N_2PNi$: N, 6.55; P, 7.22; Ni, 13.68. Found: N, 6.71; P, 7.65; Ni, 13.63.

Benzoylacetonebenzoylhydrazonenickel(II)-ethylamine.—A mixture of 1 g. of nickel(II) acetate in 20 ml. of water and 10 ml. of 33% ethylamine and 1.1 g. of benzoylacetonebenzoylhydrazone in 20 ml. of alcohol was warmed on a water-bath under reflux for few minutes. Addition of water facilitates the formation of red-orange needles of m.p. 130–131° dec.

Anal. Calcd. for $C_{19}H_{21}O_2N_3Ni$: N, 11.00; Ni, 15.36. Found: N, 11.40; Ni, 15.43.

Benzoylacetonebenzoylhydrazonenickel(II)-triethylphosphine.—A mixture of 1 g. of nickel(II) acetate in 20 ml. of alcohol and 1 g. of triethylphosphine and 1.1 g. of benzoylacetonebenzoylhydrazone in 40 ml. of alcohol was warmed on a water-bath under reflux for few minutes. On standing at 0–5° red crystals separated which melt with decomposition at 101–102°.

Anal. Calcd. for $C_{23}H_{29}O_2N_2PNi$: N, 6.15; P, 6.81; Ni, 12.89. Found: N, 6.37; P, 6.79; Ni, 12.85.

All the complexes are soluble in alcohol, ether, benzene, chloroform. Those with triethylphosphine are also soluble in petroleum ether.

Spectra of Ligands and Complexes.—Spectrophotometric measurements were made with a Beckman DU spectrophotometer using silica cells 1 cm. long, on alcohol solutions of chelating agents and nickel complexes of 8.5×10^{-5} *M* concentration.

Results

Spectral data for acylhydrazones and complexes are recorded in Table I, where ϵ signifies molecular extinction coefficient.

TABLE I

ABSORPTION CHARACTERISTIC OF LIGANDS AND COMPLEXES

	λ_{max} (mμ)	$\epsilon_{max} \times 10^{-4}$
Type I		
o-Oxyacetophenonebenzoylhydrazone	326	1.23
o-Oxyacetophenone-*p*-chlorobenzoylhydrazone	328	1.36
Salicylidenebenzoylhydrazone	328	1.51
Salicylidene-*p*-chlorobenzoylhydrazone	330	1.66
Type II		
Benzoylacetonebenzoylhydrazone	335	1.01
Benzoylacetone-*p*-chlorobenzoylhydrazone	336	1.25
Type I		
o-Oxyacetophenone-benzoylhydrazone-Ni-NH_3	400	0.97
o-Oxyacetophenone-*p*-chlorobenzoylhydrazone-Ni-NH_3	402	1.12
o-Oxyacetophenonebenzoylhydrazone-Ni-$NH_2C_2H_5$	398	1.01
o-Oxyacetophenonebenzoylhydrazone-Ni-$P(C_2H_5)_3$	394	1.07
Salicylidenebenzoylhydrazone-Ni-NH_3	402	1.02
Salicylidene-*p*-chlorobenzoylhydrazone-Ni-NH_3	404	1.16
Salicylidenebenzoylhydrazone-Ni-$NH_2C_2H_5$	400	0.90
Salicylidenebenzoylhydrazone-Ni-$P(C_2H_5)_3$	396	2.11
Type II		
Benzoylacetonebenzoylhydrazone-Ni-NH_3	405	2.10
Benzoylacetone-*p*-chlorobenzoylhydrazone-Ni-NH_3	409	2.39
Benzoylacetonebenzoylhydrazone-Ni-$NH_2C_2H_5$	404	2.03
Benzoylacetonebenzoylhydrazone-Ni-$P(C_2H_5)_3$	396	2.11

Experimental absorption curves for compounds with X = H are shown in Fig. 1. Compounds with X = Cl exhibit analogous features.

Discussion

The spectra obtained for the ligands of the type I show two bands in the 280–290 and 326–336 mμ

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

regions. The latter maximum could be considered as the 325 mμ band of the salicylaldehyde[6] shifted toward longer wave lengths owing to the formation of the benzoylhydrazone. This band can be ascribed to the existence of a chelate enol ring stabilized through hydrogen-bond formation and enol resonance.[7]

Beside showing a very strong absorption band in the ultraviolet region below 250 mμ, the spectra of the ligand molecules of type II show a maximum at 336 mμ. This band presumably can be related to the band at 310 mμ ascribed to the enol form of benzoylacetone.[6]

The spectra of the complexes of type I show four absorption bands at *ca.* 260, *ca.* 280, *ca.* 360 and 400–410 mμ. The band at *ca.* 410 mμ may be identified as the characteristic band of covalent nickel chelates, which is due to the presence of a chelate ring of which the metal is a member.[8] The intensity of this band (of $\epsilon \simeq 10^4$) is that of an allowed transition.[9]

The main features of the absorption spectra of type II complexes consist of two absorption bands in the 340 and 400–410 mμ regions. The former, of smaller intensity, is lacking in the complex with triethylphosphine. The band at 406–410 mμ can be recognized as that of the Ni chelates with dsp^2 covalent structure.

Table I shows that the molecular extinction coefficient of the nickel band maximum at 400–410 mμ increases from the values 9,000–11,600 for the complexes of the type I, to values 21,100–23,900 for the complexes of the type II. Hence the position of the aromatic nucleus, adjacent to the chelate ring in the complexes of type I, attached by a C–C bond in the complexes of type II, influences the chromophoric grouping responsible for this band, *i.e.*, the chelate ring containing the nickel atom. This fact can be related to the existence in the chelate ring of the complexes of a completely conjugated resonance which interferes with the resonance of the aromatic nucleus when the two rings are condensed. Thus a "crossed resonance" of the type already studied for some copper chelates[10] is produced. This "cross conjugation"[11] implies the participation of a nickel atom in the π-bond system of the coördinate ring.

The absence of an hyperchromic effect in the maxima at 326–336 mμ of the spectra of ligands of type II can be explained keeping in mind that the chromophore possibly responsible for such maxima is not a completely conjugated system. In fact it is obvious that the hydrogen atom which completes the enol ring in the ligand molecules is incapable of forming double bonds.

These results therefore are consistent with the concept of π-bond character of the coördinate links between nickel and donor atoms in the above complexes.

The hyperchromic and bathochromic effects caused by the presence of a chlorine atom in the molecules of both ligands and complexes must be noticed. The substitution of ethylamine and triethylphosphine for ammonia produces only a little hypsochromic shift of the band at about 400 mμ. This fact is in accordance with the assumption that this band is due to the presence of a chelate ring including the nickel atom.

The Gluconate Complexes. IV. The Cadmium–Gluconate System

BY ROBERT L. PECSOK AND JIRI SANDERA

RECEIVED MARCH 1, 1957

Cadmium in varying concentrations of gluconate has been investigated polarographically from *p*H 2 to 14. A number of complexes are formed. Those which were identified and studied have a ratio of cadmium to gluconate of 1:2 (*p*H 5 to 8), 2:3 (*p*H 13 to 14), and 2:1 (*p*H 13 to 14). Half-wave potentials and dissociation constants are given.

Although it is known that gluconic acid forms complexes with many metal ions, no previous description of the cadmium–gluconate system is available. The complexes do not give spectra suitable for study, therefore this investigation is entirely polarographic. As in most supporting electrolytes, cadmium in gluconate solutions gives well-defined, reversible polarograms which are subject to thermodynamic interpretation.

Experimental

The polarographic equipment and methods used have been described previously.[1] The purification and preparation of solutions of gluconic acid and sodium gluconate also have been described.[1] A stock solution of cadmium perchlorate was prepared by dissolving cadmium hydroxide in perchloric acid and standardized electrolytically. Conductivity water was used throughout. The ionic strength was adjusted to

1.0 with sodium perchlorate or potassium nitrate except where otherwise indicated. Sufficient time was allowed for equilibrium to become established (3–4 hr. at pH 10–11). In alkaline solutions, it is necessary to add the sodium gluconate before the sodium hydroxide in order to prevent precipitation. The temperature was maintained at 25.0 ± 0.1° by a water thermostat.

The half-wave potential of cadmium in nitrate or perchlorate media of ionic strength 1.0 was found to be −0.583 v. *vs.* the saturated calomel electrode (used throughout this study). The half-wave potentials were determined graphically on the recorded polarograms, and were reproducible to ±2 mv. The reversibility was tested by measuring the difference, $E_{3/4}$–$E_{1/4}$, which was no more than 2 mv. from the theoretical value of 28 mv. for a 2 electron reduction.[2]

Results and Discussion

The general reaction for the reduction of the cadmium–gluconate complexes at the dropping mercury electrode is assumed to be

$$\text{complex} + x\text{H}^+ + \text{Hg} + 2e^- = \text{Cd(Hg)} + p\text{GH}_4^- \quad (1)$$

or the equivalent in basic solution

$$\text{complex} + \text{Hg} + 2e^- = \text{Cd(Hg)} + p\text{GH}_4^- + x\text{OH}^- \quad (2)$$

from which it follows[3] that

$$(E_{1/2})_c - (E_{1/2})_s = 0.0296 \log K(k_s/k_c) - 0.0296(p) \log (\text{GH}_4^-) - 0.0296(x) \log (\text{OH}^-) \quad (3)$$

where K is the dissociation constant of the pertinent complex. The symbols follow those previously described.[1] (GH_4^-) represents the free gluconate ion concentration

$$(\text{GH}_4^-) = (\text{GH}_4^-)_{\text{total}}/[1 + (\text{H}^+)/K_A]$$

where the subscript "total" indicates the free ion plus the acid and lactones, and K_A is the dissociation constant of gluconic acid, 2.75×10^{-4}.

Several series of solutions were prepared, all containing 2.14×10^{-4} M cadmium, at either constant pH or constant concentration of gluconate, the other being varied. The discussion of the results can be divided conveniently into regions of pH units in which the several species are predominant and the polarographic behavior is similar. Below pH 2 no complexing is detectable, and the addition of gluconic acid does not affect the half-wave potential.

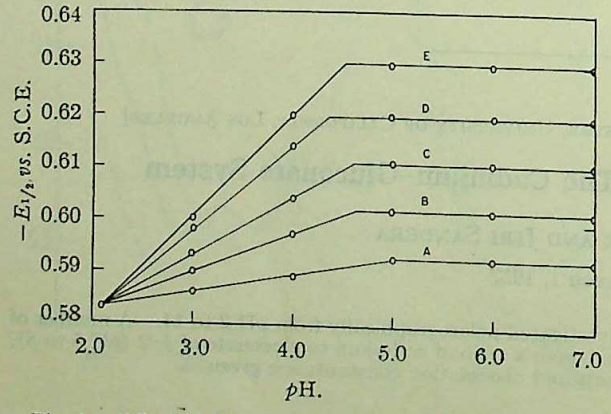

Fig. 1.—Effect of pH on the polarographic $E_{1/2}$ potential obtained with solutions 2.14×10^{-4} M Cd(II) and various sodium gluconate concentrations at ionic strength 1.0: A, 0.080 M; B, 0.200 M; C, 0.300 M; D, 0.500 M; E, 0.700 M sodium gluconate.

*p*H 2 to 5.—The half-wave potentials are plotted *vs.* pH (constant concentration of gluconate) in Fig. 1. As the pH or gluconate concentration is decreased, the degree of complexing becomes vanishingly small and the half-wave potentials approach that of the aquo-cadmium ion. Furthermore equation 3, in which it is assumed that a large excess of ligand is present, is no longer valid. The calculated values of the dissociation constant for the 1:2 complex (*vide infra*), included in Table I, likewise show deviations from the average value obtained at higher pH. There is probably a mixture of a 1:1 and a 1:2 complex present in this pH region. However, the change in half-wave potential is too small to warrant exact interpretation.

*p*H 5 to 8.—Above pH 5 the conditions of equation 3 are fulfilled, and it can be seen from Fig. 1 that a definite complex predominates. Since the half-wave potential is independent of pH in this region, the reduction does not involve hydrogen ion. For solutions containing more than 0.2 M gluconate, the half-wave potential changes by 59 mv. per tenfold change in gluconate concentration and the number of gluconates per cadmium in the complex is 1.8 ± 0.14. Therefore $p = 2$ and $x = 0$ in this region, and the formula of the complex is $\text{Cd(GH}_4)_2$. In Table I are computed values for $pK_{1:2}$ as defined by

$$pK_{1:2} = \frac{(E_{1/2})_c - (E_{1/2})_s}{-0.0296} + \log \frac{(i_d)_s}{(i_d)_c} - 2 \log \frac{(\text{GH}_4^-)_{\text{total}}}{1 + (\text{H}^+)/K_A} \quad (4)$$

The average value of $pK_{1:2}$ is 2.10 with a mean error of ± 0.05.

pH 8 to 12.—The half-wave potentials are plotted *vs.* pH (constant gluconate concentration) in Fig. 2, and *vs.* concentration of gluconate (constant pH) in Fig. 3. From the latter, it is seen that the ratio of Cd:G remains constant at 1:2; but from the former, it is apparent that in this region the complex is becoming hydroxylated (or the gluconate bound in the complex is losing hydrogen ions from the secondary hydroxyl groups). Furthermore, solutions in this region required several hours to reach equilibrium, and the data were not exactly reproducible as in the other regions. For these reasons, the nature of the complexes and their constants were not determined.

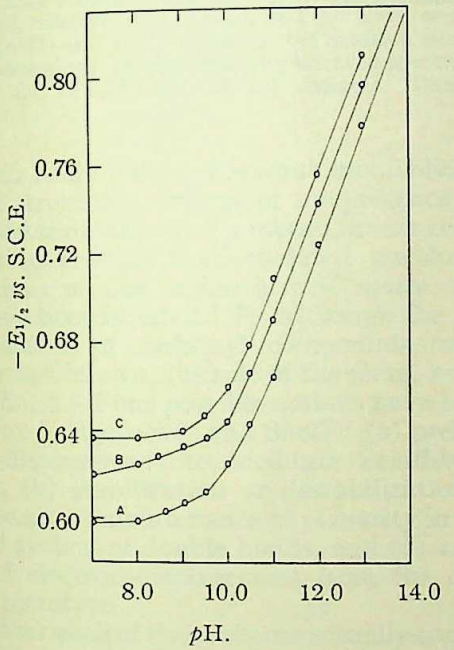

Fig. 2.—Effect of pH (above 8.00) on polarographic $E_{1/2}$ potential obtained with solutions 2.14×10^{-4} M Cd(II) and various sodium gluconate concentrations and constant ionic strength 1.0: A, 0.200 M; B, 0.500 M; C, 0.900 M sodium gluconate.

pH 13 to 14.—Solutions of cadmium, sodium gluconate and sodium hydroxide were polarographed. The data indicate that two complexes exist, one in solutions having less than 0.05 M gluconate, and another in solutions having greater than 0.05 M gluconate. Above 0.05 M gluconate, the ratio of Cd:G is 2:3 and the ratio of Cd:OH is 2:5. For calculation of the dissociation constant of this complex, equation 3 becomes

$$pK_{2:3} = \frac{(E_{1/2})_c - (E_{1/2})_s}{0.0296} - \log \frac{(i_d)_s}{(i_d)_c} - 1.5 \log (GH_4^-) - 2.5 \log (OH^-) \quad (5)$$

Values of $pK_{2:3}$ are shown in Table II, the average value being 10.25 ± 0.64. This value applies to solutions with an ionic strength of 1.0. A number of solutions were used in which the ionic strength was not adjusted to 1.0, but estimated on the basis of the concentration of the various species present. The maximum deviation in $pK_{2s:3}$ was 0.05 log unit at ionic strength 0.1.

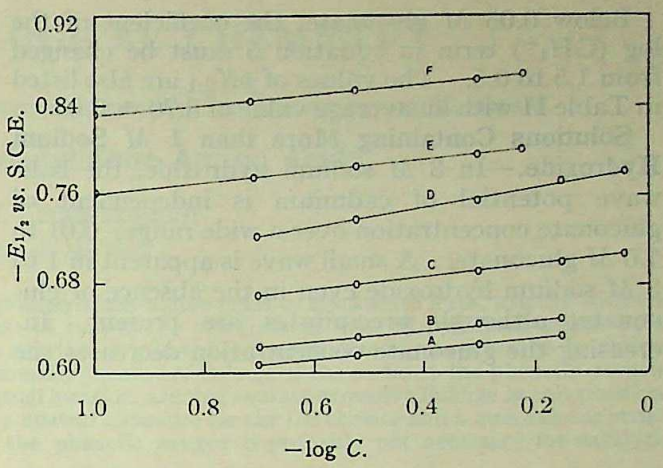

Fig. 3.—Effect of total sodium gluconate concentration on polarographic $E_{1/2}$ potential obtained with solutions 2.14×10^{-4} M Cd(II) and various pH at constant ionic strength 1.0: A, pH 9.00; B, pH 10.00; C, pH 11.00; D, pH 12.00: E, pH 13.00; F, 0.90 M sodium hydroxide.

Digitized by Arya Samaj Foundation Chennai and eGangotri

Below 0.05 M gluconate, the coefficient of the log (GH_4^-) term in equation 5 must be changed from 1.5 to 0.5. The values of $pK_{2:1}$ are also listed in Table II with an average value of 8.70 ± 0.05.

Solutions Containing More than 1 M Sodium Hydroxide.—In 3 M sodium hydroxide, the half-wave potential of cadmium is independent of gluconate concentration over a wide range: 0.01 to 1.0 M gluconate. A small wave is apparent in 1 to 3 M sodium hydroxide even in the absence of gluconate, although precipitates are present. Increasing the gluconate concentration decreases the amount of precipitate and increases the height of the wave, but does not change the half-wave potential, which becomes constant at a value of −0.86 v. in 3 M sodium hydroxide. These results indicate that cadmium forms a slightly soluble hydroxy complex (cadmiate) in high concentrations of hydroxide ion. No definite species can be identified in this region.

Metal Chelates of Pyridoxylidene Amino Acids

BY HALVOR N. CHRISTENSEN[1]

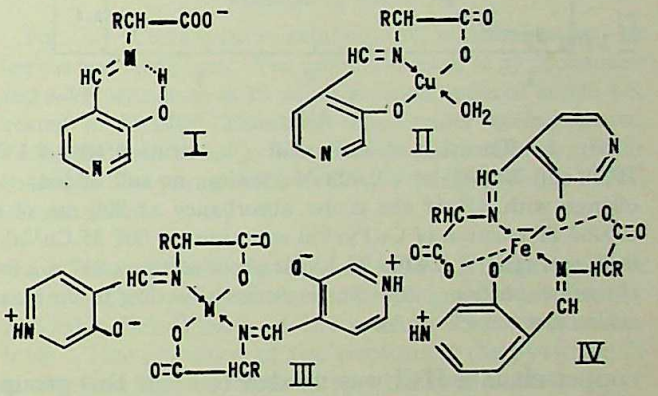
RECEIVED MARCH 15, 1957

The writer has prepared numerous metal chelates of the pyridoxylidene amino acids in crystalline form, usually with the composition M (pyridoxal·amino acid)$_2$, although in the case of copper the composition was M·pyridoxal·amino acid. For the more strongly catalytic Fe(III) and Cu chelates the titration attributed to the pyridine N was found to be shifted downward, relative to pyridoxal, by 3 *p*H units or more, presumably because of linkage of the metal to the phenolic oxygen. In the Mn(II) and Ni(II) chelates this titration was near its usual location, arguing against extensive linkage in this position. These conclusions are supported by infrared spectra showing a neutral structure for the Cu chelate and a zwitterionic structure for the Mn(II) and Ni(II) chelates. Chelation to the phenolic oxygen is probably not necessary for catalytic activity.

Amino acids undergo several metabolically important structural changes in the presence of pyridoxal and transition-group metals, under conditions permitting formation of chelated pyridoxylidene derivatives of the amino acid,[2,3] many of which now have been isolated.[4-6] Although the destabilizing action of carbonyl compounds on amino acids is well known, the role of the metal here is not well defined. Four possible actions have been suggested by Longenecker and Snell[7]: (a) preliminary proton-displacement to facilitate Schiff-base formation, (b) stabilization or destabilization of the Schiff base, (c) maintenance of planarity in the conjugated system of double bonds, and (d) reinforcement of electron-displacement from the α-carbon by the metal ion.

Whether each of these effects actually contributes to a given degradation will depend upon the structure of the catalytic intermediate and the extent of its formation. In particular, atoms of the amino acid will not be held in the plane of the aromatic ring unless the chelation joins them to this ring in a planar structure. Snell and his associates have generally written a 1:1:1 chelate (*e.g.*, formula II), which for copper probably yields 3 coplanar rings. On the other hand several metals with strong catalytic activity may or may not tend to maintain coplanarity; these may not even be chelated to the aromatic ring.

Eichhorn and Dawes[3] postulated the 3-point attachment to the Schiff-base for the Ni(II) as well as the Cu chelate on the basis of spectral changes upon adding pyridoxal to nickel plus alanine solutions. Evidence will be presented here that Mn(II), Zn(II), Fe(II) and Ni(II), in chelates crystallizing from ternary mixtures, instead are largely unbonded to the phenolic oxygen, in contrast to Fe(III) and Cu(II).



Chelate structures: I, Schiff base anion, proposed by Metzler; II to IV, proposed here for metal chelates. The 6-methyl and 5-hydroxy methyl groups have been omitted.

The procedures used have permitted the crystallization of chelates of a large variety of amino acids; of these the chelates of L-valine were selected for this comparison; these were uniformly crystalline. The investigation actually began as an attempt to explain the paradox that an electrically neutral chelate crystallized out when either Mn(II) or Fe(II) combined with two pyridoxylidenevaline anions (formula I) or when Cu(II) combined with only one pyridoxylidenevaline. If one Mn(II) suffices to neutralize the charge of two pyridoxylidenevaline anions, then one Fe(III) should yield a positively charged product, and one Cu(II) combining with a single Schiff-base anion should also form a cation.

These difficulties appear to be avoided if we may freely place protons on the pyridine nitrogens or not as is required for electroneutrality. The isoelectric form of the chelate may be much less soluble than the anionic or cationic forms, so that it crystallizes out, enriching the solution with or depriving it of a hydrogen ion as the case may be. If so the Fe(III) chelate should require for optimal precipitation a more alkaline solution than the Mn(II), Fe(II) or Ni(II) chelate. This is by no means the case. Indeed one can separate the Fe(II) from the Fe(III) chelate by raising the *p*H to 6.0, whereby the Fe(III) chelate, crystallizing at *p*H 4.5 to 5, is redissolved. In order to explain this paradox the *pK* of at least one dissociating group must have very different values in some of these chelates than in others.

Evidence for the Structure of the Chelates from Titrations.—The titration of each of the chelates showed a sigmoid area with a slope approximately appropriate to the dissociation of a free group, taken to be the pyridine N (Figs. 1, 2). In the copper chelate HCl was needed to show this group, titrating with a mid-point at *p*H 5.6 (Fig. 1). One equivalent of OH^- per mole of the Fe(III) chelate showed for it a similarly situated dissociation, centered at *p*H 5.4 and having the theoretical slope. The other pyridine N known to be present in this chelate presumably associated a proton below *p*H 4.5, but the titration could not readily be followed because of the intense destabilization of the chelate in this region.

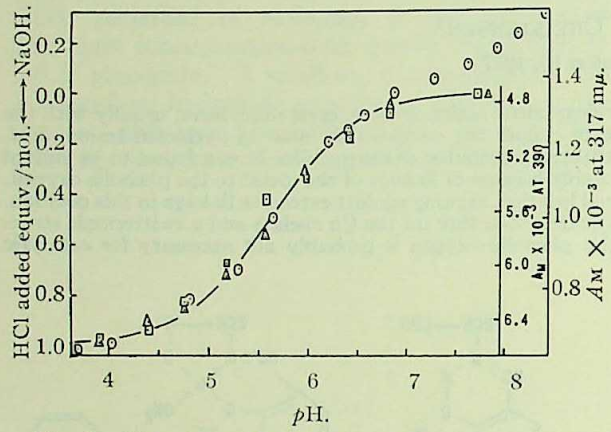

Fig. 1.—Titration of CuPyrVal: ⊙, titration with 0.1 *N* HCl (and NaOH) of a 0.023 *M* solution, no salt added; △, change with *p*H of the molar absorbancy at 390 mμ of a 0.0005 *M* solution of CuPyrVal containing 0.007 *M* $CuVal_2$; ionic strength = 0.016; ⊡, molar absorbancy at 317 mμ for the same solution. The line is drawn according to the mass action law for $pK = 5.6$.

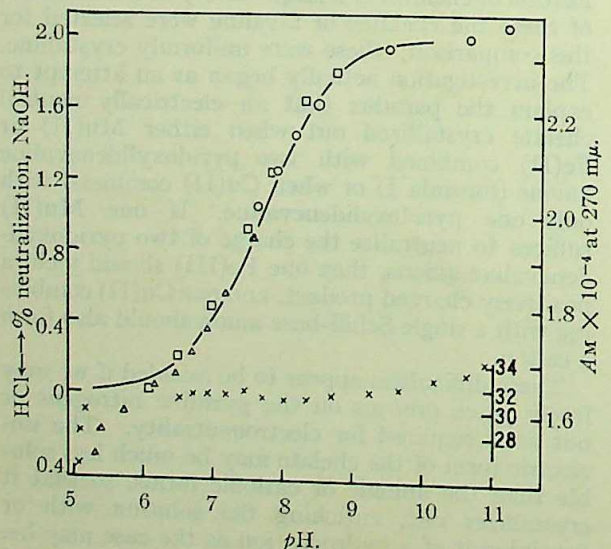

Fig. 2.—Titration of $Ni(PyrVal)_2$: circles, % neutralization *versus* *p*H for 0.05 *M* $Ni(PyrVal)_2$ prepared by dissolving the chelate in 0.45 equivalent NaOH; scale at left. Triangles, titration curve continued into region of lower solubility using 0.005 *M* $Ni(PyrVal)_2$. Squares, the molar absorbancy index for $Ni(PyrVal)_2$ 0.0001 *M* in 0.01 *M* $Ni(Val)_2$, scale at right. Crosses, the molar absorbancy index at 940 mμ *versus* *p*H, 0.005 *M* $Ni(PyrVal)_2$, scale at lower right. Ionic strengths 0.05. The solid line is drawn according to the mass action law for $pK_1 = 7.3$, $pK_2 = 8.1$.

These two titrations were bounded above and in the case of Cu also below by regions of much weaker buffering so that their positions were not equivocal. The Fe(III) chelate consumed little OH^- from *p*H 7 to 9, and the spectral transmittance between 270 and 600 mμ was scarcely altered. Above *p*H 10 it became highly unstable to OH^-. CuPyrVal[8] consumed OH^- all the way from *p*H 7 to 11. This behavior could be differentiated from the group titration under study not only by its low slope, but also by two other observations: (a) changes in the absorbancies at 317 and 390 mμ which occurred symmetrically about the pK' of about 5.6 were terminated at about *p*H 7; (b) the absorbancy at the peak at 670 mμ was nearly constant from *p*H 4 to 7, but was decreased steadily by the further addition of alkali. This titration was attributed to displacement of other ligands from the Cu by OH^-.

The writer has not determined why the absorbancy changes at 317 and 390 mμ occurred when a proton was associated at *p*H 5.6. Possibly a part of the uncharged chelate takes the form of a chelated aminoacetal[9] absorbing at 317 mμ and is converted to the aldimine chelate absorbing at 390 mμ upon proton-addition. Titration of the 0.5 m*M* CuPyrVal in the presence of 20 m*M* $Cu(Val)_2$ (Fig. 1) led to essentially the same results, except that the very rapid destabilization which otherwise occurred just below *p*H 4.0 was prevented. Accordingly the titration behavior was attributed to CuPyrVal and not to its dissociation products, pyridoxal or PyrVal. Clearly CuPyrVal hydrolyzes only slightly even in dilute solution.

The pK's of the dissociating group of the Ni(II) and Mn(II) chelates were not as readily fixed. The Ni chelate gave a dissociation curve centered at about *p*H 7.5; the upper limits of the titrations were quite distinct (Fig. 2), especially when shown in fairly concentrated solutions. The lower limit was also distinguishable, although rapid breakdown took place below *p*H 5.3. H^+ consumption by the group-titration and by the cleavage of the chelate were differentiated as follows. The absorption at 940 mμ, characteristic of the Ni-chelated aldimine structure,[3] remained constant from *p*H 6 to 10; it increased moderately above *p*H 10 (exaggerated in Fig. 3 by the use of a dilute solution) and decreased rapidly below *p*H 6.3, in association with the extra OH^- and H^+ requirements. The titration of the free chemical group in the Ni(II) chelate also was described by an increase in absorbancy at 270 mμ (Fig. 3). The shape of the dissociation curve for $Ni(PyrVal)_2$ suggested that the two dissociating groups had pK's of approximately 7.3 and 8.1 (Fig. 3).

The much less stable Mn(II) and Zn(II) chelates split enough in saturated watery solution to raise the *p*H to 7.8 and 7.4, respectively, and after adjustment to a *p*H below 7.2 and 7.0, respectively,

(8) Abbreviations: Pyr = pyridoxylidene; Val = valine; Orn = ornithine; Pro = proline; Aib = α-aminoisobutyrate.

H^+ consumption continued for many minutes. Accordingly the limit and position of the lower part of the pyridine N dissociation was not obtained accurately; $MnVal_2$ and $ZnVal_2$ were themselves not sufficiently stable to serve as stabilizers above *p*H 8. By dissolving in slightly more than an equivalent of NaOH per mole, the concentration of the chelate could be brought to 0.05 *M*, thereby improving the stability; the part of the titration obtained by adding more alkali to this solution supported a mid-point of about 8.2 for the entire titration attributed to the two pyridine N's in each chelate. In addition the titration above *p*H 7.3 was marked by much less change in stability (as indicated by change in absorbancy at 390–412 mμ) than below *p*H 7.3. These results, together with the infrared spectral demonstration that these two chelates are zwitterionic, indicate that they resemble the Ni(II) chelate.

Interpretation.—The foregoing titration behaviors are the ones required by the isoelectric formulations shown above for the crystalline chelates: the Cu chelate without a proton on the pyridine N; the Fe(III) chelate with a proton on only one pyridine N, and the Ni(II), Mn(II) and Zn(II) chelates with protons on both pyridine N's. Accordingly, the Ni(II), Mn(II) and Zn(II) chelates lose H^+ from their pyridine N's at much higher *p*H values than the Cu and Fe(III) chelates. What is the significance of this difference?

In CuPyrVal and Fe(III)$(PyrVal)_2$ the shift in the position of the pK_a' of the pyridine N from its normal position at about *p*H 8.6 in pyridoxal to about *p*H 5 is a predictable consequence of linkage to the phenolic oxygen. For comparison, O-methylation of pyridoxal lowers this *pK* to 4.75.[10] Similarly, Metzler[9] has concluded recently that this *pK* is lowered to 5.9 in pyridoxylidenevaline by bonding of a proton to the phenolic O, the proton being stabilized in this position by H-bonding to the imine N.[9] Displacement of this proton by a metal ion should reproduce this effect, unless the metal remains unbonded to the phenolic O.

Three explanations may be considered for the absence of the expected downward shift in the *pK* of the pyridine N in the Ni(II), Mn(II) and Zn(II) chelates:

1. Bonding between the metal and the phenolic oxygen may be totally absent.
2. The bonding may be so unstable that the *pK* shift is small.
3. The bonding may have less influence on the acidity of the pyridinium ion whenever it makes the metal electronegative.

According to the last alternative the Fe(III) chelate also ought to have a high *pK* for at least one pyridinium group. The second explanation, which is considered the most likely, means that the linkage of metal to the phenolic oxygen is broken most of the time in solution.[11]

According to this interpretation the most abundant form of the chelates of Mn(II), Ni(II) and zinc at isoelectric *p*H values is zwitterionic, and simply a double Schiff-base of the amino acid–metal chelate. The presence of the proton on the pyridine N is attested by the infrared spectra (see below).

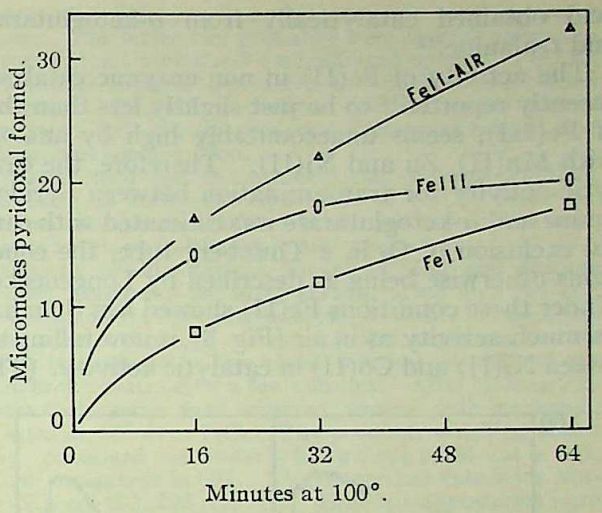

Fig. 3.—Comparative catalysis of transamination by ferrous and ferric ions. Ten millimoles each of pyridoxamine and α-ketoglutarate in 10 ml. of solution buffered at *p*H 4.8, heated in N_2-filled Thunberg tubes under boiling water. Fe, 0.000125 *M* added as ferrous ammonium sulfate or ferric chloride. The triangles show values we obtained with Fe(II) in open tubes.

The Fe(II) chelate was not readily prepared free of Fe(III); its titration was difficult because of intense instability to O_2 and OH^-; presumably it resembled the Mn(II), and Ni(II) chelates in structure. The much greater stability of the Ni than the Mn and Zn chelates discourages one from attributing the structural difference merely to low chelate stability.

The somewhat lower catalytic activity in transaminations and similar reactions of the Mn(II). Zn(II) and Ni(II) chelates suggests a rather limited role for linkage to the phenolic O in this function. These results do not permit us to conclude whether bonding to the phenolic O facilitates catalysis by producing planarity or by stabilizing the aldimine link or not at all. Incidentally, a low pK_a for the pyridine N, other factors being equal, might appear to handicap the catalytic activity of the chelate at higher *p*H values, if the proton carried on this group must receive an electron in the electromeric shift believed to underly the catalysis.[2]

The illustrated bonding of both carboxyl groups to Fe(III) has not been proved, but is proposed for the following reason: If an amino acid–metal chelate reacts with pyridoxal, bonding of the metal to the phenolate ion requires at above *p*H 6, as shown here, the displacement of a proton from the pyridinium group. Accordingly, the link to the carboxylate group probably is more stable than that to the phenolic O. The chelate does not contain a pyridine N titrating in the *p*H range 7–9; accordingly, Fe(III) is taken to be bonded to both phenolic oxygens; hence both carboxyl groups also may well be bonded. Incidentally, the bonding of a second Schiff-base to the metal shown here has been proposed to explain the excess of L-glutamic

(10) D. E. Metzler and E. E. Snell, THIS JOURNAL, 77, 2431 (1955).

(11) The finding that the zinc chelate has the composition $Zn(PyrVal)_2$ provides additional support for assigning structure III to this group of chelates. With a coördination number of 4 it is unlikely that the zinc ion is joined to each of the two Schiff base residues at three points.

acid obtained catalytically from α-ketoglutarate and L-alanine.[12]

The activity of Fe(II) in non-enzymic catalysis, recently reported[13] to be just slightly less than that of Fe(III), seems unaccountably high by analogy with Mn(II), Zn and Ni(II). Therefore, the catalytic activity for transamination between pyridoxamine and α-ketoglutarate was estimated with careful exclusion of O_2 in a Thunberg tube, the conditions otherwise being as described by Longenecker. Under these conditions Fe(II) showed less than half as much activity as in air (Fig. 3), it now falling between Ni(II) and Co(II) in catalytic activity. (This experiment was kindly made by Mr. Walter B. Dempsey of this Laboratory.)

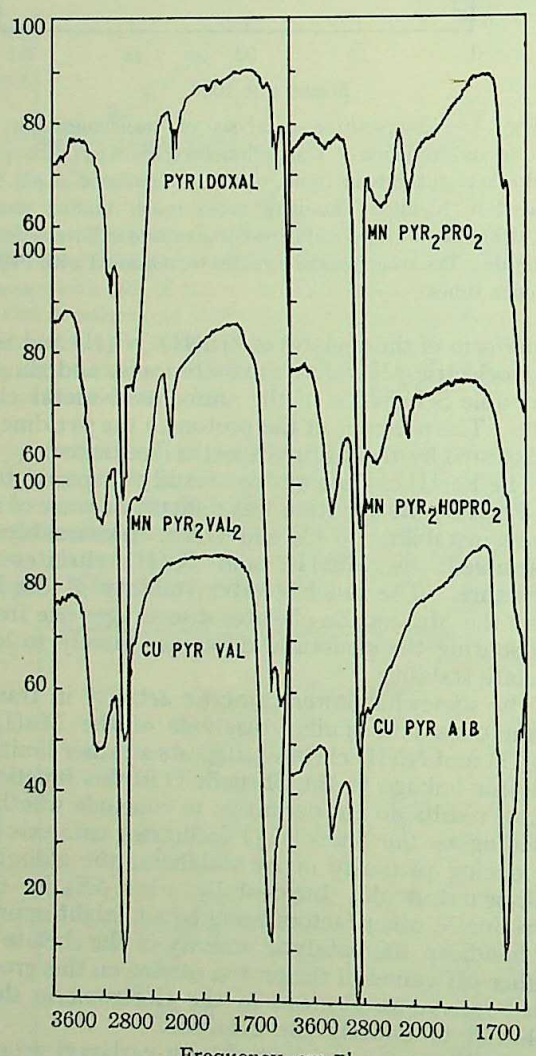

Fig. 4.—Portions of infrared spectra of chelates compared with that of pyridoxal. One frequency scale interval is 400 cm.$^{-1}$ from 4000 to 2000 cm.$^{-1}$ and 100 cm.$^{-1}$ below 2000 cm.$^{-1}$. Attention is directed to: (a) increased aliphatic hydroxyl absorption (*ca.* 3200 cm.$^{-1}$) and appearance of the aldimine absorption (*ca.* 1600 cm.$^{-1}$) upon formation of the amino acid but not the imino acid derivatives; and (b) the ionic properties (1900 to 2600 cm.$^{-1}$) of Mn but not of Cu chelates. Ni(II) and Zn(II) chelates gave curves resembling those of Mn(II) chelates.

Infrared Absorption.—The infrared spectrum of CuPyrVal on one hand is very different from the spectra of the corresponding Mn(II), Zn(II), Ni(II) chelates, on the other. The latter two resemble pyridoxal in having prominent peaks at about 2100 and 2700 cm.$^{-1}$ (Fig. 4), thus supporting their zwitterionic structure. The isoelectric copper chelate in contrast, shows essentially no absorption in this region, revealing it to be uncharged. This result confirms the presence of protons on the pyridine N atoms in crystals of the Mn and Ni chelates precipitating at neutral *p*H, and the absence of such a proton on CuPyrVal precipitated at similar *p*H values. The spectrum of the Fe(III) chelate in the indicated region has an appearance intermediate between the non-ionic Cu and the strongly ionic Mn chelate. Figure 4 also shows portions of the infrared spectra of chelated pyroxylidene derivatives of proline and α-aminoisobutyric acid, showing also the non-ionic nature of the copper chelates and the decreased absorption attributable to the hydroxymethyl group and to an aldimine group, undoubtedly arising from their being largely in aminoacetal forms.

Isotopic Study of Metal Exchange.—The usual procedure is to mix the chelate under investigation with a labeled complex of the same metal (the latter complex being known to exchange rapidly) and then to reseparate the two complexes. Instead, in the cases of Fe(III) and Mn(II) use was made of the soluble monopyridoxylideneornithine chelates (which appear to have below *p*H 7.5 the usual structure involving only one amino group). A large portion of the less-soluble pyridoxylidenevaline chelate readily was reisolated for radioactive counting. (More could have been recovered but with an undesirable delay.) The method yields information on the exchange rate between the two chelates without telling which exchange is rate-limiting. For the copper chelate, exchange between $Cu^{64}Val_2$ and CuPyrVal was studied, the latter being reisolated upon concentration of the solution.

The Fe of Fe(III)$(PyrVal)_2$ recrystallized from a solution also containing half the molar quantity of $Fe^{59}(PyrOrn)_2$ by lowering the *p*H from 7.3 to 4.7, and collected in a minimal operating time of 5 min., had only 11% of the specific activity shown by the 46% of the Fe remaining in solution. When the solution was first incubated 30 min. at 0°, the exchange was 43% complete; in 15 min. at 25°, 58% complete.

$Mn(PyrVal)_2$ in contrast exchanged completely with the corresponding labeled ornithine chelate in the minimal 20 min. (mostly at 0°) required for mixing, concentrating to reprecipitate it, and collecting the precipitate. The proportions taken and reisolated were similar to those used with Fe. The copper of CuPyrVal likewise exchanged very rapidly with Cu^{64} of $CuVal_2$ (representing 1/5 of the total Cu), being completely exchanged in the 15 minutes at 0–15° required to reisolate the CuPyrVal.

These results appeared to limit to the Fe(III)

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

the possibility of testing for biological acceleration of exchange. Another method, however, gave a lower rate of exchange for CuPyrVal. When a 0.0005 *M* solution was brought to 0.1 *M* in valine at *p*H 7, the decrease in absorbancy at 380 mμ due to the reaction CuPyrVal + Val → Cu⁺Val + Pyr⁻Val, continued for more than an hour at 25°, with a half-time of over 5 min.

Acknowledgments.—The writer is grateful to Miss Jane LeFever for assistance with some of the experiments, to Miss Lois Walker for copper and amino acid analyses, and to Mr. Walter B. Dempsey for performing the experiments of Fig. 3. He has benefited from discussing the infrared spectra with Dr. J. L. Johnson of the research laboratories of the Upjohn Company.

Experimental

Apparatus and Materials.—A Beckman model G *p*H meter and model DU spectrophotometer were used. To permit reading solutions as concentrated as possible (to diminish dissociation) 0.5 cm. photometer cells usually were used. Highly active Fe^{59} and Cu^{64} were obtained from Carbon and Carbide Co., Oak Ridge, and Mn^{54} from Nuclear Science and Engineering Corporation, Pittsburgh; all were used as the chlorides. Disintegrations were counted in a Nuclear-Chicago well-type scintillation counter, at 20 to 200 times background rates. Infrared spectra were obtained in a Nujol mull using a Perkin–Elmer instrument.

Pyridoxal hydrochloride (Merck and Co.) was converted to the free base by adjusting a strong aqueous solution to *p*H 6.5 with potassium hydroxide; the crystals were washed, and dried over P_2O_5 at room temperature. The inorganic salts were of analytical reagent grade. The amino acids, when optically active, were the L-forms, and were obtained from Nutritional Biochemicals, Inc., or in a few cases from the H. M. Chemical Company. Reagent grade methanol and ethanol were used without purification.

General Procedure for Preparation of Chelates.—The amino acid was dissolved in an equivalent quantity of methanolic or aqueous sodium hydroxide, and a mole of pyridoxal dissolved in this solution to form the sodium salt of the Schiff base, which remained in solution. The metal salt was then added in aqueous or methanol solution, using the metal acetate in the latter case. If crystallization did not follow from methanolic solutions, ethanol (for small-molecular amino acids) or water (for large-molecular amino acids) was added, often by way of the vapor phase. Acetate added either as the metal salt, or separately as an acetate buffer, in several cases served to accept hydrogen ion from the chelate to facilitate crystallization in the isoelectric form.

Composition of the chelates could be determined by analyzing colorimetrically a solution in 0.1 *N* sulfuric acid for pyridoxal,[14] for amino acids[15] and for the metal, Cu being determined as the diphenyldithiocarbamate derivative,[16] manganese after oxidation to permanganate,[17] iron as the complex ferric thiocyanate ion,[18] and nickel as the dimethylglyoxime chelate.[19]

Procedure for Cu Chelates, Illustrated by CuPyrVal.—One hundred and fifty micromoles of the Schiff-base in 0.5 ml. of methanol was treated with 0.36 *M* (approximately saturated) aqueous cupric acetate, followed by 2 ml. of ethanol. In a few minutes the solution filled with long green needles. After cooling at 5° overnight, the crystals were removed and washed with ethanol, and dried at 56° over P_2O_5. The product, weighing 35 to 40 mg., contained one valine in 343 g., one pyridoxal in 338 g. and one copper in 329 g.; the theoretical 1:1:1 composition $C_{13}H_{16}O_4N_2Cu$ corresponds to a molecular weight of 328. The chelate dissolved in water to about 0.025 *M* at 25°. Similarly, 1:1:1 compositions were shown by the isoleucine, methionine, β-alanine, phenylalanine, α-aminoisobutyric and sarcosine chelates. The latter two probably were largely aminoacetals rather than aldimines[9] (see infrared spectra, Fig. 5); the α-aminoisobutyric derivative was dark brown rather than green. Crystalline chelates obtained with several other amino acids showed moderate excesses of copper over the theoretical composition.

Chelates could also be obtained from aqueous solution, often using an additional equivalent of NaOH to render them less soluble; the chelates of alanine and proline were obtained in this way although in amorphous form.

Procedure for Manganous, Nickelous, Zinc and Ferrous Chelates, Illustrated for Mn(PyrVal)₂.—One hundred and fifty micromoles of the Schiff base in 0.5 ml. of methanol was treated with 0.15 ml. of a fresh 0.5 *M* manganous acetate solution in methanol. The brown solution crystallized out square brown plates after a few minutes. After chilling 2 or 3 hours the crystals were removed, washed with methanol, and dried at 56° over P_2O_5. The product, weighing about 25 mg., contained one valine in 310 g., one pyridoxal in 305, and one manganese in 603. The theoretical values for Mn(PyrVal)₂ are 292, 292 and 583. Similar compositions were obtained for chelates from alanine, serine, threonine, isoleucine, proline and hydroxyproline. The latter two probably were aminoacetals, the Schiff bases and the chelates being light yellow in color. For Mn, glycine is the only amino acid so far obtained in a 1:1:1 chelate, and that from a non-aqueous solution.[5]

Manganous pyridoxylidenevaline and zinc pyridoxylidenevaline also were obtained readily by dissolving 200 micromoles each of L-valine and pyridoxal in 0.2 ml. of *N* NaOH, and then adding 0.1 ml. of *M* aqueous manganous acetate or zinc chloride. The square plates were washed with water, in which the solubility was, for Mn(II), about 5.6 m*M* at 0°, 8.5 m*M* at 25°, and 12 m*M* at 37°; for Zn, about 4 m*M* at 25°.

Ni(PyrVal)₂ was obtained readily by the latter procedure (clear yellow rectangular blocks), as was Fe(II)(PyrVal)₂ (clear blue square and octagonal plates) at 0° although oxygen had to be excluded strictly in the latter case to prevent autoöxidation to the red Fe(III) chelate.

Fe(III)(PyrVal)₂.—0.2 ml. of a molar aqueous solution of the sodium salt of the Schiff base, formed as usual, was treated with 0.1 ml. of a molar aqueous solution of ferric chloride. A deep red color resulted, and crystallization began at once. 0.1 ml. of an acetate buffer (1.5 molar each in acetic acid and sodium acetate) was then added. After standing overnight in the refrigerator the crystals were separated and washed with cold water to yield 45 mg. of chelate. This was recrystallized by dissolving carefully in 0.3 *N* NaOH, keeping the *p*H below 8 and centrifuging to clarify the deep red solution. Upon adding 0.1 ml. of the acetate buffer the chelate recrystallized in beautiful red complexly truncated right-triangular prisms (orthorhombic hemimorphic). The crystals upon redissolving in water produced a *p*H below 4.5 which rose rapidly because of the low stability at this *p*H, until the dissociation products reached levels which stabilized the chelate.

The crystalline product contained one pyridoxal in 290, one valine in 287, one Fe in 579 mg. (theoretical m.w. = 583).

Titrations were made at 25–26° at the ionic strengths indicated in the figures, disregarding the ionic strength arising from any dipolar ion.

Isotopic Exchange.—0.5 ml. of an aqueous solution, *p*H 7.3, containing 80 micromoles of previously crystallized Fe(III)(PyrVal)₂ chilled to 0° was mixed with 0.25 ml. of a similarly cold solution of 40 micromoles of Fe^{59}(III)(PyrOrn)₂ (prepared in solution by mixing the components) also at *p*H 7.3. Instantly 0.15 ml. of 3 *M* acetate buffer *p*H 4.7 was mixed with the solution. Within 40 sec. of the original mixing centrifuging was begun and continued 4 min. at high speed. The crystalline precipitate was washed three times with water at 0°. In other experiments an interval at 0 or 25° was allowed before addition of the acetate buffer.

Four ml. of a saturated Mn(PyrVal)₂ solution (50 micromoles) was concentrated to 1.5 ml., and chilled in ice; then 25 micromoles of Mn^{54}(PyrOrn)₂ was added in 0.3 ml. of water (both solutions at *p*H 7.0). Concentration *in vacuo* 4 min. (10–15°) started crystallization; this was continued 10 min. at 0°. After 5 min. of centrifuging the liquor was removed and the precipitate washed 3 times. Forty per

cent. each of the Mn and of the radioactivity was precipitated; the precipitate contained the appropriate amounts of pyridoxal and amino acid.

To 4 ml. of ice-cold 0.020 *M* CuPyrVal, previously crystallized, was added 0.33 ml. of 0.060 *M* $Cu^{64}Val_2$, both solutions at *p*H 7.2 and the solution concentrated quickly in the cold to about 0.5 ml. After holding 5 min. at 0°, the suspension was centrifuged 4 min. at high speed, and the crystals washed twice with water. In a representative test, 32.2% of the copper and 33.1% of the radioactivity had been precipitated.

The Hydrogen Ion Equilibria of a Single Group Attached to Serum Albumin: Some Implications as to the Surface Characteristics of Protein Molecules

BY IRVING M. KLOTZ AND JANET AYERS

RECEIVED MARCH 18, 1957

The ionization equilibria of the dimethylamino group of $(CH_3)_2N$—⟨⟩—N=N—⟨⟩—Hg— attached to bovine serum albumin have been studied in various aqueous solvents. In water the pK_a of this dye when attached to cysteine is 3.3; when linked to protein, 1.8. In 8 *M* urea, the pK_a is approximately 3.3 for the dye on the protein or amino acid, near 5 in 0.03 *M* dodecyl sulfate in both cases. These results and the more detailed behavior of the ionization equilibria are not in concordance with electrostatic expectations. It is suggested that the pK_a's reflect the structure of the water envelope of the protein. A variety of observations can be described in terms of changes in the order in this aqueous framework.

Introduction

Proton equilibria of acid–base groups on proteins have been the subject of numerous investigations for over 50 years. The early literature has been summarized by Cohn and Edsall[1] and more recent work has been reviewed by Steinhardt.[2] In general, the maximum uptake or release of protons corresponds well with the number of acidic and basic groups presumed to be on the protein from analyses of its content of specific amino acids. The course of the *p*H-titration curve, however, usually differs markedly from what one might calculate for the corresponding number of comparable proton-dissociating groups in an ordinary aqueous environment.

The modified acidity of groups on a protein molecule has been ascribed in part to electrostatic interactions between successively dissociating sites.[3–6] These interactions account reasonably well for the titration curves of some proteins[4,7] but more often there are large deviations, in both directions, from electrostatic predictions. Such discrepancies have been attributed to changes in molecular weight or shape,[8–10] to binding of small ions[6] and to the influence of hydrogen bonding between polar groups on the *pK*'s of proton-dissociating groups.[7,11]

The interpretation of acid–base ionizations of protein molecules is complicated in part by the fact that the measurements reflect the composite behavior of a large number of groups. Even in limited regions of *p*H, for example, 3–5, where only one type of equilibrium is involved, —COOH ⇌ —COO^-, the number of participating carboxyl groups is very large. There are usually fewer imidazole or tyrosine groups in a protein, but even these are commonly present in appreciable number and their proton equilibria overlap those of amino groups, so that a sharp separation cannot be made by electrometric methods.

The proton-donor group usually present in smallest number in proteins is the sulfhydryl. A direct study of its dissociation by electrometric methods is not feasible, however, since the equilibria of amino and tyrosine groups would obscure the contribution of –SH. In principle, it might be possible to adapt the optical method used by Benesch and Benesch[12] for the determination of pK_{SH} of cysteine, a method which takes advantage of the appearance of an absorption peak at 240 mμ when –SH is converted to $-S^-$. In most proteins, however, absorption of light at this wave length is very strong even in dilute solution and even when the mercaptan group is not ionized. It would be difficult, therefore, to measure the small differences in absorption accompanying ionization of the –SH, against the strong background absorption of the relatively concentrated protein solution which would be needed to supply an appreciable concentration of mercaptan groups.

An alternative approach which could still take advantage of the small number of –SH groups on a protein would be to introduce a molecule which reacts specifically with the mercaptan side-chain, and which contains a substituent whose proton uptake, or release, is accompanied by a marked change in visible absorption spectrum. A class of such molecules are the azomercurials, (I), in which

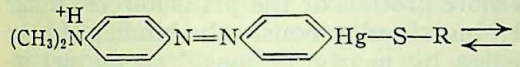
X is the substituent with acidic or basic properties (*e.g.*, $(CH_3)_2N-$ or $-OH$). These substances combine specifically with the mercaptan groups of proteins[13] and undergo marked alterations in absorption over a characteristic *p*H range, depending on the nature of the substituent. From changes in the spectra one can follow the ionic state of these substituents in the protein environment without obscurant effects from other groups of the protein which are simultaneously involved in acid–base equilibria.

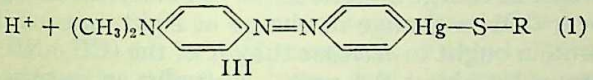
The complex between one such mercurial, 4-(*p*-dimethylaminobenzeneazo)-phenylmercuric acetate [(I) with X = $(CH_3)_2N-$], and a protein with one –SH group, bovine serum albumin, has been previously prepared.[13] Its proton equilibria, described in this paper, provide a basis for examining the surface characteristics of this protein.

Experimental

The acidity constant for the ionization



II



III

(1)

was computed from changes in the visible absorption spectrum with *p*H. The acidic species II has an absorption peak near 520 mμ, the conjugate base at about 460 mμ. The fraction of the azomercurial in the acid form, α, was calculated by means of the equation

$$\alpha = \frac{\text{optical density soln. } \alpha - \text{optical density basic soln.}}{\text{optical density very acid soln.} - \text{optical density basic soln.}} \quad (2)$$

the optical densities all being measured at the same wave length, usually 520 mμ. A graph was then made of α *vs.* *p*H. For most comparisons the value of the *p*H at which α = 0.50 was taken as the *pK*, since for reaction 1

$$pK = p\text{H} - \log \frac{(\text{III})}{(\text{II})} = p\text{H}_{\alpha=0.5} \quad (3)$$

Where α = 0.5, (II) = (III). For some purposes, *pK*'s were calculated at several *p*H's by substitution of the appropriate values for II and III in eq. 3.

In eq. 1, R represents either the protein, bovine serum albumin, or a small-molecule mercaptan, such as cysteine. When the protein was studied, a 0.2% solution (3×10^{-5} *M*) was prepared in the desired solvent and to this was added a few crystals of azomercurial. The solution was stirred gently for several hours, until an appreciable amount of dye had dissolved, as judged by the intensity of the color. The protein-linked dye was in the range $(0.8–1.5) \times 10^{-5} M$. A similar procedure was used with cysteine, except that cysteine hydrochloride was at a concentration of 1×10^{-4} *M*; the cysteine–azomercurial complex, nevertheless, was maintained at about 1×10^{-5} *M*.

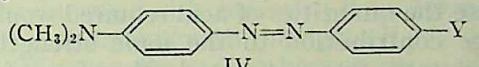
To the solution of bound azomercurial was added a small portion of hydrochloric acid (0.05–0.5 *M*) or sodium hydroxide (0.01 *M*) and the optical density was measured. A second portion of acid or base was then added and the absorption measured again. This was repeated[14] until some 20 points were available for graphing. Suitable corrections were made for dilution of the solution by added acid or base. In most cases a full absorption spectrum was taken over the region 350–600 mμ. From a graph of optical density *versus* *p*H, α was computed, and then it was plotted as a function of *p*H, so that the *pK*'s could be determined readily.

Crystallized bovine serum albumin was purchased from Armour and Company. Previous experiments[13] with the same samples have shown 0.66 mole SH per mole protein. Cysteine hydrochloride was obtained from Nutritional Biochemical Corp., and cysteine ethyl ester and glutathione from Schwarz Laboratories. Thioglycolic acid was given to us by the Toni Research Laboratories and thiomalic acid by Evans Chemetics. The sodium dodecyl sulfate was a specially purified sample supplied by the Fine Chemicals Division of E. I. du Pont de Nemours and Company. The urea and inorganic salts were reagent grade. Sorbitol monohydrate was purchased from Mann Research Laboratories.

The absorption of light was measured with the Beckman spectrophotometer, model DU, at about 25°; *p*H was obtained with a Beckman model G *p*H meter.

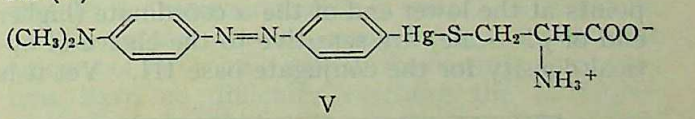
Results

Choice of Reference Compound.—The pK_a of dimethylaminoazobenzene (IV, Y = H)



IV

in aqueous solution is 3.5 and is not very sensitive to the nature of the opposite substituent Y.[15] For example, with Y = OH or Y = SO_3^-, the *pK* is 3.4. Nevertheless, if we wish to examine the effect of protein environment on the acidity of the $(CH_3)_2N-$ group, it seemed desirable to have information on the behavior of the azomercurial attached to a small-molecule mercaptan, so that any effect of the –Hg–S– linkages could be accounted for. Among the small molecules examined were thioglycolic acid, thiomalic acid, glutathione, cysteinyl ethyl ester and cysteine. The last proved most convenient experimentally, for it combined with the azomercurial rapidly and the complex obtained was stable over long periods of time. S-(*p*-Dimethylaminobenzeneazophenylmercuric) - cysteine (V)



V

was used, therefore, as a reference compound to ascertain the behavior of the $(CH_3)_2N-$ group in a non-protein environment.

Effect of Salts on pK_a.—Titrations with the cysteine–azomercurial (V) were carried out in water and in 0.1 *M* NaCl. The optical titration curves (Fig. 1) were normal, that is, similar to those

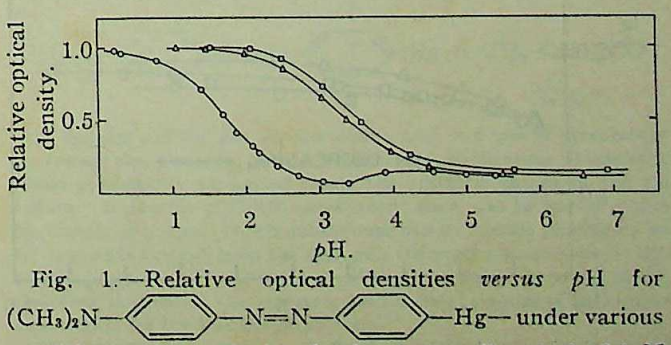


Fig. 1.—Relative optical densities *versus* *p*H for $(CH_3)_2N-C_6H_4-N=N-C_6H_4-Hg-$ under various conditions: O attached to bovine serum albumin in 0.1 *M* NaCl; △, attached to cysteine, in aqueous solution, with no salt; □, attached to cysteine, in 0.1 *M* NaCl.

for related substituted azobenzenes in aqueous solution, and the pK in solutions of constant ionic strength (3.39) was not appreciably different from that in water (3.26). For an ionization of the type represented by eq. 1, one would not expect much sensitivity to ionic strength.

When the azomercurial is attached to the protein, the titration curve of the $(CH_3)_2N-$ group is markedly different than in the cysteine complex. The course of a typical titration is shown in Fig. 1. Proceeding from pH 6 down, we find first a plateau, followed by a region between pH's 5 to 3.5 with a small hill and then a very steep rise in absorption between pH 3 to about 1, with every indication of a plateau below pH 1. It was not feasible to determine the height of the acid plateau by adding further quantities of strong acid both because of the instability of the protein in such solutions and because the quantities of acid required would make a large contribution to the ionic strength. The acid plateau was estimated, therefore, from an extrapolation of the optical density readings *versus* $1/(H^+)$. Having obtained the absorption of the fully acid form and taking the lowest readings of the optical density, near pH 3, as the absorption of the basic form of the dye, we can read off the pK readily as the pH at which the absorption is midway between the two extremes. For the azomercurial attached to bovine serum albumin in water the pK is 1.9 (Table I), in 0.1 M NaCl, 1.72.

One can also compute pK's from *each* of the optical density readings not too close to the completely acid or basic forms. Such a calculation has been made for the experiments in 0.1 M and in 0.5 M NaCl, and the results have been assembled in Fig. 2. There is some indication of an increase in pK with decreasing pH. We are not certain, however, that this trend is significant, for the points at the lower end of the α coördinate (higher end of pH scale) are sensitive to the choice of optical density for the conjugate base III. Yet it is in this range (pH 3) that the protein undergoes some modification leading to changes in the spectrum of III, as is apparent from the small hill in Fig. 1.

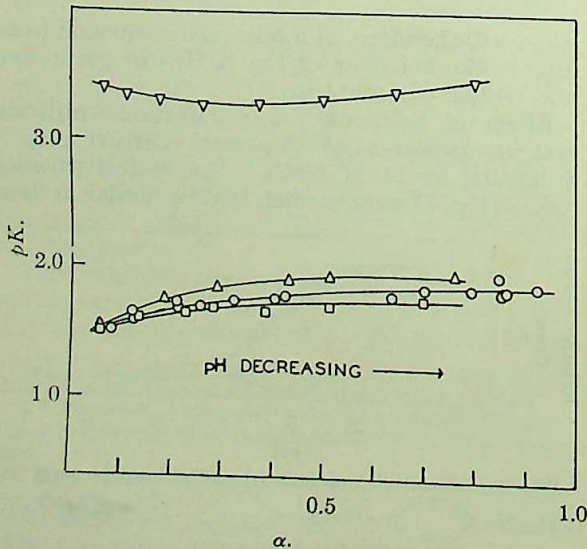

Fig. 2.—Variation of pK with extent of formation (α) of $(CH_3)_2\overset{+}{N}H$-form of the azomercurial attached to protein: △, in water; ⊡, in 0.1 M NaCl; ⊙, in 0.5 M NaCl; ▽, in 8 M urea.

In any event, whether the trend in Fig. 2 is real or negligible, it is apparent that the pK does *not decrease* with decrease in pH as one might expect from a consideration of electrostatic factors. As the pH is lowered, one would expect the protein to acquire an increasingly positive charge which ought to lower the pK of the $(CH_3)_2NH^+-$ group. In solutions of moderate ionic strength, bovine albumin becomes almost saturated with hydrogen ions when the pH drops to near[10,16] 2; thus that portion of the ionization of the azomercurial on the protein which takes place below pH 2 occurs at essentially constant protein charge and the pK's in this region should not change appreciably with pH. In the range from pH 2 to 3, however, the protein does change its charge appreciably. In the absence of salt, for example, bovine albumin acquires 25 more protons as the pH is lowered from[16] 2.8 to 2.1; but simultaneously the binding of chloride increases by nearly 17 ions,[16] so the net increase in charge is eight units. For an ionic strength near 0.01, a change in charge of eight units on the protein ought to *decrease* the pK of the $(CH_3)_2NH^+-$ group by about 0.4 unit. Actually an *increase* is observed (Fig. 2) over the pH range 3 to 2. It would seem, therefore, that the ionization of the $(CH_3)_2NH^+-$ group is unaffected by changes in charge on the protein, at least within the pH region open to examination.

TABLE I

ACIDITY CONSTANTS OF

$(CH_3)_2\overset{+}{N}H-C_6H_4-N=N-C_6H_4-Hg-S-R$ AT 25°

R	Solution	pK_a
$-CH_2-\underset{\displaystyle NH_3^+}{\underset{\vert}{CH}}-COO^-$	Water	3.26
	0.1 M NaCl	3.39
	8 M urea	3.42
	0.03% sodium dodecyl sulfate	(~3)
	1.0% sodium dodecyl sulfate	5.18
Bovine serum albumin[a]	Water	1.9
	0.1 M NaCl	1.72
	0.5 M NaCl	1.80
	1 M urea	2.38
	6 M urea	3.25
	8 M urea	3.32
	0.03% sodium dodecyl sulfate	<1.3
	1% sodium dodecyl sulfate	4.7
	40% sorbitol	1.4
	60% sorbitol	1.3

[a] It should be emphasized that in the presence of protein, the pK_a listed refers only to the midpoint of the titration curve, for titrations of the azomercurial linked to serum albumin cannot be fitted to the simple form of equation (3).

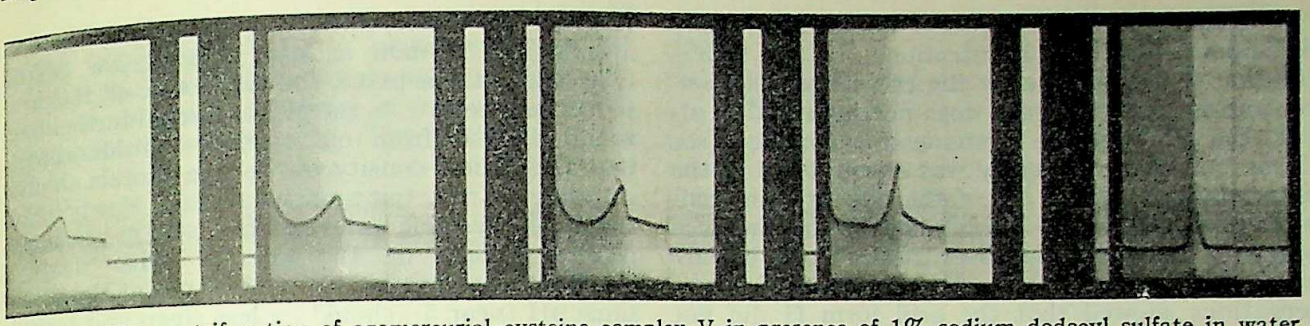

Fig. 3.—Ultracentrifugation of azomercurial–cysteine complex V in presence of 1% sodium dodecyl sulfate in water. The boundary of the dye, shown by the edge of the yellow color (dark area), coincides with the boundary of the dodecyl sulfate micelles, given by the peak in the schlieren pattern. Spinco ultracentrifuge model E was used with synthetic boundary cell rotating at 59,780 r.p.m. Purple filter inserted to increase color contrast. Times (in minutes) after formation of boundary (reading from right to left): 0, 11, 27, 43, 59. In absence of dodecyl sulfate, the color of a corresponding dye (methyl orange) diffused throughout the entire field in about 20 minutes.

A similar conclusion would be reached from the small effect of 0.5 *M* NaCl, as compared to water, on the *p*K of this group (Table I).

Effect of Urea.—The significance of *p*H, as measured with a glass electrode standardized in aqueous buffer, may be somewhat ambiguous in concentrated urea solutions. This ambiguity was minimized by obtaining first the *p*K of the $(CH_3)_2NH^+-$ group of the azomercurial complex of cysteine. This *p*K in 8 *M* urea, 3.42 (Table I), is not significantly different from that in water, and hence the mercurial attached to the small molecule provides a stable reference point.

Turning to the protein complex, we find a marked change in *p*K in 8 *M* urea, 3.32 as compared to 1.9 in water. It is particularly interesting that in aqueous urea the dye attached to protein behaves in its ionization just like the dye in water free from the protein. The urea thus acts like an "unmasking" reagent just as it does in connection with other groups, such as mercaptan, on proteins. An important distinction must be made in the present instance, however, in that naturally masked groups (such as –SH) were built into the protein during its biosynthesis, whereas the $(CH_3)_2N-$ group was attached thereafter.

A 6 *M* concentration of urea has about the same influence as the 8 *M* solution (Table I). Substantially lower concentrations, such as 1 *M*, have much smaller effects, but nevertheless in the same direction, *i.e.*, an increase in *p*K in the presence of urea. Our observations with $(CH_3)_2NH^+-$ thus parallel those of Foster and Sterman[17] in their electrometric titrations of the carboxyl groups of serum albumin in the presence of urea.

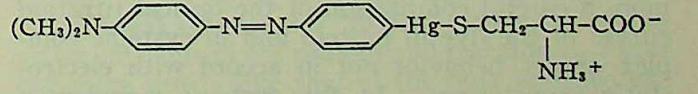
Effect of Sodium Dodecyl Sulfate.—This reagent, in a class with urea as a denaturant, has markedly different effects on the ionization of the $(CH_3)_2NH^+-$ group than does urea. In a 1% solution (0.03 *M*), sodium dodecyl sulfate forms micelles[18] which carry a large negative charge. In this solution the cysteine complex of the azomercurial has a *p*K of 5.18 (Table I), very substantially higher than in water alone. This elevation of the *p*K might be due to the preferential absorption of the cationic acid form of the dye by the anionic micelles, or to the existence of a higher concentration of protons within the micelles. The former explanation may be ruled out, however, from ultracentrifugation experiments with the dye and 1% dodecyl sulfate (Fig. 3); the yellow basic form of the dye travels with the anionic micelle. Thus it seems clear that a mixed micelle is formed by the azomercurial and dodecyl sulfate and that the equilibrium of eq. 1 is shifted to the left because of the higher H^+ concentration within the anionic micelle.[19] If the *p*H of the solution external to the micelle is used to compute pK_a within the micelle, the resultant pK_a comes out higher than that in the aqueous phase.

The behavior of the azomercurial attached to the protein in the presence of 1% dodecyl sulfate is similar to the cysteine complex, the *p*K, 4.7, being almost three *p*H units above that in water alone. It seems fair to conclude, therefore, that this detergent forms micelles on the protein surface, since the dye attached to the protein shows acid–base properties very similar to those of the cysteine–dye complex in the mixed micelle in water. The micelle on the protein surface must have a substantial amount of water built into its framework, since protons have no difficulty reaching the $(CH_3)_2N-$ group buried within. The strong negative charge of the sulfate groups at the ends of the aliphatic chains produces an increase in the local concentration of hydrogen ions, so that the concentration of $(CH_3)_2\overset{H^+}{N}-$ is greatly increased.[20]

(17) J. F. Foster and M. D. Sterman, THIS JOURNAL, **78**, 3656 (1956).

(18) M. L. Corrin and W. D. Harkins, *ibid.*, **69**, 683 (1947).

(19) It is of interest to note in passing that these results give some insight into the constitution of detergent micelles. In a mixed micelle of



with dodecyl sulfate, the dipolar amino acid end would presumably be facing the aqueous phase, whereas the azobenzene framework would presumably be buried inside the aliphatic chains of the C_{12} sulfate. Hence the $(CH_3)_2N-$ substituent must also be buried within the lipophilic phase. If this substituent has no trouble picking up an H^+ ion, as is evident from the high *p*K, the proton must have no difficulty penetrating the cluster of aliphatic chains. It seems likely, therefore, that within this cluster is a substantial amount of H_2O acting as a vehicle for the transfer of protons.

(20) Micelle formation on the surface of protein molecules would also shift the equilibrium

The effect of sodium dodecyl sulfate is critically dependent on its concentration. In an 0.03% solution (0.001 *M*), below the critical micelle concentration, the detergent does not appreciably affect the pK[21] of the cysteine–dye complex (see Table I). Some difficulty was encountered in the determination of the pK of the dye–protein compound because of its insolubility in the presence of 0.03% dodecyl sulfate over the *p*H range 5.4–2.7 and below *p*H 0.8. Nevertheless the optical observations showed that the acid form II did not even begin to form until the *p*H dropped to about 2, and that the pK for the ionization of eq. 1 must be below 1.3. It is immediately evident, therefore, that at 0.001 *M* concentration the detergent does not form micelles on the surface of the protein; otherwise the pK ought to be much above 1.8–1.9. There can be little doubt, nevertheless, that the detergent ions are bound to the protein since even at higher *p*H's where the protein carries a negative charge essentially all of the anionic detergent in solution is bound to the protein.[22] In our solutions, acid to the isoelectric point, binding would be further strengthened by the positive charge of the protein.

Despite the binding of some 30 anions by each albumin molecule[23] and the consequent acquisition of some 30 negative charges by the protein, the pK_{H^+} of the $(CH_3)_2N-$ group was not elevated, as one would expect from simple electrostatic considerations. Quite the contrary, its acidity was increased by at least 0.6 *p*H unit over that in water in the absence of detergent (see Table I). It is of interest in this connection that very concentrated sorbitol solutions have a similar effect on the pK of the protein-linked dye (Table I) as does sodium dodecyl sulfate, the pK being lowered to approximately 1.3.

Discussion

The fact that the pK of the $(CH_3)_2NH^+-$ group is 1.8–1.9 when it is attached to the protein and 3.3 when it is in a small molecule in water shows that the protein environment has a very profound effect on the ionizing abilities of this group. It seems unlikely that electrostatic effects are directly responsible. As has been mentioned above, appreciable changes in the charge of the protein, either by change in *p*H in the region of 2.7 to 2 or by addition of some 30 dodecyl sulfate anions, do not shift the pK_a in the expected direction. Furthermore a careful comparison of the optical titration curves of the dye in protein and in cysteine complex shows behavior not in accord with electrostatic expectations. In the cysteine complex, a rise in absorption becomes detectable with increasing acidity as soon as one passes below *p*H 5 (Fig. 1). The same initial rise is shown by the dye attached to protein as one drops below *p*H 5 (Fig. 1). At this point, the net charge on the protein is near zero. As the *p*H is lowered further one would expect, from electrostatic considerations, that the optical density of the dye–protein should continue to rise, but somewhat more slowly than that of the cysteine complex, due to the increasingly positive charge on the protein. The titration curve in the protein should start to rise at about the same *p*H (near 5), should be less steep and spread out more over a wider *p*H range, but should be of the same general form as the cysteine complex.

Actually the optical density of the azomercurial on the protein reaches a small maximum at about *p*H 4.2 and then drops rapidly to a minimum at about *p*H 3.3. Clearly some profound change has occurred in the environment of the dye as the *p*H drops below about 4.2. This effect is shown even more strikingly if one examines the full spectra (Fig. 4). A marked shift in spectrum occurs at about *p*H 3, with the maximum of the dye (on the protein) shifting from about 455 to 420 mμ. (Only at much lower *p*H's does the characteristic spectrum of the acid form of the dye appear with a peak at 520 mμ.)

It is of course well known[24] now from a variety of experiments that serum albumin undergoes marked changes in physical characteristics at *p*H's below 4, and these have usually been interpreted in terms of swelling of the protein molecule.[8,10,24] Such an expansion is not in itself adequate to explain our observations, however, for the net result should be merely a decrease in the electrostatic broadening effect on the titration curve of the $(CH_3)_2NH^+-$ group.

The actual appearance of the optical titration curve of the dye–protein in the region below *p*H 3, where the absorption rises smoothly with decreasing *p*H (Fig. 1), is similar to that of the dye–cysteine complex except that the whole curve is displaced by about 1.5 *p*H units. The steepness of rise, once it starts, is if anything greater with protein than with cysteine. From electrostatic influences plus molecular expansion, one would expect the titration curve of dye–protein not to be displaced but to start upwards at about the same *p*H as does the cysteine complex, to rise less steeply at first and to increase in steepness, without exceeding that of the cysteine complex, as the *p*H is lowered further. The observed displacement of the titration curve of the dye–protein suggests that the protein effect is rather one of "masking" or hindering access to the $(CH_3)_2N-$ group similar to the masking of other, but naturally occurring, functional groups in protein molecules.

It seems inappropriate in the present case to attribute such masking to hydrogen-bonding between $(CH_3)_2\ddot{N}-$ and a donor group (see formula VI) because of our background of spectroscopic information. The dye–cysteine complex has a peak at 458 mμ. In the protein the absorption peak of the dye is much flatter, but the maximum is near 455 mμ at *p*H 5 and drops to 420 mμ below *p*H 4. If hy-

toward the right. Perhaps this effect is responsible for the catalysis of amide and peptide hydrolysis in the presence of dodecylsulfonate described by J. Steinhardt and C. H. Fugitt, *J. Research Natl. Bur. Standards*, **29**, 315 (1942). The explanation offered by these authors is slightly different; they attributed the catalysis to the binding of anion directly to the amide or peptide group.

(21) The pK could not be determined precisely in these solutions because of instability of the dye–cysteine complex in the presence of these low concentrations of dodecyl sulfate.

(22) F. Karush and M. Sonenberg, THIS JOURNAL, **71**, 1369 (1949).

(23) The concentration of dodecyl sulfate was 1×10^{-3} *M*, of serum albumin 3×10^{-5} *M*.

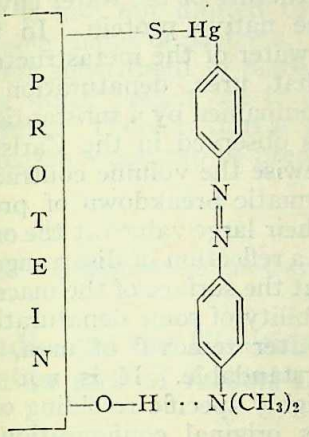
drogen bonding occurred in the protein one would expect the peak to shift to higher wave lengths ($\sim$ 500 mμ) instead of lower, and to higher extinctions, as seems to occur in related dimethylaminobenzeneazo dyes.[25,26] The observed shifts



VI

with the azomercurial albumin to lower wave lengths and reduced extinctions argue against a hydrogen bond from protein to $(CH_3)_2N-$ substituent.

In essence the phenomena observed show that the azo dye attached to serum albumin does not behave as it would in a normal aqueous environment, that attachment to the protein hinders access from the water to the $(CH_3)_2N-$ group. One is led to ask, therefore, whether the water in the vicinity of the protein is not different in structure from that in the bulk of the solution.

The importance of "icebergs" around polar (and non-polar) species in an aqueous environment was perhaps first emphasized by Frank and Evans,[27] who also mentioned that these structures might be of significance biologically. We have previously obtained good indications that "frozen" water molecules play a role in determining the enthalpy and entropy changes accompanying the formation of protein complexes.[28] Likewise Jacobson[29] has shown that dielectric behavior of aqueous protein solutions may be interpreted in terms of oriented water molecules. From a variety of very striking fluorescence experiments in ordinary ice, Szent-Györgyi[30] has suggested that muscular contraction and relaxation (as well as other biological phenomena) may be a response to a rearrangement in structure of the water envelope of proteins.

In the context of the present experiments we would view the drop in pK_a of the dimethylamino group in the environment of the protein as a consequence of the rigid iceberg structure in the neighborhood of the macromolecule. With serum albumin this freezing seems to become extensive as the pH drops below about 4.2. In the neighborhood of pH 5 to 4.2, the dye gives indications of normal ionization behavior and hence, at least in

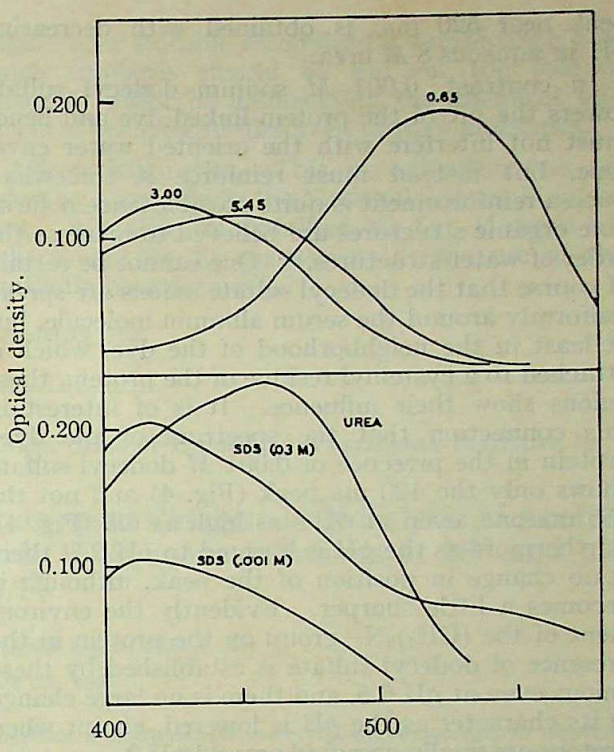

Fig. 4.—Spectra of $(CH_3)_2N-C_6H_4-N=N-C_6H_4-Hg-$ attached to bovine serum albumin: top, in water at pH's 5.45, 3.00 and 0.65; bottom: in 8 M urea at pH 7.22; in 0.001 M sodium dodecyl sulfate at pH 6.50; in 0.03 M sodium dodecyl sulfate at pH 5.45.

the vicinity of the $(CH_3)_2N-$ group of the dye attached to the cysteinyl residue of the protein, there is no indication of "frozen" water. Below pH 4.2, the accumulation of substantial net positive charge may increase strongly the extent and rigidity of the hydration envelope of the protein so as to produce effects on ionization properties as well as perhaps to contribute to the marked changes in hydrodynamic properties and other optical characteristics described in the literature.[24]

In line with this viewpoint, the effect of urea, bringing the pK_a back up to 3.3, is easy to understand. In essence in the presence of urea, the dye attached to protein behaves in its ionization just like the dye in water, free from the protein. An appropriate inference might be, therefore, that urea, because of its strong hydrogen-bonding characteristics, breaks down the "frozen" structure of the water envelope of the protein and transforms it into one more nearly like that of the bulk aqueous environment.[30a] It is of interest in this connection that the absorption spectrum of the protein-linked dye in the presence of 8 M urea shows a peak only at about 455 mμ (Fig. 4) and fails to develop the absorption peak at 420 mμ, characteristic of the masked $(CH_3)_2N-$ group, as the pH is lowered. Only the usual acid spectrum of azo dye, with a

(30a) In terms of the picture of masking as a steric effect, it is difficult to see (1) how the protein can provide side chains to block the $(CH_3)_2N-$ group at the extreme end of the azomercurial substituent attached to the surface of the protein; (2) why urea, a hydrogen-bond breaker, should be able to abolish completely any such lipophilic type of interaction even if it could be established *de novo*.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

peak near 520 mμ, is obtained with decreasing *p*H in aqueous 8 *M* urea.

In contrast, 0.001 *M* sodium dodecyl sulfate lowers the *pK* of the protein-linked dye and hence must not interfere with the oriented water envelope, but instead must reinforce it somewhat. Such a reinforcement is quite possible since polarizable organic structures are believed to increase the order of water structures.[27] One cannot be certain of course that the dodecyl sulfate anions are spread uniformly around the serum albumin molecule, but at least in the neighborhood of the dye, which is attached to a cysteinyl residue of the protein, these anions show their influence. It is of interest in this connection that the spectrum of the dye–protein in the presence of 0.001 *M* dodecyl sulfate shows only the 420 mμ peak (Fig. 4) and not the 455 mμ one, even at *p*H's as high as 6.5 (Fig. 4). Furthermore as the *p*H is lowered to *p*H 2.7, there is no change in position of the peak, although it becomes a little sharper. Evidently the environment of the $(CH_3)_2N-$ group on the protein in the presence of dodecyl sulfate is established by these anions even at *p*H 6.5, and there is no large change in its character as the *p*H is lowered, except when protons are finally accepted around *p*H 2.

At a higher concentration of dodecyl sulfate, 0.03 *M*, the nature of the water envelope is dominated by the surface micelles. It is clear that these micelles must have water within their framework since protons have no difficulty reaching the $(CH_3)_2N-$ group attached to the protein. At the surface of the protein, the micellar water seems to be highly ordered, nevertheless, for the spectrum of the protein-linked dye shows a peak at 420 mμ even at *p*H 7.5. As with more dilute detergent, this peak remains unchanged as the *p*H is lowered. With 0.03 *M* dodecyl sulfate, however, the micellar charge more than compensates for the rigidity of the water and protons are bound by the $(CH_3)_2N-$ groups at a much higher *p*H.

It is perhaps worthwhile to extend the scope of concepts of protein structure to include the organization which the macromolecule imposes upon its aqueous envelope. One might speak perhaps of the *meta*-structure of the protein, the framework which it imposes upon its environment beyond its own boundaries. The ordering of water molecules so produced may be limited to local regions of the surface or may be general around the whole protein molecule, and would probably depend on the distribution of polar groups within the protein. In the present studies with serum albumin and, as far as ionization of the specific dye of the class I is used as a probe (over the limited *p*H range of about 5 and below), the freezing of the water seems to be general. For the region of "masking" of the $(CH_3)_2N-$ group parallels that in which hydrodynamic properties indicate an increase in effective volume.

"Masking" of other, *naturally occurring*, functional groups of proteins might also be due to a "freezing" of the water structure in the neighborhood of the group. Lack of reactivity of such hindered groups (*e.g.*, mercaptan) is usually only relative and dependent on the reagent. The effectiveness of a reagent in combining with a masked group might very well be related to its ability to "dissolve" in the iceberg covering the group. Similarly, the effects of denaturing agents, such as urea, in "unmasking" blocked functional groups may be due to the rearrangements which they produce in the structure of the water envelope characteristic of the native protein. In terms of the "melting" of water of the metastructure it is quite reasonable that urea denaturation of proteins should be accompanied by a substantial contraction in volume, as observed in the Carlsberg Laboratory.[30b] Likewise the volume contractions accompanying enzymatic breakdown of proteins,[30b] and particularly their large values at the onset of proteolysis, may be a reflection of disarrangements in the water lattice at the surface of the macromolecule.

The reversibility of some denaturation processes, for example after removal of urea, is also more readily understandable. It is not necessary to postulate a highly specific refolding of the peptide chain into its original configuration but merely the refreezing of water when the disturbing, melting influence has been removed. Other denaturing factors, such as strong acid or alkali, or increased temperature can also be interpreted in terms of their influence on the structure of bound water. For example, the marked decrease in rate of exchange of deuterium in ribonuclease[30c] as the temperature is lowered would seem most plausible since the extent of the rigid iceberg structure should surely increase as the solution is cooled.

Likewise coöperative effects, such as the increased reactivity of the successively reacting sites after the first one on a protein has combined with a substrate,[31] may be transmitted through the water envelope. The original protein would have a *meta*-structure determined in part by its prosthetic groups and in part by its specific amino acid residues. When a molecule, *e.g.*, O_2, combines with the prosthetic group or specific site, the structure of water at that point could be changed significantly. Since the structure at this point is part of a more extensive water framework, it is evident that the effects due to combination at a specific site could be transmitted some distance and result in a disordering of the water structure some distance away. In consequence, a prosthetic group or specific site at a distance from the initially reactive one could have its water mask loosened and hence access to the second site could be significantly eased. Similarly specific ions bound at one site or region of a protein molecule could modify the framework for some distance by changing the water structure at that point and hence produce effects on a reactive site not in its immediate vicinity.

As has been mentioned, the present experiments have been limited in range of *p*H and in protein used. However, it is readily evident that corresponding experiments can be carried out with the present class of dye (I) and other proteins with mercaptan groups.[13] In addition analogous investigations can be made over other *p*H ranges by sub-

stituting groups in place of the $(CH_3)_2N-$ substituent on the azobenzene nucleus of I. A corresponding dye with a *para* O–H group, for example, would allow one to study ionization behavior in the region near *p*H 7–8, an *ortho* O–H group, higher *p*H ranges. One is also not limited to attachments at mercaptan side chains of proteins. The use of a sulfonyl chloride substituent in place of –HgAc in I, for example, would permit one to make adducts to lysine residues. There is thus a wide range of covalent complexes which can be prepared. These should offer suitable examples for establishing how much emphasis should be put on the role of "frozen" water in determining the chemical and physical behavior of dissolved protein molecules.

Further Studies on the Kinetics of the α-Chymotrypsin Catalyzed Hydrolysis of Acetyl-L-tyrosinamide and of Acetyl-L-tryptophanamide in Aqueous Solutions at 25° and *p*H 7.9 ± 0.1[1]

BY RICHARD A. BERNHARD AND CARL NIEMANN[2]

RECEIVED JANUARY 25, 1957

It has been found that the values of K_S, k_3 and K_P for the system α-chymotrypsin-acetyl-L-tyrosinamide, in aqueous solutions at 25° and *p*H 7.9 ± 0.1, obtained by observing the rate of formation of either one of the two reaction products, are identical within the limits of experimental error, that the values of K_S and K_P are independent of the nature and concentration of the buffer components of the four buffer systems investigated and that the values of k_3 are dependent upon the concentration of the buffer components and indirectly upon the nature of the buffer species. More limited observations with the system α-chymotrypsin–acetyl-L-tryptophanamide suggest that the behavior of this system is identical with that observed for the system α-chymotrypsin–acetyl-L-tyrosinamide. An experimental criterion for the recognition of bi- and trifunctionality in anionic competitive inhibitors of the type $RCH_2CO_2^-$ and $R'CONHCHRCO_2^-$ has been noted.

In a previous study Thomas, MacAllister and Niemann[3] examined the kinetics of the α-chymotrypsin catalyzed hydrolysis of acetyl-L-tyrosinamide in aqueous solutions at 25° and *p*H 7.9 ± 0.1 and 0.02 *M* in the THAM[4] component of a THAM–HCl buffer, or 0.02 *M* in the EDA[5] component of an EDA–HCl buffer, by determining the rate of formation of acetyl-L-tyrosinate ion. The results obtained by these investigators were re-evaluated by Foster and Niemann[6] and by Foster, Shine and Niemann[7] and it was concluded that the above reaction systems could be represented throughout their course by equations 1 and 2, where P_{1f} is acetyl-L-tyrosinate ion and P_{2f} either ammonia or ammonium ion, and that their rates could be described, within the limits of experimental error, by eq. 3, where $K_S = (k_2 + k_3)/k_1 = 32 \pm 4 \times 10^{-3}$ *M*[6], $K_P = k_5/k_4 = 110 \pm 30 \times 10^{-3}$ *M*[7] and $k_3 = 2.4 \pm 0.3 \times 10^{-3}$ *M*/min./mg. protein nitrogen per ml.[6].

$$E_f + S_1 \underset{k_2}{\overset{k_1}{\rightleftharpoons}} ES \xrightarrow{k_3} E_f + P_{1f} + P_{2f} \quad (1)$$

$$E_f + P_{1f} \underset{k_5}{\overset{k_4}{\rightleftharpoons}} EP_1 \quad (2)$$

$$k_3[E]_t = K_S\,(1 + [S]_0/K_P)\ln([S]_0/[S]_t) + (1 - K_S/K_P)([S]_0 - [S]_t) \quad (3)$$

When the above values of K_S and k_3 are compared with those reported earlier,[8–11] and which were obtained by determining the rate of formation of ammonia and ammonium ion in aqueous solutions at 25° and *p*H 7.8 and 0.1 *M* in an unspecified phosphate buffer containing sufficient lithium chloride to bring the initial ionic strength to 0.292, it is seen, *cf.* Table I, that such a comparison leaves unanswered a number of questions whose answers are required for a more complete understanding of the reaction under consideration. It is the purpose of

this communication to provide answers to several of these questions, *i.e.*, are the same values of K_S, k_3 and K_P obtained when the reaction is examined by observing the rate of formation of both P_{1f} and P_{2f}, are the values of K_S, k_3 and K_P derived from studies of the reaction in THAM–HCl and EDA–HCl buffers identical with those observed for systems containing sodium or potassium phosphate buffers and is there any dependence of the values of K_S, k_3 and K_P upon the concentration of the buffer components?

A colorimetric procedure for the determination of ammonia, based upon the earlier work of Moore and Stein,[12] was developed with due consideration being given to its applicability in systems containing α-chymotrypsin, acetyl-L-tyrosinamide, acetyl-L-tyrosine and THAM hydrochloride as well as ammonium chloride. This procedure was capable of determining quantities of ammonia, present as ammonium chloride, of from 0 to 0.6×10^{-3} *M*.

With the above analytical procedure it became possible to examine the α-chymotrypsin catalyzed hydrolysis of acetyl-L-tyrosinamide in aqueous solutions at 25° and *p*H 7.9 ± 0.1 and 0.02 *M* in the THAM component of a THAM–HCl buffer with respect to the rate of formation of ammonia and ammonium ion. Thirty-two experiments were conducted, *cf.* Table II, and it was found that with 18 the extent of reaction was sufficient to permit the use of the graphical procedure of Foster and Niemann[13–15] for the evaluation of the experimental data. The above graphical procedure could not be used for the evaluation of the remaining fourteen experiments because of a more limited extent of reaction. Therefore, in these latter cases the corrected initial velocities were evaluated by the procedure of Jennings and Niemann[16–18] and these values of v_0 were then used in an Eadie plot[15] to obtain values of K_S and k_3 but not of K_P.

Two separate evaluations were performed. In the first the experimental data obtained from the ten experiments conducted at [E] = 0.200 mg. protein-nitrogen per ml., *cf.* Table II, were presented in a $([S]_0 - [S]_t)/t$ *vs.* $(\ln ([S]_0/[S]_t))/t$ plot[13–15] and from this plot the following values were obtained: $K_S = 34 \pm 2 \times 10^{-3}$ *M*, $k_3 = 2.5 \pm 0.1 \times 10^{-3}$ *M*/min./mg. protein-nitrogen per ml. and $K_P = 80 \pm 20 \times 10^{-3}$ *M*. As the preceding values were derived from experimental data obtained under conditions where $[E] = 5.7 \times 10^{-5}$ *M*,[19] E's = $[E]/K_S = 0.2 \times 10^{-2}$ and S's = $[S]/K_S = 0.15$ to 1.28 it follows that all assumptions inherent in the evaluation procedure have been satisfied.[6,7]

In the second evaluation, based upon the results obtained in all 32 experiments, *cf.* Table II, the initial velocities, obtained from either a $([S]_0 - [S]_t)/t$ *vs.* $(\ln ([S]_0/[S]_t))/t$ plot or by the procedure of Jennings and Niemann,[16–18] were normalized to an enzyme concentration of 0.200 mg. protein-nitrogen per ml. assuming that the initial velocities were directly proportional to the enzyme concentrations. A line was then fitted to the 32 values of v_0 and of $v_0/[S]_0$ and from the slope and intercepts of this line and the slopes of the 18 lines of slope $-K_S(K_P + [S]_0)/(K_P - K_S)$ the following values were obtained; $K_S = 34 \pm 4 \times 10^{-3}$ *M*, $k_3 = 2.5 \pm 0.3 \times 10^{-3}$ *M*/min./mg. protein-nitrogen per ml. and $K_P = 80 \pm 20 \times 10^{-3}$ *M*. With [E] between the limits of 0.76 to 6.3×10^{-5} *M*,[19] E's between 0.02 and 0.2×10^{-2} and S's between 0.09 and 1.28 it is clear that the conditions required for a proper evaluation of K_S, k_3 and K_P were satisfied.[6,7]

A comparison of the values of K_S, k_3 and K_P for the α-chymotrypsin catalyzed hydrolysis of acetyl-L-tyrosinamide in aqueous solutions at 25° and *p*H

7.9 ± 0.1 and 0.02 M in the THAM component of a THAM–HCl buffer with respect to the rate of formation of acetyl-L-tyrosinate ion, *i.e.*, $K_S = 32 \pm 4 \times 10^{-3}$ M, $k_3 = 2.4 \pm 0.3 \times 10^{-3}$ M/min./mg. protein-nitrogen per ml. and $K_P = 110 \pm 30 \times 10^{-3}$ M,[3,6,7] and with respect to the rate of formation of ammonia and ammonium ion, *i.e.*, $K_S = 34 \pm 2 \times 10^{-3}$ M, $k_3 = 2.5 \pm 0.1 \times 10^{-3}$ M/min./mg. protein-nitrogen per ml. and $K_P = 80 \pm 20 \times 10^{-3}$ M[20] shows that within the limits of experimental error the same values of K_S, k_3 and K_P are obtained irrespective of whether the reaction is studied by determining the rate of formation of P_{1f} or P_{2f}.

From a series of experiments based upon the determination of the amount of ammonia and ammonium ion liberated in aqueous solutions at 25° with [E] = 0.200 mg. protein-nitrogen per ml., $[S]_0 = 5 \times 10^{-3}$ M and $t = 110$ minutes it was found that the *p*H optimum for the α-chymotrypsin catalyzed hydrolysis of acetyl-L-tyrosinamide in a system 0.02 M in the phosphate component of a sodium phosphate buffer is *ca.* 7.9.

With the knowledge that the *p*H optimum for the above reaction system is identical, within the limits of experimental error, with the *p*H optima for the comparable systems 0.02 M in the THAM or EDA component of a THAM– or EDA–HCl buffer[3] it was decided to evaluate K_S, k_3 and K_P for the α-chymotrypsin catalyzed hydrolysis of acetyl-L-tyrosinamide in aqueous solutions at 25° and *p*H 7.9 ± 0.1 and 0.1 M in the phosphate component of a sodium or potassium phosphate buffer[21] by determining the rate of formation of ammonia and ammonium ion. The experimental conditions employed in this study are summarized in Table III.

TABLE III

α-CHYMOTRYPSIN CATALYZED HYDROLYSIS OF ACETYL-L-TYROSINAMIDE IN AQUEOUS SOLUTIONS AT 25° AND *p*H 7.9 ± 0.1 AND 0.1 M IN THE PHOSPHATE COMPONENT OF A SODIUM OR POTASSIUM PHOSPHATE BUFFER[a]

$[S]_0$[b]	t_{max}[c]	% Hydrol.	$[S]_0$[b]	t_{max}[c]	% Hydrol.
Sodium phosphate buffer			Potassium phosphate buffer		
5	110	88.0	5	110	87.0
10	110	81.6	10	110	81.2
30	150	85.8	20	150	88.7
40	150	80.3	30	150	83.7
			35	120	74.1
			40	150	80.0

[a] With [E] = 0.200 mg. protein-nitrogen per ml. of Armour preparation no. 00592. [b] In units of 10^{-3} M. [c] Maximum time of observation in minutes with a total of seven observations taken within the time indicated.

Since data were available for the extended reaction each set was evaluated by the procedure of Foster and Niemann.[13–15] From the two $([S]_0 - [S]_t)/t$ *vs.* $(\ln ([S]_0/[S]_t))/t$ plots the following values were obtained. For the 0.1 M sodium phosphate buffer; $K_S = 32 \pm 2 \times 10^{-3}$ M, $k_3 = 3.3 \pm 0.2 \times 10^{-3}$ M/min./mg. protein-nitrogen per ml., $K_P = 70 \pm 20 \times 10^{-3}$ M, [E] = 5.7×10^{-5} M,[19] E's = 0.2×10^{-2} and S's = 0.16 to 1.25. For the 0.1 M potassium phosphate buffer; $K_S = 33 \pm 2 \times 10^{-3}$ M, $k_3 = 3.25 \pm 0.15 \times 10^{-3}$ M/min./mg. protein-nitrogen per ml., $K_P = 80 \pm 20 \times 10^{-3}$ M, [E] = 5.7×10^{-5} M,[19] E's = 0.2×10^{-2} and S's = 0.15 to 1.21.

The identity, within the limits of experimental error, of the above two sets of values of K_S, k_3 and K_P demonstrates that in the α-chymotrypsin-catalyzed hydrolysis of acetyl-L-tyrosinamide in aqueous solutions at 25° and *p*H 7.9 ± 0.1 there is no detectable difference in the behavior of systems containing either 0.1 M sodium or potassium phosphate buffers. However, it will be noted that whereas the values of K_S and K_P evaluated in these latter systems, *i.e.*, 32 ± 2 and 33 ± 2 × 10^{-3} M and 70 ± 20 and 80 ± 20 × 10^{-3} M, are identical, within the limits of experimental error, with the values of K_S and K_P obtained in comparable systems 0.02 M in the THAM component of a THAM–HCl buffer, *i.e.*, 32 ± 4[3,6,7] and 34 ± 2 + 10^{-3} M and 110 ± 30[3,6,7] and 80 ± 20 × 10^{-3} M, the corresponding values of k_3 in systems 0.1 M in a sodium or potassium phosphate buffer, *i.e.*, 3.3 ± 0.2 and 3.25 ± 0.15 × 10^{-3} M/min./mg. protein-nitrogen per ml., are significantly greater than those observed in systems 0.02 M in the THAM component of a THAM–HCl buffer, *i.e.*, 2.4 ± 0.3[3,6,7] and 2.5 ± 0.1 × 10^{-3} M/min./mg. protein-nitrogen per ml.

Since the situation noted immediately above could be due to a difference in the nature of the buffer component and/or their concentrations it was decided to examine the α-chymotrypsin catalyzed hydrolysis of acetyl-L-tyrosinamide in aqueous solutions at 25° and *p*H 7.9 ± 0.1 and 0.2 M and 0.4 M in the phosphate component of a sodium phosphate buffer. As before data were obtained with respect to the rate of formation of ammonia and ammonium ion for the extended reaction, *cf.* Table IV, and K_S, k_3 and K_P were evaluated from $([S]_0 - [S]_t)/t$ *vs.* $(\ln ([S]_0/[S]_t)/t$ plots.[13–15] For the system 0.2 M in phosphate $K_S = 30 \pm 2 \times 10^{-3}$ M, $k_3 = 3.85 \pm 0.3 \times 10^{-3}$ M/min./mg. protein-nitrogen per ml., $K_P = 80 \pm 20 \times 10^{-3}$ M,

TABLE IV

α-CHYMOTRYPSIN CATALYZED HYDROLYSIS OF ACETYL-L-TYROSINAMIDE IN AQUEOUS SOLUTIONS AT 25° AND *p*H 7.9 ± 0.1 AND 0.2 M AND 0.4 M IN THE PHOSPHATE COMPONENT OF A SODIUM PHOSPHATE BUFFER[a]

$[E] = 5.7 \times 10^{-5}\ M$,[19] $E'_S = 0.2 \times 10^{-2}$ and $S'_S = 0.17$ to 1.33. For the system 0.4 M in phosphate, $K_S = 31 \pm 3 \times 10^{-3}\ M$, $k_3 = 5.0 \pm 0.3 \times 10^{-3}\ M$/min./mg. protein-nitrogen per ml., $K_P = 75 \pm 20 \times 10^{-3}\ M$, $[E] = 5.7 \times 10^{-5}\ M$,[19] $E'_S = 0.2 \times 10^{-2}$ and $S'_S = 0.16$ to 1.29.

The information that is now available with respect to the dependence or independence of values of K_S, k_3 and K_P for the system α-chymotrypsin–acetyl-L-tyrosinamide in aqueous solutions at 25° and pH 7.9 ± 0.1 upon components of the reaction system that are not represented in eq. 1 and 2 is summarized in Table V. Having established for the case at hand that the same values of K_S, k_3 and K_P are obtained irrespective of whether the reaction is followed by determining the rate of formation of P_{1f} or P_{2f}, *vide ante*, it is seen from the information given in Table V that the values of K_S and K_P are independent, within the limits of experimental error, of the nature or concentration of any of the components of the reaction system which may have been added to maintain the system at a constant pH but that the values of k_3 are clearly dependent upon either the nature and/or concentration of such components.

TABLE V

SUMMARY OF KINETIC CONSTANTS FOR THE α-CHYMOTRYPSIN CATALYZED HYDROLYSIS OF ACETYL-L-TYROSINAMIDE IN AQUEOUS SOLUTIONS AT 25° AND pH 7.9 ± 0.1

Buffer system	K_S[a]	k_3[b]	K_P[a]	Ref.

[a] In units of 10^{-3} M. [b] In units of 10^{-3} M/min./mg. protein-nitrogen per ml. [c] System 0.02 M in the THAM component of a THAM–HCl buffer or 0.02 M in the EDA component of an EDA–HCl buffer and followed by determining the rate of formation of acetyl-L-tyrosinate ion. [d] System 0.02 M in the THAM component of a THAM–HCl buffer and followed by determining the rate of formation of ammonia and ammonium ion. [e] System 0.1 M in the phosphate component of a sodium phosphate buffer and followed by determining the rate of formation of ammonia and ammonium ion. [f] Same as *e* except system 0.1 M in the phosphate component of a potassium phosphate buffer. [g] System 0.1 M in an unspecified phosphate buffer containing sufficient lithium chloride to bring the ionic strength to 0.292 and followed by determing the rate of formation of ammonia and ammonium ion. [h] Same as *e* except system 0.2 M in the phosphate component. [i] Same as *e* except system 0.4 M in the phosphate component. [j] Preferred values.

The observation that the value of K_S for the system α-chymotrypsin–acetyl-L-tyrosinamide in aqueous solutions at 25° and pH 7.9 ± 0.1 appears to be independent of added THAM and its hydrochloride, EDA and its hydrochloride or sodium or potassium phosphate recalls the experience of Shine and Niemann[22,23] who found that the value of K_S for the system α-chymotrypsin–chloroacetyl-L-tyrosinamide in aqueous solutions at 25° and pH 7.75 and 0.02 M in the THAM component of a THAM–HCl buffer is essentially independent of added sodium or potassium chloride[22] or of added sucrose.[23] In view of the relatively high concentrations of sodium and potassium phosphate employed in the present studies we can now regard these two salts along with sodium and potassium chloride as members of that class of electrolytes which appear to have no demonstrable effect upon the K_S value of an amide type trifunctional specific substrate.

It is known that the K_I values, *i.e.*, the enzyme-inhibitor dissociation constants, of certain bifunctional anionic competitive inhibitors of α-chymotrypsin, when evaluated in aqueous solutions at 25° and pH 7.9 ± 0.1, are strikingly dependent upon whether the value was obtained by examination of a reaction system 0.02 M in the THAM component of a THAM–HCl buffer or one 0.1 M in an unspecified phosphate buffer.[24–26] Since it was noted previously[26] that no information was available with respect to the behavior of a single trifunctional anionic competitive inhibitor of the type $R'CONHCHRCO_2^-$ in 0.02 M THAM–HCl and 0.1 M phosphate buffers it was of particular interest to find that the K_P value, *i.e.*, the K_I value, of acetyl-L-tyrosinate ion determined in this study was essentially independent of the nature of the buffer systems which included not only 0.02 M THAM–HCl but also 0.1, 0.2 and 0.4 M sodium phosphate, *cf.* Table V. With the knowledge that under certain conditions the K_I values of a trifunctional anionic competitive inhibitor of α-chymotrypsin is independent of the presence of added phosphate and the K_I value of a comparable bifunctional anionic competitive inhibitor of this enzyme appears to be dependent upon the presence of added phosphate it is clear that we now possess an experimental basis for recognizing bi- and trifunctionality in anionic competitive inhibitors of the type $RCH_2CO_2^-$ and $R'CONHCHRCO_2^-$.

In contrast to the essential independence of values of K_S and K_P upon the concentration of the sodium phosphate buffer it is seen from the information summarized in Table V that the value of k_3 for the system α-chymotrypsin–acetyl-L-tyrosinamide in aqueous solutions at 25° and pH 7.9 ± 0.1 increases with increasing concentration of the sodium phosphate buffer. It was noted previously[22] that with added sodium or potassium chloride the value of k_3 for the α-chymotrypsin catalyzed hydrolysis of chloroacetyl-L-tyrosinamide in aqueous solutions at 25° and pH 7.75 and 0.02 M in the THAM component of a THAM–HCl buffer increased linearly in accordance with the relation $\log (k_3/k_3^0) = 0.30 \pm 0.01\sqrt{M}$ where k_3^0 is the value observed in the absence of added sodium or potassium chloride and M the molality of the added salt. When the limited data summarized in Table V were examined with respect to possible relationships between values of k_3 and sodium phosphate concentration, or some function thereof, it was noted that with plots of k_3 *vs.* M, log k_3 *vs.* M, log

k_3 *vs.* $\sqrt{M}$ and log k_3 *vs.* $\sqrt{\mu}$[27] only the first and third gave reasonably linear plots although all could have been considered to be linear within the limits of experimental error. The log k_3 *vs.* $\sqrt{M}$ plot was selected as the most suitable for an empirical extrapolation and from the relation log $(k_3/k_3^0) = 0.575\sqrt{M}$ the following values of k_3^0, *i.e.*, the value of k_3 in the absence of sodium phosphate, were computed: 2.2, 2.1 and 2.2 $\times 10^{-3}$ M/min./mg. protein-nitrogen per ml. With log $k_3^0 = 0.333 \times 10^{-3}$ M/min./mg. protein-nitrogen per ml. the above relation gave an expected value of $k_3 = 2.6 \times 10^{-3}$ M/min./mg. protein-nitrogen per ml. for a system 0.02 M in the phosphate component of a sodium phosphate buffer of *p*H 7.9 ± 0.1. The agreement of this value of k_3 with that obtained for the comparable system 0.02 M in the THAM component of a THAM–HCl buffer, *i.e.*, $2.5 \pm 0.1 \times 10^{-3}$ M/min./mg. protein-nitrogen per ml. suggests that values of k_3 are basically independent of the nature of the buffers considered in this study but that the dependency of the value of k_3 for a particular specific substrate upon the concentration of the buffer components may vary with the nature of the buffer.

It has been shown[6,7,28] that for the α-chymotrypsin catalyzed hydrolysis of acetyl-L-tryptophanamide in aqueous solutions at 25° and *p*H 7.9 ± 0.1 and 0.02 M in the THAM component of a THAM–HCl buffer $K_S = 5.0 \pm 0.5 \times 10^{-3}$ M, $k_3 = 0.55 \pm 0.1 \times 10^{-3}$ M/min./mg. protein-nitrogen per ml. and $K_P = 10 \pm 2 \times 10^{-3}$ M when the reaction is followed by determining the rate of formation of acetyl-L-tryptophanate ion. In order to determine whether several of the results noted previously could be observed with a second specific substrate the above system was re-examined under conditions where the 0.02 M THAM–HCl buffer was replaced by a potassium phosphate buffer which was 0.1 M in the phosphate component and where the reaction was followed by determining the rate of formation of ammonia and ammonium ion. The reaction conditions employed in this latter study are summarized in Table VI and when the primary data were evaluated through the use of a $([S]_0 - [S]_t)/t$ *vs.* $(\ln ([S]_0/[S])_t)/t$ plot[13-15] the following values were obtained: $K_S = 5.7 \pm 0.3 \times 10^{-3}$ M, $k_3 = 0.68 \pm 0.02 \times 10^{-3}$ M/min./mg. protein-nitrogen per ml., $K_P = 7.3 \pm 0.6 \times 10^{-3}$ M, $[E] = 6.3 \times 10^{-5}$ M,[19] E's = 0.1×10^{-2} and S's = 1.75 to 7.05.

A comparison of the above values of K_S, *i.e.*, 5.0 ± 0.5 and 5.7 ± 0.3 $\times 10^{-3}$ M, k_3, *i.e.*, 0.55 ± 0.1 and 0.68 ± 0.02 $\times 10^{-3}$ M/min./mg. protein-nitrogen per ml. and $K_P = 10 \pm 2$ and 7.3 ± 0.6 $\times 10^{-3}$ M reveals a common pattern in the behavior of acetyl-L-tyrosinamide and acetyl-L-tryptophanamide. As with the former specific substrate the value of K_S for the latter appears to be independent of the nature and/or concentration of the buffer components and whether the reaction is followed by determining the rate of formation of P_{1f} or P_{2f}. In contrast, the value of k_3 again appears to be dependent upon the concentration of the buffer components and it is noteworthy that the percentage increase in the value of k_3 in passing from a 0.02 M THAM–HCl buffer to a 0.1 M potassium phosphate buffer is *ca.* 30% for acetyl-L-tyrosinamide and *ca.* 20% for acetyl-L-tryptophanamide. Finally, it may be noted that the value of K_P for the system α-chymotrypsin–acetyl-L-tryptophanate ion in aqueous solutions at 25° and *p*H 7.9 ± 0.1 also appears to be independent of the nature and/or concentration of the buffer components. In this connection it is of interest to recall that Cunningham and Brown[29] have reported that the K_I value of acetyl-L-tryptophanate ion in aqueous solutions at 25° and *p*H 8 and 0.0033 M in the THAM component of a THAM–HCl buffer and 0.1 M in calcium chloride is $8.7 \pm 2 \times 10^{-3}$ M, a value which may be compared with the values of 10 ± 2 and 7.3 ± 0.6 $\times 10^{-3}$ M given above.

Table VI

α-Chymotrypsin Catalyzed Hydrolysis of Acetyl-L-tryptophanamide in Aqueous Solutions at 25° and *p*H 7.9 ± 0.1 and 0.1 M in the Phosphate Component of a Potassium Phosphate Buffer[a]

40	150	41.9

[a] With [E] = 0.222 mg. protein-nitrogen per ml. of Armour preparation no. 00592. [b] In units of 10^{-3} M. [c] Maximum time of observation in minutes with a total of seven observations taken within the time indicated.

Experimental[30]

Analytical Procedure.—The procedure used in this study was based upon one described by Moore and Stein.[12] Because of the necessity, in some cases, of determining small amounts of ammonia in the presence of substantial amounts of THAM many precautions had to be taken beyond those required for a more conventional application of the original procedure. The procedure to be described was the result of a large number of experiments designed to establish optimum conditions for the determination of ammonia in the presence of THAM and phosphate buffers. While these experiments[31] will not be described here it should be realized that the directions given below are based upon a large number of observations and are in no sense arbitrary. Strict adherence to the described procedure is required if satisfactory results are to be obtained.

A. Reagents.—Commercial ninhydrin was recrystallized from hot water, after decolorization with Norite A, the product dried *in vacuo* and stored in a sealed amber colored container. Anhydrous stannous chloride, prepared from the crystalline dihydrate by reaction with acetic anhydride,[32] was dried *in vacuo* and stored in a sealed container. Reagent grade citric acid monohydrate was further purified by recrystallization from hot water. Peroxide-free Methyl Cellosolve was prepared by refluxing the commercial product with anhydrous stannous chloride until a negative test for peroxides was obtained. The reaction mixture was then

(27) Based upon the following dissociation constants for phosphoric acid: $k_1 = 1.1 \times 10^{-2}$, $k_2 = 7.5 \times 10^{-8}$ and $k_3 = 4.8 \times 10^{-13}$.

fractionally distilled and the fraction b.p. 123–125° stored in a sealed amber colored container. Peroxide-free isopropyl alcohol is also required.

B. Reagent Solutions.—A 0.2 *M* sodium citrate buffer of *p*H 4.8 ± 0.1 was prepared from 42 g. of recrystallized citric acid monohydrate and 16 g. of reagent grade sodium hydroxide pellets in 1000 ml. of distilled water. A few crystals of thymol were added and the solution stored at 4° prior to use. This solution was prepared weekly. The ninhydrin reagent was prepared by first dissolving 0.0240 g. of C.P. stannous chloride dihydrate in 15.0 ml. of the citrate buffer and passing dry nitrogen through the solution for three minutes. A solution of 0.600 g. of recrystallized ninhydrin in 15.0 ml. of peroxide-free Methyl Cellosolve was then prepared and dry nitrogen passed through the solution for three minutes. The first solution now was added to the second and the resulting ninhydrin reagent stored in a polyethylene container under an atmosphere of nitrogen. This reagent was prepared immediately prior to use. A diluent solution was prepared daily from equal volumes of distilled water and peroxide-free isopropyl alcohol.

C. Procedure.—Prior to the starting of a given kinetic experiment a series of G. S. volumetric flasks were assembled, the capacities being determined by the amount of ammonia expected in a 1.0-ml. aliquot of the reaction mixture, *i.e.*, for 0.0–3.0 × 10^{-3} *M* a 5-ml. flask, for 3.0–7.0 × 10^{-3} *M* a 10-ml. flask, for 7.0–17.5 × 10^{-3} *M* a 25-ml. flask and for 17.5–35.0 × 10^{-3} *M* a 50-ml. flask. To each of the 10-ml. flasks was added *ca.* 8.5 ml. of the 0.2 *M* citrate buffer and when 5-, 25- and 50-ml. flasks were employed the amount of buffer added was *ca.* 3.5, 23.5 and 47.5 ml., respectively. At selected time intervals 1.0-ml. aliquots were withdrawn from the reaction mixture and added to the contents of the above flasks and the solutions made up to volume with the citrate buffer. After the completion of the experiment 1.0-ml. aliquots of each of the above solutions were added to 1.0-ml. aliquots of the ninhydrin reagent contained in a series of 13 cm. rimless Pyrex test-tubes, the tubes capped with close fitting cylindrical aluminum caps and heated in a water-bath maintained at 99–100° for exactly 20 minutes. The tubes were then withdrawn from the bath, allowed to cool for five minutes and a 50-ml. aliquot of the diluent solution added to each of the tubes. The optical density of the resulting solutions, for a 1 cm. path in a Corex cell at 565 mμ, was then promptly determined in a model B Beckman spectrophotometer. A sample of the diluent solution was used as a control.

D. Calibration Curves and Blanks.—The examination of solutions of the 0.2 *M* citrate buffer of *p*H 4.8 ± 0.1 containing aliquots of simulated reaction mixtures composed of varying amounts of acetyl-L-tyrosinamide, acetyl-L-tyrosine and ammonium chloride and fixed amounts of α-chymotrypsin and the buffer system employed in the original reaction mixture revealed that for concentrations of ammonia up to 0.04 *M* in the original reaction mixture the optical density was proportional to the ammonia concentration within the limits of experimental error. However, the proportionality constant was found to depend upon the particular ninhydrin reagent employed and upon the concentration of the THAM-HCl buffer when this buffer system was used in the original reaction mixture. Therefore, for each particular reaction system a standard calibration curve was prepared and coincidently with each series of determinations two solutions, one containing all of the components of the original reaction mixture except the specific substrate and the other containing all components present in the first and in addition a known amount of a standard ammonium chloride solution, were prepared and analyzed along with the other solutions of the series.

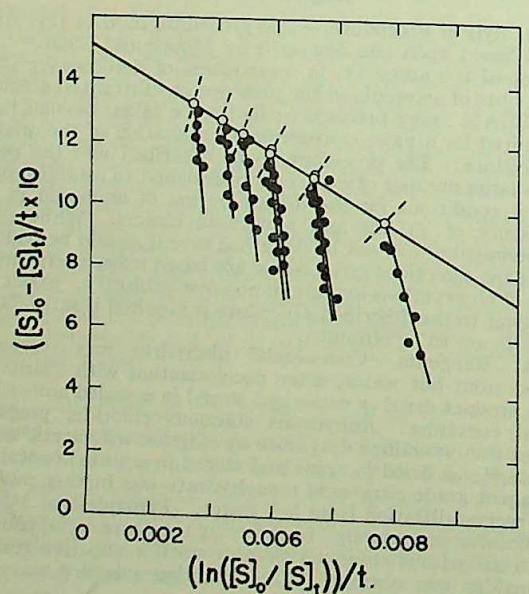

Fig. 1.—Foster–Niemann plot of data obtained for the α-chymotrypsin catalyzed hydrolysis of acetyl-L-tryptophanamide in aqueous solutions at 25° and *p*H 7.9 ± 0.1 and 0.1 *M* in the phosphate component of a potassium phosphate buffer.

Specific Substrates.—Acetyl-L-tyrosinamide, m.p. 226–228°, $[\alpha]^{24}D$ +52 ± 1° (*c* 0.8% in water) was prepared as directed by Thomas, MacAllister and Niemann.[3] Acetyl-L-tryptophanamide, m.p. 192–193°, $[\alpha]^{25}D$ +20 ± 1° (*c* 2% in methanol) was prepared as described by Huang and Niemann.[28]

Buffer Systems.—A stock solution 0.20 *M* in the thrice recrystallized THAM component of a THAM–HCl buffer of *p*H 8.0 at 25° was prepared. A 1:10 dilution of this stock solution in the reaction mixture gave a solution of *p*H 7.90 ± 0.05 at 25°. Sodium phosphate stock solutions 1.0, 2.0 and 4.0 *M* in the phosphate component were prepared by the addition of sufficient 5 *N* aqueous sodium hydroxide to aqueous solutions of reagent grade sodium dihydrogen phosphate to give solutions of *p*H 8.05 at 25° after the solutions were made up to volume. One to ten dilutions of these stock solutions in the reaction mixture gave solutions of *p*H 7.9 ± 0.05 at 25°. A 1.0 *M* potassium phosphate stock solution was prepared similarly from potassium dihydrogen phosphate and 5 *N* aqueous potassium hydroxide.

Enzyme Solutions.—Crystalline bovine α-chymotrypsin containing magnesium sulfate (Armour lot no. 10705) and crystalline bovine α-chymotrypsin salt-free (Armour lot no. 00592) were employed in these studies. Stock solutions of these preparations were prepared daily.

TABLE VII

α-CHYMOTRYPSIN CATALYZED HYDROLYSIS OF ACETYL-L-TRYPTOPHANAMIDE[a]

t (min.)	O.D.[b]	$([S]_0 - [S]_t)$[c]	$([S]_0 - [S]_t)/t$	$(\ln([S]_0/[S]_t))/t$
20	0.462	2.175	0.109	0.00784
25	.504	2.550	.102	.00746
50	.748	4.775	.096	.00767
75	.930	6.450	.086	.00749
100	1.105	8.050	.081	.00768
125	1.237	9.225	.074	.00763
150	1.383	10.575	.071	.00814

[a] In aqueous solutions at 25° and *p*H 7.9 ± 0.1 and 0.1 *M* in the phosphate component of a potassium phosphate buffer with [E] = 0.222 mg. protein-nitrogen per ml. of Armour preparation no. 00592 and $[S]_0$ = 15 × 10^{-3} *M*. [b] Optical density based upon a 1:25 dilution of a 1-ml. aliquot of the reaction mixture and a blank value of 0.227. [c] Based upon a value of O.D. = 1.976 for 16 × 10^{-3} *M* ammonium chloride.

Enzyme Experiments.—The substrate was dissolved in 3 to 7 ml. of distilled water contained in a 10-ml. G. S. volumetric flask, 1.0 ml. of the appropriate buffer stock solution added and the solution placed in a 25.0 ± 0.05° bath for 20 to 25 minutes. At minus 20 seconds from time zero the volumetric flask was withdrawn from the bath and at time zero 1.0 ml. of the enzyme stock solution was added and the solution made up to volume with distilled water. The contents of the flask were mixed by gently inverting the flask 12 times and the flask then returned to the bath. 1.0-

The Dependence of the Enzyme-Inhibitor Dissociation Constants of Several Bifunctional Anionic Competitive Inhibitors of α-Chymotrypsin upon Added Potassium Phosphate[1]

BY RICHARD A. BERNHARD AND CARL NIEMANN[2]

RECEIVED FEBRUARY 9, 1957

It has been observed that the enzyme-inhibitor dissociation constants of two representative bifunctional anionic competitive inhibitors of α-chymotrypsin, *i.e.*, β-(β-indole)-propionate and phenyl acetate, when evaluated in aqueous solutions at 25° and *p*H 7.9 ± 0.1 may be decreased by increasing the concentration of the uni-univalent buffer system, or by the addition of sodium chloride or potassium phosphate. A detailed analysis has indicated that the effect produced by added potassium phosphate is to be associated with a general increase in ionic strength and a specific ion effect.

It has been recognized that the enzyme-inhibitor dissociation constants of a number of bifunctional anionic competitive inhibitors of α-chymotrypsin, when evaluated in aqueous solutions at 25° and *p*H 7.9 and 0.02 *M* in the THAM[3] component of a THAM–HCl buffer,[4-6] are substantially greater than the constants obtained for the same inhibitors in aqueous solutions at 25° and *p*H 7.8 and 0.1 *M* in an unspecified phosphate buffer.[7,8] However, the lack of a suitable analytical procedure has prevented, until recently, a more direct comparison of the behavior of certain bifunctional anionic competitive inhibitors of α-chymotrypsin in the presence of THAM–HCl and phosphate containing buffers. With the development of a procedure which was suitable for following the rate of the α-chymotrypsin catalyzed hydrolysis of acetyl-L-tyrosinamide in aqueous solutions at 25° and *p*H 7.9 ± 0.1 in the presence of THAM–HCl or sodium or potassium phosphate buffers[9] it was thought desirable to re-examine several of the experiments reported earlier[4-8] and if possible to clarify and explain the behavior noted above.

In the first series of experiments the α-chymotrypsin catalyzed hydrolysis of acetyl-L-tyrosinamide in aqueous solutions at 25° and *p*H 7.0 ± 0.1 and 0.02 *M* in the THAM component of a THAM–HCl buffer was examined in the presence of added potassium β-(β-indole)-propionate, β-(β-indole)-propionamide, potassium phenylacetate, phenylacetamide or tryptamine hydrochloride. As before[9] the reaction was followed by determining the rate of formation of ammonia and ammonium ion and the primary data so obtained were graphically evaluated by the method of Foster and Niemann.[10-12] The experimental conditions employed in this study are summarized in the footnotes to Table I. It will be seen from these data that the extent of reaction was sufficient to justify the use of the above evaluation procedure.[13] From the evaluated data given in Table I it is evident that all values of K_I were obtained under conditions that were compatible with the assumptions inherent in the procedures used for their evaluation.[6,10-12,14,15]

TABLE I

K_I VALUES OF FIVE COMPETITIVE INHIBITORS OF α-CHYMOTRYPSIN EVALUATED IN AQUEOUS SOLUTIONS AT 25° AND *p*H 7.9 ± 0.1 AND 0.02 *M* IN THE THAM COMPONENT OF A THAM–HCl BUFFER[a]

Competitive inhibitor	K_I[b]	E_I'[c]	I_I
Potassium β-(β-indole)-propionate	11 ± 1.5[e]	0.52	3.6
β-(β-Indole)-propionamide	1.7 ± 0.3[f]	3.4	0.88
Potassium phenylacetate	170 ± 15[g]	0.03	0.88
Phenylacetamide	10 ± 1[h]	0.57	1.0
Tryptamine hydrochloride	1.5 ± 0.3[i]	3.8	6.7

[a] Evaluated against acetyl-L-tyrosinamide with $K_S = 32 \times 10^{-3}$ *M*, [E] = 5.7×10^{-5} *M*, [d] $E_S' = 0.17 \times 10^{-2}$ and $S_S' = 0.625$ to 1.25. [b] In units of 10^{-3} *M*. [c] In units of 10^{-2}. [d] Based upon an assumed molecular weight of monomeric α-chymotrypsin of 22,000 and a nitrogen content of 16.0%. [e] Based upon 4 sets of experiments with $[S]_0 = 20, 25, 30$ and 40×10^{-3} *M*, [I] = 40×10^{-3} *M*, *t* = 150 minutes with a total of 7 observations of extent of reaction within this time interval, with a total extent of reaction of 36.5, 35.4, 32.2 and 30.0%, respectively, and with [E] = 0.200 mg. protein-nitrogen per ml. of Armour preparation no. 00592. [f] Same as *e* but with [I] = 1.5×10^{-3} *M* and total extent of reaction of 66.3, 64.0, 61.8 and 58.0% respectively. [g] Same as *e* but with [I] = 150×10^{-3} *M* and total extent of reaction of 61.3, 59.0, 56.8 and 52.8%, respectively. [h] Same as *e* but with [I] = 10×10^{-3} *M* and total extent of reaction of 58.5, 57.3, 55.2 and 53.4%, respectively. [i] Same as *h* but with total extent of reaction of 24.3, 23.8, 22.7 and 22.4%, respectively.

In a second series of experiments, *cf.* Table II, the α-chymotrypsin catalyzed hydrolysis of acetyl-L-tyrosinamide in aqueous solutions at 25° and *p*H 7.9 ± 0.1 and 0.1 *M* in the phosphate component of a potassium phosphate buffer was examined in the presence of the above five competitive inhibitors using the same procedures as before.

TABLE II

K_I VALUES OF FIVE COMPETITIVE INHIBITORS OF α-CHYMOTRYPSIN EVALUATED IN AQUEOUS SOLUTIONS AT 25° AND *p*H 7.9 ± 0.1 AND 0.1 *M* IN THE PHOSPHATE COMPONENT OF A POTASSIUM PHOSPHATE BUFFER[a]

Competitive inhibitor	K_I[b]	E_I'[c]	I_I'
Potassium β-(β-indole)-propionate	4.0 ± 0.4[e]	1.4	2.5
β-(β-Indole)-propionamide	1.8 ± 0.2[f]	3.2	0.83
Potassium phenylacetate	60 ± 5[g]	0.10	0.83
Phenylacetamide	11 ± 1[h]	0.52	0.90
Tryptamine hydrochloride	1.4 ± 0.3[i]	4.5	3.6

[a] Evaluated against acetyl-L-tyrosinamide with K_S = 32 × 10^{-3} *M*, [E] = 5.7 × 10^{-5} *M*[d], E_S' = 0.17 × 10^{-2} and S_S' = 0.156 to 1.25. [b] In units of 10^{-3} *M*. [c] In units of 10^{-2}. [d] Based upon an assumed molecular weight of monomeric α-chymotrypsin of 22,000 and a nitrogen content of 16.0%. [e] Based upon 4 sets of experiments with $[S]_0$ = 5, 10, 30 and 40 × 10^{-3} *M*, [I] = 10 × 10^{-3} *M*, *t* = 110 minutes for values of $[S]_0$ = 5 and 10 × 10^{-3} *M* and 150 minutes for values of $[S]_0$ = 30 and 40 × 10^{-3} *M* with a total of 7 observations of extent of reaction within these time intervals, with a total extent of reaction of 44.8, 43.7, 51.3 and 46.9%, respectively, and with [E] = 0.200 mg. protein-nitrogen per ml. of Armour preparation no. 00592. [f] Based upon 4 sets of experiments with $[S]_0$ = 20, 25, 30 and 40 × 10^{-3} *M*, [I] = 1.5 × 10^{-3} *M*, *t* = 150 minutes with a total of 7 observations of extent of reaction within this time interval, with a total extent of reaction 74.4, 72.8, 70.7 and 68.3%, respectively, and with [E] = 0.200 mg. of protein-nitrogen per ml. of Armour preparation no. 00592. [g] Same as *f* but with [I] = 50 × 10^{-3} *M* and total extent of reaction of 74.4, 72.8, 70.7 and 68.3%, respectively. [h] Same as *e* but with extent of reaction of 64.6, 61.3, 66.7 and 63.4%, respectively. [i] Same as *e* but with [I] = 5 × 10^{-3} *M* and extent of reaction of 40.4, 37.8, 47.3 and 44.6%, respectively.

The enzyme-inhibitor dissociation constants obtained from the two series of experiments are given in Table III where they are compared with the previously determined values.[4-6,8] It will be seen that in general the values of K_I obtained in this study are in reasonable agreement with those reported earlier. Where significant differences exist the more recent values are to be preferred.

TABLE III

SUMMARY OF ENZYME-INHIBITOR DISSOCIATION CONSTANTS

Competitive inhibitor	K_I × 10^3, *M* In 0.02 *M* THAM H + N[a]	In 0.02 *M* THAM This study	In 0.1 *M* phosphate N + G[b]

[a] Value of Huang and Niemann.[4-6] [b] Value of Neurath and Gladner[8]. [c] Present as the potassium salt. [d] Present as the hydrochloride. [e] Formed from the amide in the reaction mixture. [f] Actually K_P values, see ref. 9.

From the constants given in Table III we may conclude as before[4-6] that the K_I values of the two bifunctional uncharged competitive inhibitors, *i.e.*, β-(β-indole)-propionamide and phenylacetamide, and the single bifunctional cationic competitive inhibitor, *i.e.*, tryptammonium ion, for aqueous systems at 25° and *p*H 7.9 ± 0.1 and 0.02 *M* in the THAM component of a THAM–HCl buffer or 0.1 *M* in the phosphate component of a potassium phosphate buffer, are identical within the limits of experimental error. In contrast to the above situation it is again seen[4-6] that the K_I values of the two bifunctional anionic competitive inhibitors, *i.e.*, β-(β-indole)-propionate and phenylacetate, in aqueous solutions at 25° and *p*H 7.9 ± 0.1 and 0.02 *M* in the THAM component of a THAM–HCl buffer are substantially greater than those observed in comparable systems 0.1 *M* in the phosphate component of a potassium phosphate buffer. While the K_I values observed in this study, *i.e.*, 11 ± 1.5 and 4.0 ± 0.4 × 10^{-3} *M* and 170 ± 15 and 60 ± 5 × 10^{-3} *M*, lead to differences which are but *ca.* 3-fold in both cases and are thus but *ca.* one-half of the 5–6 fold differences inferred from the earlier values of K_I[4-6,8] there can be no doubt that the observed differences are real and that they suggest a basic difference in the behavior of this class of competitive inhibitors in THAM–HCl and potassium phosphate buffers of *p*H 7.9 ± 0.1. Furthermore, with the above difference in the behavior of two representative bifunctional anionic competitive inhibitors of α-chymotrypsin in 0.02 *M* THAM–HCl and 0.1 *M* potassium phosphate buffers of *p*H 7.9 ± 0.1, which has now been verified by a new set of observations, we can reaffirm our earlier conclusion[9] that the different behavior of bi- and trifunctional anionic competitive inhibitors of this enzyme, with respect to the dependence or lack of dependence of the values of K_I upon the nature of the buffer components in two specified buffers, *cf.* Table III, provides an experimental basis for recognizing bi- and trifunctionality in anionic competitive inhibitors of the type $RCH_2CO_2^-$ and $R'CONHCHRCO_2^-$.

From the observations noted above it is not clear whether the different behavior of β-(β-indole)-propionate and of phenylacetate in 0.02 *M* THAM–HCl and 0.1 *M* potassium phosphate buffers of *p*H 7.9 ± 0.1 is due to a general ionic strength and/or a specific ion effect. To answer this question the inhibition of the α-chymotrypsin catalyzed hydrolysis of acetyl-L-tyrosinamide in aqueous solutions at 25° and *p*H 7.9 ± 0.1 by potassium β-(β-indole)-propionate and by potassium phenylacetate was examined in systems containing varying amounts of the THAM–HCl and/or potassium phosphate buffer components and in one case added sodium chloride, *cf.* Table IV.

A summary of all available information relative to the dependence of values of K_I for β-(β-indole)-propionate and for phenylacetate upon the composition of the reaction system is presented in Table V. Examination of these data and of the plot presented in Fig. 1 indicates that there are at least two factors that appear to have an influence on values of K_I for the bifunctional anionic competi-

tive inhibitors considered in this study. That one factor may be ionic strength and the other the nature of the ion species is seen from the observation that while an increase in ionic strength associated with an increasing concentration of the THAM–HCl buffer components causes a measurable decrease in the enzyme-inhibitor dissociation constants of this class of competitive inhibitors, the presence of significant amounts of potassium phosphate either alone or in the above buffer system produces a still greater decrease in the value

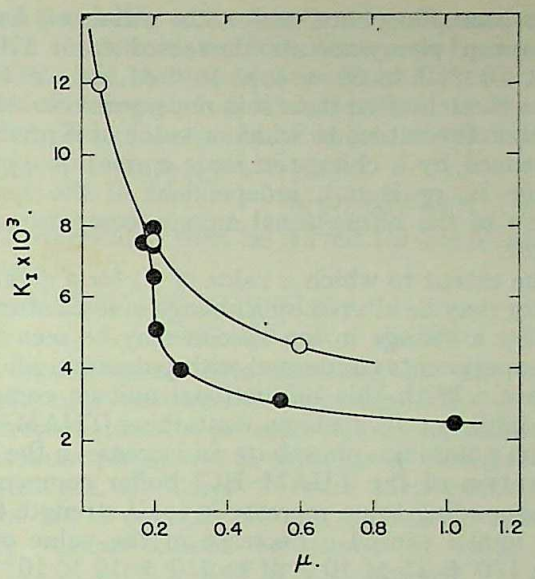

Fig. 1.—Effect of ionic environment upon the enzyme-inhibitor dissociation constants of β-(β-indole)-propionate; open circles THAM–HCl or THAM–HCl and sodium chloride, filled circles potassium phosphate with or without THAM–HCl.

of K_I when the comparisons are made for systems of comparable ionic strength.

TABLE V

EFFECT OF IONIC ENVIRONMENT UPON THE ENZYME-INHIBITOR DISSOCIATION CONSTANTS OF TWO BIFUNCTIONAL ANIONIC COMPETITIVE INHIBITORS

Competitive inhibitor	THAM concn.[a]	Phos. concn.[b]	μ[c]	K_I[d]
β-(β-Indole-propionate[e]	0.02	0.00	0.05	11 ± 1.5
	.40	.00	.20	7.6 ± 0.4
	.40	.00	.60[f]	4.7 ± .4
	.40	.0001	.20	7.5 ± .5
	.40	.001	.20	8.0 ± .3
	.27	.01	.17	7.6 ± .4
	.20	.04	.20	6.6 ± .4
	.00	.0725	.20	5.1 ± .3
	.00	.10	.28	4.0 ± .4
	.00	.20	.55	3.2 ± .5
	.00	.40	1.09	2.5 ± .3
Phenylacetate[e]	.02	.00	0.16	170 ± 15
	.30	.00	.30[g]	110 ± 10
	.00	.10	.30[g]	60 ± 5

[a] Molar concentration of the THAM component of a THAM-HCl buffer of pH 7.9 ± 0.1 at 25°. [b] Molar concentration of the phosphate component of a potassium phosphate buffer at pH 7.9 ± 0.1 at 25°. [c] Ionic strength. [d] In units of 10^{-3} M for aqueous solutions at 25° and pH 7.9 ± 0.1. [e] Present as the potassium salt. [f] 0.4 M sodium chloride also present. [g] 0.15 M in potassium phenylacetate.

In passing from a system in which the ionic strength was 0.05 in the presence of a 0.02 M THAM–HCl buffer to one in which the ionic strength was 0.28 in the presence of a 0.1 M potassium phosphate buffer the value of K_I for potassium β-(β-indole)-propionate decreased from 11 ± 1.5 $\times 10^{-3}$ M to 4.0 ± 0.4 $\times 10^{-3}$ M, *i.e.*, *ca.* 64%. Similarly, in passing from a system in which the ionic strength was 0.16 in the presence of a 0.02 M THAM–HCl buffer to one in which the ionic strength was 0.8 in the presence of a 0.1 M

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

potassium phosphate buffer the value of K_I for potassium phenylacetate decreased from 170 ± 15 × 10^{-3} M to 60 ± 5 × 10^{-3} M, *i.e.*, *ca.* 65%. From these limited data it is not possible to decide whether the extent to which a value of K_I may be influenced by a change in ionic species or concentration is, or is not, independent of the specific nature of the bifunctional anionic competitive inhibitor.

The extent to which a value of K_I for a given inhibitor may be altered by a change in ionic strength and by a change in ion species may be seen from the experiments conducted with potassium phenylacetate. With this bifunctional anionic competitive inhibitor in systems containing THAM–HCl but no potassium phosphate an increase in the concentration of the THAM–HCl buffer components corresponding to an increase in ionic strength from 0.16 to 0.3 caused a decrease in the value of K_I from 170 ± 15 × 10^{-3} M to 110 ± 10 × 10^{-3} M, *i.e.*, *ca.* 35%, corresponding to a decrease in $-\Delta F^0$ of *ca.* 320 cal. per mole. However, in passing from a system containing the THAM–HCl buffer components in an amount corresponding to an ionic strength of 0.16 to one containing the potassium phosphate buffer components in an amount corresponding to an ionic strength of 0.3 the value of K_I was observed to decrease from 170 ± 15 × 10^{-3} M to 60 ± 5 × 10^{-3} M, *i.e.*, *ca.* 65%, corresponding to a decrease in $-\Delta F^0$ of *ca.* 670 cal. per mole. Thus, the presence of the 0.1 M potassium phosphate buffer components caused a decrease in $-\Delta F^0$, in addition to that associated with an increase in ionic strength caused by an increase in the concentration of the THAM–HCl buffer components, of *ca.* 350 cal. per mole.

Since there is reason to believe that there are one or more negatively charged groups at or near the catalytically active site of α-chymotrypsin, when this enzyme is present in aqueous solutions at 25° and pH 7.9 ± 0.1,[4-8,16,17] an increase in the ionic strength of the reaction medium would be expected to facilitate the approach of a negatively charged anionic competitive inhibitor to the negatively charged region of the catalytically active site of the enzyme. Thus, since combination would be enhanced the value of K_I would be reduced. While this effect has been observed with the two bifunctional anionic competitive inhibitors considered in this study the fact that the enzyme-inhibitor dissociation constants of the two trifunctional anionic competitive inhibitors that have been examined to date[9] appear to be uninfluenced by the presence of substantial amounts of added potassium phosphate[9] or of calcium chloride[17] suggests that even with what may be regarded, as a first approximation, as an ionic strength effect associated with an increased dielectric constant of the reaction medium there is a striking difference in the nature of the interaction of α-chymotrypsin with bifunctional and trifunctional anionic competitive inhibitors. It is not obvious at the present time as to why the K_I values of trifunctional anionic competitive inhibitors of α-chymotrypsin should be independent of the ionic strength of the reaction system particularly since it is known that the apparent protonation of one or more of the negatively charged groups which are present in the region of the catalytically active site of α-chymotrypsin does result in an expected decrease in the values of K_I for both bi- and trifunctional anionic competitive inhibitors of this enzyme.[5,17,18]

With regard to the possible nature of the specific ion effect noted earlier it may be assumed that the interaction of α-chymotrypsin with a bifunctional anionic competitive inhibitor, in aqueous solutions at 25° and pH 7.9 ± 0.1 in the absence of potassium phosphate, proceeds, in large part, *via* a R_2–ρ_2 interaction[19] with the R_3–ρ_3 interaction[19] being either small or of a negative character particularly in systems of low ionic strength. Thus, the principal attractive forces leading to combination of the enzyme with a bifunctional anionic competitive inhibitor of the type $R_2CH_2R_3$, where R_3 is a carboxylate group, would arise from a one center, *i.e.*, a R_2–ρ_2, interaction. However, if it is also assumed that there is a region of the active site of the enzyme, adjacent to the ρ_3 center, that is receptive to interaction with phosphate[20] then in the presence of phosphate and upon the approach of a bifunctional anionic competitive inhibitor a R_2–ρ_2 interaction would occur and the R_3 group, *i.e.*, the carboxylate group, would attempt to make its usual R_3–ρ_3 approach. However, the presence of combined phosphate near the ρ_3 center of the active site would provide an additional negative charge which would repel the negatively charged carboxylate group more effectively than would the negatively charged group or groups which are normally present at the catalytically active site and the inhibitor would be forced from its normal modes of combination into alternate modes of combination wherein the R_3 group could contribute more effectively to the total binding energy either in a positive or in a less negative sense. Thus phosphate combined with the site would supply the energy required to consummate alternative and more effective modes of combination which are denied to bifunctional anionic competitive inhibitors in the absence of phosphate. Presumably these alternative modes of combination would be unavailable to the trifunctional anionic competitive inhibitors because of steric reasons and thus this class of competitive inhibitors would be unaffected by the presence of phosphate in the reaction system.

For the case of immediate interest the interaction of enzyme, specific substrate and bifunctional anionic competitive inhibitor in the presence of phosphate may, in the first instance, be represented by equations 1 to 7 inclusive where B is taken to be the combining phosphate species. It is not necessary to consider equations such as $E_f + B_f \rightleftarrows EB$ since this implies competitive inhibition by B and it

is known[9] that this situation does not obtain. It is also appropriate to recall[9] that the constant $K_S = (k_2 + k_3)/k_1$ is essentially independent of the ionic strength and of the concentration of B.

$$BE + S_f \rightleftarrows BES \xrightarrow{k_3'} BE + P_{1f} + P_{2f} \quad (5)$$

$$BE + I_f \rightleftarrows BEI \quad (6)$$

$$B + EI \rightleftarrows BEI \quad (7)$$

If it is assumed that all equilibria are attained rapidly relative to the rate of appearance of the reaction products and that [S] >> [E], [B] > [E], $[S_f] \doteq [S]$; $[I_f] \doteq [I]$, $[B_f] \doteq [B]$, $d[ES]/dt \doteq 0$ and $d[BES]/dt \doteq 0$ then with $K_S = [E][S]/[ES]$, K_I^0[21] $= [E][I]/[EI]$, $K_{BE} = [B][E]/[BE]$, $K_{BES} = [B][ES]/[BES]$, $K_{BES'} = [BE][S]/[BES]$, $K_{BEI} = [BE][I]/[BEI]$ and $K_{BEI'} = [B][EI]/[BEI]$ it can be shown that $K_S K_{BES} = K_{BE} K_{BES'}$, $K_I^0 K_{BEI'} = K_{BE} K_{BEI}$ and $K_{BE} = K_S K_{BES}/K_{BES'} = K_I^0 K_{BEI'}/K_{BEI}$. From the relations $[E_f] = [ES]\,K_S/[S] = ([E] - [ES] - [EI] - [BE] - [BES] - [BEI])$ and $v_0 = -d[S]/dt = (k_3[ES] + k_{3'}[BES]) = (k_3 + k_{3'}[B]/K_{BES})[ES]$ we may derive equations 8, 9 and 10.

$$v_0 = \{(k_3 + k_3'[B]/K_{BES})[E]\}/\{1 + (K_S/[S])[1 + [I]/K_I^0 + [B]/K_{BE} + [B][I]/K_{BEI'}K_I^0] + [B]/K_{BES}\} \quad (8)$$

$$K_{BE} = [B]/\{[([E]/v)(k_3 + k_3'[B]/K_{BES}) - 1 - [B]/K_{BES}][[S]/K_S] - 1 - [I]/K_I^0 - [B][I]/K_{BEI'}K_I^0\} \quad (9)$$

$$K_{BEI'} = [B][I]/\{K_I^0\{[([E]/v)(k_3 + k_3'[B]/K_{BES}) - 1 - [B]/K_{BES}][[S]/K_S] - 1 - [I]/K_I^0 - [B]/K_{BE}\}\} \quad (10)$$

Since values of K_S are unaffected by the presence of B in the reaction system one is led to two conclusions, *i.e.*, either K_{BE} and K_{BES} are infinitely large relative to K_S and K_I^0 and hence there is little or no BE and BES formed, or K_S is equal to $K_{BES'}$ and there effectively is no difference between the path by way of ES to products and by way of BES to products. If one examines the latter case and assumes that K_S is equal to $K_{BES'}$ and that k_3 is equal to $k_{3'}$[22] then from the relation $K_{BE} = K_S K_{BES}/K_{BES'}$, K_{BE} may be considered as being equal to K_{BES}. Substituting K_{BE} for K_{BES} in equation 9 and solving for K_{BE} leads to equation 11. An approximate evaluation of equation 11, insofar as the experimental data permitted, indicated that values of K_{BE} will be extremely large relative to values of K_S and K_I^0. Thus, it may be assumed as a reasonable approximation that values of K_{BE}, K_{BES} and K_{BEI} will be so large that they may be ignored for the case at hand. If the validity of this assumption is granted we may regard equations 3, 5 and 6 as being of no practical significance and represent the situation under discussion by equations 1, 2, 4 and 7 where equations 1 and 4 are to be regarded as being equivalent, *vide ante*. It is now possible to simplify equation 8 and to obtain equation 12 which may then be solved for $K_{BEI'}$ as in equation 13.

$$K_{BE} = \{[B][k_3 - (v/[E])[(K_S/[S]) + 1]]\}/\{-k_3 + (v/[E])[1 + (K_S/[S])(1 + [I]/K_I^0 + [B][I]/K_{BEI'}K_I^0)]\} \quad (11)$$

$$v_0 = k_3[E]/\{1 + (K_S/[S])(1 + [I]/K_I^0 + [I][B]/K_I^0 K_{BEI'}\} \quad (12)$$

$$K_{BEI'} = [B]/\{(K_I^0/[I])\{(k_3[E][S]/v) - [S](1/K_S) - 1 - [I]/K_I^0\}\} \quad (13)$$

The experimental data obtained for the system α-chymotrypsin–acetyl-L-tyrosinamide–β-(β-indole)-propionate in the presence of varying amounts of potassium phosphate in systems of comparable ionic strength, *cf.* Table V, were then evaluated with the aid of equation 13 and the known values for the various kinetic constants. A value of $K_{BEI'} = 150 \pm 50 \times 10^{-3}\ M$ was obtained.

It should be noted that meaningful values of $K_{BEI'}$ cannot be obtained for low values of B because the anticipated small differences in values of v_0 would be well within the limits of error associated with the evaluation of K_I^0. It will also be noted that the value of $K_{BEI'}$ is large relative to values by K_I^0. Consequently, contributions of BEI will be quite small for low values of B. This is in agreement with the experimental observations given in Table V.

It is now possible to relate changes in the values of K_I to changes in the concentration of B. In the absence of inhibition by the hydrolysis products, *i.e.*, for initial rates, the velocity expression is given by equation 14. From equation 12 we may obtain equation 15. By equating equations 14 and 15 and solving for K_I we may obtain equation 16.

$$v_0 = k_3[E][S]_0/\{K_S(1 + [I]/K_I) + [S]_0\} \quad (14)$$

$$v_0 = k_3[E][S]/\{K_S(1 + [I]/K_I^0 + [I][B]/K_I^0 K_{BEI'} + [S]\} \quad (15)$$

$$K_I = K_I^0 + [B]/K_{BEI'} \quad (16)$$

Equation 16 yields values of K_I which are in reasonable agreement with the experimentally determined values of K_I, *cf.* Table VI. Thus it may be seen that for the case at hand the argument given above provides a satisfactory description of the inhibition of the α-chymotrypsin catalyzed hydroly-

sis of acetyl-L-tyrosinamide by two representative bifunctional anionic competitive inhibitors in aqueous solutions at 25° and *p*H 7.9 ± 0.1 in the presence of varying amounts of potassium phosphate.

The authors wish to express their indebtedness to Drs. Robert Bock, Ralph Lutwack and Myron Arcand for many helpful suggestions and criticisms offered during the course of this investigation.

Experimental[23]

Specific Substrate and Competitive Inhibitors.—Acetyl-L-tyrosinamide, colorless needles, m.p. 226–228°, $[\alpha]^{24}D$ + 51.8° (*c* 0.8%, in water) was prepared as described previously.[9] β-(β-Indole)-propionic acid, colorless needles, m.p. 133–134°, was recrystallized twice from a mixture of water and methanol. β-(β-Indole)-propionamide, fine, stunted colorless needles, m.p. 205–207°, was prepared as described previously.[4] Phenylacetic acid, shiny platelets, m.p. 77–78°, was recrystallized three times from a mixture of ethanol and water. Phenylacetamide, short, colorless needles, m.p. 157–158°, was prepared as described previously.[4] Tryptamine hydrochloride, short dense colorless prisms, m.p. 250–251°, was recrystallized twice from aqueous 5 *N* hydrochloric acid.

Enzyme Experiments.—The analytical procedure described previously[9] was employed without modification. The anionic competitive inhibitors were introduced into the reaction mixtures in the form of their potassium salts. The buffer compounds were prepared as before.[9] Crystalline bovine α-chymotrypsin Armour lot no. 00592 was employed in all experiments. The primary data were evaluated as before.[9]

The Availability of the Disulfide Bonds of Human and Bovine Serum Albumin and of Bovine γ-Globulin to Reduction by Thioglycolic Acid

BY EPHRAIM KATCHALSKI, GEORGE S. BENJAMIN AND VIOLET GROSS

RECEIVED FEBRUARY 18, 1957

The extent of reduction of the disulfide bonds of human and bovine serum albumin and of bovine γ-globulin by thioglycolic acid at different *p*H values was investigated. Upon reduction human and bovine serum albumin acquired a maximum of one thiol group per molecule in the *p*H range 5.0 to 7.0. Beyond this range an increasing number of disulfide bonds became susceptible to reduction. In the case of bovine γ-globulin a maximum of one thiol group per molecule appeared upon reduction in the range of *p*H 3.5 to 5.0. With an increase in *p*H an increasing number of disulfide bonds could be reduced. The effect of *p*H on the number of disulfide bonds available for reduction was found to be reversible for bovine serum albumin and for bovine γ-globulin in the *p*H ranges of 1.2 to 10.2 and 5.0 to 10.2, respectively. In the three proteins investigated reduction of most of the disulfide bonds could be effected at *p*H values above 10 in the presence of guanidine. The conversion of unreactive disulfide bonds into reactive ones is explained as being due to changes in the configuration of the protein molecule, which may be either reversible or irreversible ones.

In contrast to the extensive literature dealing with the chemical reactivity of the thiol groups of native and denatured proteins,[1] only a few investigations on the reactivity of the disulfide groups of proteins have been published. Most of the work on the chemical reactivity of protein disulfide groups is concerned with their reduction which can be performed under mild experimental conditions. Reductions of the disulfide bonds of insulin,[2] keratin[3] and lactogenic hormone[4] have been reported. In the case of egg and serum albumin[5] and insulin[6] it was demonstrated that complete reduction of the disulfide bonds by thioglycolic acid can only occur after denaturation. The number of detectable –SH and S–S groups were found by Mirsky and Anson[7] to be closely linked with the extent of denaturation. On reversal of denaturation the number of detectable S–S groups decreased.

In the present article the reduction of the disulfide bonds of human and bovine serum albumin and of bovine γ-globulin by thioglycolic acid at different *p*H values will be described. The results obtained suggest that reversible as well as irreversible changes in the configuration of these proteins may occur.

Experimental

Materials.—Human serum albumin was prepared according to Cohn, *et al.*,[8] and crystallized three times in the presence of decanol. Its thiol content, determined by titration with methyl mercury nitrate (see below), was about 0.3 mole –SH per mole of albumin, assuming 65,000 as the molecular weight of the protein.[9] For the discussion below the value of 17 cystine residues per serum albumin molecule reported by Hughes[9] will be accepted.

Mercaptalbumin.—Mercury–mercaptalbumin dimer was prepared according to Hughes[10,11] and recrystallized five times before use. A pure aqueous solution of mercaptalbumin monomer was obtained from the mercury dimer according to the procedure of Dintzis.[12,13] Titration of the resulting concentrated mercaptalbumin solution with

methyl mercury nitrate (see below) indicated that the mercaptalbumin regenerated contained 0.95 to 1.00 sulfhydryl groups per protein molecule assuming a molecular weight of 65,000.

Bovine serum albumin was obtained from Armour Laboratories, Lot No. 66706, and found to contain 0.25 to 0.35 sulfhydryl group per molecule assuming a molecular weight of 65,000.[9] Also in this case the presence of 17 cystine residues per molecule will be assumed.[9]

Bovine γ-globulin was obtained from Armour Laboratories, Lot B. P. 201–204. No sulfhydryl groups could be detected in this protein on titration with methyl mercury nitrate. The analytical data of Smith and Greene[14] show that the protein contains 18 cystine residues per molecule assuming a molecular weight of 150,000.[9]

Thioglycolic acid was obtained from Eastman Kodak Co. and distilled *in vacuo* before use.

Guanidine Reagent.—Concentrated hydrobromic acid (48%) was added to solid guanidine carbonate until the *p*H was neutral to Hydrion paper. The mixture was filtered and brought to *p*H 10 to 11 with anhydrous sodium carbonate. Solid ethylenediaminetetraacetic acid (Sequestrene, Alrose Chemical Co.) was added to make the solution 0.01 molar in this substance. The ethylenediaminetetraacetic acid was included to bind any traces of heavy metal ions which interfere with the nitroprusside reaction.[11] The final concentration of the guanidine hydrobromide was approximately 5 *M*.

Methyl Mercury Nitrate Solution.—Methyl mercury iodide was crystallized three times from ethanol and a weighed amount of the purified material dissolved in a minimal amount of 95% ethanol. The solution was mixed with an equivalent amount of silver nitrate which had been dissolved in a small volume of water. The precipitated silver iodide was filtered and washed thoroughly with water. The filtrate and washings were combined and diluted with water to give a 10^{-3} *M* methyl mercury nitrate solution. The 10^{-3} *M* methyl mercury nitrate solution could be stored without change for several months in a brown bottle at 0°.

Methods. Reduction of Protein Disulfide Bonds.—Protein solutions of approximately 8% were prepared. Water was used as solvent for human and bovine serum albumin and 2% aqueous sodium chloride for bovine γ-globulin. The desired *p*H was obtained by the addition of 0.1 *N* hydrochloric acid for values below the isoelectric point, of 4% aqueous sodium carbonate for values between the isoelectric point and *p*H 10, or of 1 *N* sodium hydroxide for *p*H values above 10. Protein concentration was then determined by Kjeldahl nitrogen analysis.

The protein solution (5 ml.) was mixed in a Thunberg tube with 0.2 *M* aqueous thioglycolate (5 ml.), previously adjusted to the *p*H of the protein solution, and with water (10 ml.). The resultant *p*H did not differ significantly from that of the component solutions. The reaction mixture was frozen in an ice–salt-bath and the tubes were evacuated and filled with oxygen-free nitrogen. This procedure was repeated three times to ensure complete removal of oxygen. The reduction was finally allowed to proceed at 0°. When the reduction was carried out in the presence of guanidine, a 5 *M* guanidine hydrobromide solution (10 ml.), previously adjusted to the required *p*H, was added to the protein–thioglycolate mixture instead of water.

The final reduction mixtures contained approximately 10 to 20 molecules of reducing agent per protein disulfide bond. The data of Bersin and Steudel[15] for the reduction of cystine seem to indicate that the excess of reducing agent used is adequate for the complete reduction of all available protein disulfide links in the *p*H range investigated.

Titration of Protein –SH Groups.—Sufficient protein to contain approximately 0.5 micromole –SH (*e.g.*, 50 mg. of albumin) was dissolved in 2 ml. of cold guanidine hydrobromide reagent. (Some proteins including serum albumin coagulate as a gel when treated in the dry state with concentrated guanidine salt solution. In such cases, it was advantageous to dissolve the protein first in a small amount, 0.5 ml. or less, of water or diluted guanidine reagent.) A drop of 10% $Na_2Fe(CN)_5NO$ was added and the solution was then titrated with 10^{-3} *M* methyl mercury nitrate to the disappearance of the purple color. The titration was carried out in the cold near 0°. If the solution was not properly cooled or if the titration was unnecessarily prolonged, the end-point was confused by a persistent orange or yellow color. The titration values obtained for a given sample did not deviate by more than 5% from their average.

The protein present in the reduction mixture was prepared for SH– analysis as follows: To an aliquot (2 ml.) of the reduction mixture, 3% trichloroacetic acid (10 ml.) was added and the precipitated protein was centrifuged. The supernatant containing excess thioglycolic acid was discarded and the precipitate resuspended in 3% trichloroacetic acid (10 ml.). The protein was again centrifuged and the procedure repeated five times. The final supernatant contained no thiol groups and the sulfhydryl content of the protein precipitated remained unaltered on further washing with 3% trichloroacetic acid.

Results

Reduction of Human Serum Albumin.—The course of reduction of human serum albumin at different *p*H values in the range of *p*H 3.0 to 10.0 is given in Fig. 1. The figure shows that at each

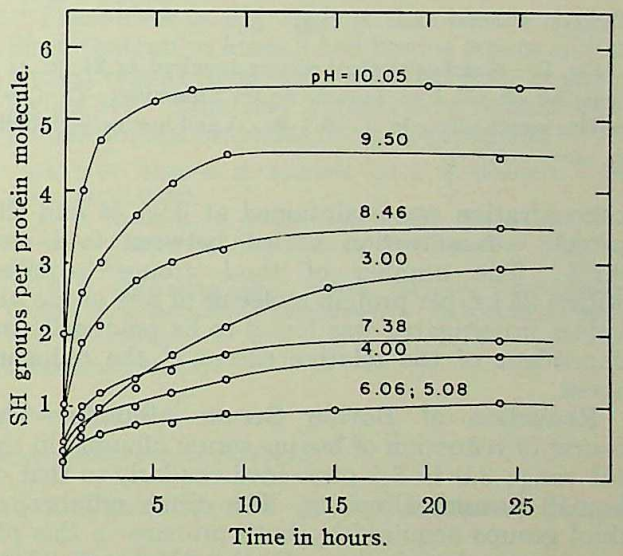

Fig. 1.—Course of reduction of human serum albumin at different *p*H values.

of the *p*H values investigated the number of thiol groups acquired per albumin molecule approached a final value within 24 hr. This value as a function of *p*H is given in Fig. 2, curve 1. The protein reduced in the *p*H range 5.0 to 7.0 was found to contain only one thiol group per molecule. Decreasing or increasing the *p*H of reduction beyond this range resulted in an increase in the number of thiol groups per molecule, the increase being greater in the alkaline range.

When mercaptalbumin was treated with thioglycolic acid in the *p*H range 5.0 to 7.0, no thiol groups in addition to the one originally present per molecule appeared. Furthermore a plot of the data obtained for mercaptalbumin over the whole *p*H range 3.0 to 10.0 gave a curve identical with that obtained with human serum albumin (Fig. 2, curve 1).

Reduction of human serum albumin in the presence of guanidine at *p*H 10.3 caused the appearance of 30 to 31 thiol groups per molecule as compared to the appearance of only 6 thiol groups per molecule at *p*H 10.0 in the absence of guanidine.

In order to ascertain whether the excess of thioglycolate used was sufficient to reduce all the susceptible disulfide bonds, reductions were carried out at *p*H 4.2, 6.0 and 8.45, where the thioglycolate

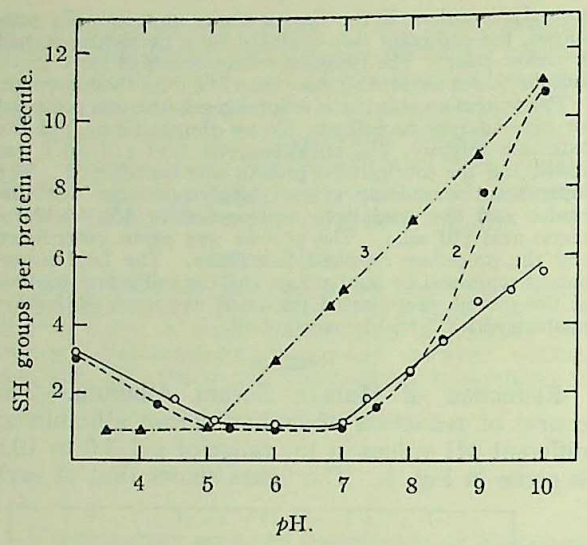

Fig. 2.—Number of thiol groups acquired in 24 hr. as a function of *p*H by: human serum albumin (—○—○—), bovine serum albumin (- - -●- - -●- - -) and bovine γ-globulin (·—▲·—·—▲·—).

concentration was maintained at 0.05 *M* and the protein concentration varied between 0.46 and 3.7%. The number of thiol groups acquired within 24 hr. per protein molecule at any of the *p*H values investigated was found to be practically independent of the relative excess of the reducing agent.

Reduction of Bovine Serum Albumin.—The course of reduction of bovine serum albumin in the *p*H range 3.0 to 8.5 proceeded similarly to that of human serum albumin. The final number of thiol groups acquired by both proteins in this *p*H range was also similar. In the *p*H range 8.5 to 10.0, however, bovine serum albumin acquired a considerably larger number of thiol groups than human serum albumin (see Fig. 2, curve 2). In the presence of guanidine approximately 26 thiol groups were acquired by bovine serum albumin upon reduction at *p*H 11.0. Denaturation of the protein leads therefore, as in the case of human serum albumin, to the exposure of most of the protein disulfide bonds to reduction.

To study whether the effect of *p*H on the availability of disulfide bonds to reduction is reversible, the following experiments were performed. Solutions of bovine serum albumin of various hydrogen ion concentrations were allowed to stand at 0° for different periods of time. The *p*H was then adjusted to 6.0 and the protein reduced with thioglycolate as already described. It was found (Table I) that samples of bovine serum albumin kept at *p*H ranges 1.2 to 3.5 and 8.1 to 10.2 acquired on reduction approximately one thiol group per albumin molecule. As the same number of thiol groups was obtained upon the reduction of freshly prepared protein solutions at *p*H 6.0, it can be concluded that the changes in the albumin molecule in the above acidic and basic ranges are reversible. Samples which were kept at *p*H 13.0 for as little as 1.5 hr. acquired on reduction at *p*H 6.0 four SH-groups per albumin molecule. This indicates that at *p*H 13.0 an irreversible change occurred. A similar irreversible change, but to a somewhat lesser extent, occurred at *p*H 11.0 and 11.9.

TABLE I

THE EXTENT OF REDUCTION OF BOVINE SERUM ALBUMIN AT *p*H 6.0 AFTER PRIOR EXPOSURE TO DIFFERENT *p*H VALUES

*p*H Prior to reduction[a]	Time of exposure, hours	SH/protein molecule after reduction[b]
1.2	24	0.85
1.7	24	.90
2.35	24	.94
3.5	24	.98
8.1	24	.95
9.0	24	.99
9.6	2.5	.95
10.2	24	1.00
11.0	2	0.97
11.0	6.5	1.00
11.0	24	1.35
11.9	3	1.10
11.9	24	1.80
13.0	1.5	4.03
13.0	6.0	4.80

[a] Concentration of albumin 6.5 to 7.0% (w./v.). [b] The reduction mixture contained approximately 2% albumin and thioglycolic acid at a 0.05 *M* concentration. The values given were obtained after reduction at *p*H 6.0 for 24 hr.

Reduction of Bovine γ-Globulin.—The rate of reduction of bovine γ-globulin was as a rule somewhat faster than that of human or bovine serum albumin. The maximum number of thiol groups acquired on reduction with thioglycolic acid at different *p*H values is recorded in Fig. 2, curve 3. In the *p*H range 5.0 to 10.0 the number of protein –SH groups increased almost linearly with *p*H. In the *p*H range 3.5 to 5.0 only one thiol group per protein molecule was found. At *p*H 10.0 in the presence of guanidine hydrobromide 20 to 22 sulfhydryl groups per γ-globulin molecule appeared.

Experiments to study the reversibility of the exposure of disulfide bonds of bovine γ-globulin to reduction analogous to those carried out with bovine serum albumin were performed. The protein was kept in solution at 0° for 24 hr. at *p*H values in the range of *p*H 5.0 to 12.0. The *p*H of the aqueous solutions was then adjusted to *p*H 5.0 and the reduction with thioglycolate carried out as usual. The samples thus treated in the *p*H range 5.5 to 10.2 acquired on reduction at *p*H 5.0 approximately one thiol group per globulin molecule. The exposure of disulfide bonds of γ-globulin in the above *p*H range is therefore reversible. Bovine γ-globulin samples exposed to *p*H 12.0 for only 2 hr. acquired on reduction at *p*H 5.0, 3.5 SH–groups per molecule, indicating that an irreversible change occurred.

Discussion

The results reported above show that each of the three proteins investigated is characterized by a *p*H range at which no significant reduction of disulfide bonds by thioglycolic acid takes place. Beyond this region the number of disulfide bonds susceptible to reduction increases. The change in reactivity of the protein disulfide groups toward thioglycolic acid may be explained by assuming a change in the shape and configuration of the protein mole-

cule transforming chemically unreactive groups to chemically active ones.

Extensive unfolding of the peptide chains of native proteins caused by the breaking up of intramolecular hydrogen bonds is known to take place in the presence of denaturing agents such as urea and guanidine.[1] Such a far reaching change in the configuration of the protein molecule would explain the result obtained where in the presence of guanidine at *p*H 10 most of the disulfide bonds of each of the three proteins investigated were reduced.

The respective *p*H ranges at which human and bovine serum albumin and bovine γ-globulin were found to have a minimal number of disulfide bonds available for reduction correspond to those *p*H ranges where these proteins are known to have a relatively small net electrical charge. Increasing the acidity or alkalinity beyond this *p*H range led to an increase in the number of disulfide bonds reduced. This suggests that increasing the net electrical charge leads to some unfolding of the protein molecule due to electrostatic repulsion thereby exposing a few disulfide bonds to reduction. The observed reversal of the number of disulfide bonds available for reduction implies that the change in configuration of bovine serum albumin in the *p*H range 1.2 to 10.2 (see Table I) and of bovine γ-globulin in the *p*H range 5.0 to 10.2 are reversible.

Similarly, other investigators have concluded that bovine serum albumin can undergo reversible configurational changes within limited *p*H ranges. Klotz, *et al.*,[16] observed that the binding of anionic dyes by this protein is reversible and increases from *p*H 6.8 to 9.2. This was explained as being due to a reversible change in the intramolecular bonding of the protein leading to the exposure of new side chains capable of interaction within the specific dye molecules. Tanford[17] found that the electrostatic interaction factor w decreases for bovine serum albumin from *p*H 5.0 to 2.5. The decrease in w was interpreted to be the result of a corresponding increase in the radius of the molecule. Champagne and Sadron[18] measured the viscosity and diffusion of bovine serum albumin over the *p*H range 3.5 to 10.0. From the data obtained they concluded that the shape of the molecule undergoes a reversible change from a sphere at its isoelectric point, *p*H 5.3, to an elongated ellipsoid of revolution in the *p*H ranges 5.3 to 3.45 and 5.3 to 7.4.

The curves in Fig. 2 show that bovine γ-globulin in contrast to human and bovine serum albumin already exists in a partially unfolded state at physiological *p*H. This may somehow be related to the immunological functions of the γ-globulins.

The Carbonyl Absorption of Carbamates and 2-Oxazolidones in the Infrared Region

BY S. PINCHAS AND D. BEN-ISHAI

RECEIVED JANUARY 28, 1957

The data for the C=O frequency in 21 carbamates show that each type of a carbamic group has its own characteristic absorption region. Primary carbamates, both in the solid phase and in solution in chloroform, absorb at 1725 ± 3 cm.$^{-1}$. Secondary carbamates absorb at 1705–1722 and tertiary at 1687 ± 4 cm.$^{-1}$. The C=O frequency of the carbamic group in linear carbamates with a cyclic nitrogen atom depends upon the electronic effects of the ring and its substituents. Fourteen 2-oxazolidones showed their cyclic carbamic C=O frequency at 1746–1810 cm.$^{-1}$. An appreciable absorption band at 1029–1059 cm.$^{-1}$ is characteristic for the 2-oxazolidone ring.

Although the carbonyl absorption band of the carbamates, $R_1R_2N\text{-}\overset{\overset{O}{\|}}{C}\text{-}OR_3$, has already been reported to appear in the 1690–1736 cm.$^{-1}$ region,[1] only two exact values for this frequency in the case of simple carbamates could be found in the literature[2] these being 1661 cm.$^{-1}$ for an oil paste of ethyl carbamate (urethan) and 1706 cm.$^{-1}$ for a liquid layer of ethyl N-methylcarbamate (methylurethan). Recently the carbonyl frequency of various esters of phenylcarbamic acid (phenylurethans) was measured[3] and was also found to be in this region being about 40 cm.$^{-1}$ higher than in anilides.

Since simple amides can usually be recognized as primary, secondary or tertiary amides from the frequency of their C=O stretching vibration in dilute non-polar solutions, this frequency appearing at about 1690, 1680 and 1650 cm.$^{-1}$, respectively,[4] it was interesting to see whether a parallel regularity could also be found for the similar carbamates. In view of the already mentioned lack of data for the carbonyl frequency in individual simple carbamates, their measurement seemed worth while and, since a series of such compounds was at our disposal, this measurement was undertaken.

Table I summarizes the results obtained for the carbamic carbonyl group frequency in 21 various carbamates.

[a] Shows the amide C=O band at 1675 $cm.^{-1}$. [b] Shows the chlorocarboxy C=O band at 1768 $cm.^{-1}$.

Discussion

It can be seen from Table I that, as in the case of amides, the different classes of simple carbamates, primary, secondary and tertiary, may in fact be identified by their characteristic carbonyl frequency. Thus, a frequency of 1725 ± 3 $cm.^{-1}$ is common to all the primary carbamates reported here, a frequency of 1714 ± 9 $cm.^{-1}$ (1722–1705 $cm.^{-1}$) is typical for all the secondary carbamates and a value of 1687 ± 4 $cm.^{-1}$ represents the frequency of all the tertiary carbamates. The somewhat wide limits of the secondary carbamate frequency region are caused by having them include two secondary carbamates in which two special effects are operating to respectively increase and decrease the normal carbonyl frequency. If these cases are ignored, the limits can be set as 1714 ± 3 $cm.^{-1}$ but then only on the basis of two examples. In the case of the primary–secondary carbamate (no. 4) there appears only one carbonyl band as can be expected from the nearness of the characteristic ranges for the primary and secondary carbamic groups, which probably causes the merging together of the two carbonyl absorptions. The united carbonyl band would be expected to occur about half way between 1714 and 1725 $cm.^{-1}$, in good agreement with the observed value of 1718 $cm.^{-1}$. In the case of the primary–tertiary carbamate (no. 11) the interval between the corresponding regions is bigger, and the two absorptions appear therefore as two separate bands at 1687 and 1722 $cm.^{-1}$.

The value of 1728 $cm.^{-1}$ found here for the carbonyl group absorption of an oil paste of ethyl carbamate is in line with that obtained for an oil paste of the similar compound no. 3 (1726 $cm.^{-1}$) and agrees with the value of 1725 $cm.^{-1}$ obtained for it in solution as well as with the value of 1724 $cm.^{-1}$

of benzyl carbamate in solution. This value contradicts, however, the value of 1661 cm.$^{-1}$ given by Randall, *et al.*,[2] for the C=O frequency of an oil paste of ethyl carbamate (urethan), although their spectrum also shows a shoulder at 1730 cm.$^{-1}$, which after subtracting the atmospheric water vapor absorption in this region may turn out to be a strong band. It is true that an oil paste (but not a chloroform solution) of ethyl carbamate shows also strong and diffuse bands at about 1662 and 1614 cm.$^{-1}$, but none of these can be ascribed to the C=O frequency as can be judged from the values cited above for this frequency in similar compounds. Another argument against such an assignment is that in analogy to amides[4] one must assume the primary carbamate C=O group to absorb at a higher frequency than the C=O group of secondary and tertiary carbamates because of a stronger contribution from the resonating structure VI to the actual structure of the carbamates in the

$$R_1R_2N^+=C-OR_3$$
$$\qquad\quad |$$
$$\text{VI}\qquad O^-$$

latter case. It can be seen from Table I that this is the case if we assign, as was done above, the 1725 cm.$^{-1}$ band to the C=O stretching vibration of primary carbamates. If, however, the 1662 cm.$^{-1}$ band is assigned to this stretching vibration, then the primary carbamate C=O absorption is not higher than the secondary and tertiary carbamate C=O absorption at 1714 and 1687 cm.$^{-1}$, respectively, but lower. This 1662 cm.$^{-1}$ band also cannot be due to a strongly hydrogen bonded C=O frequency of the solid state since the C=O oil paste frequency of N-carboxyglycine dibenzyl ester (no. 5; see also no. 3) appearing at 1715 cm.$^{-1}$ is not materially different from the solution frequency while it is still mainly due to the carbamic group as can be judged from the fact that there is no other remarkable band down to 1530 cm.$^{-1}$. This means that in contradistinction to the amidic groups[4] the carbamic groups are not much affected by hydrogen bonding. This might be due to the lower polarization of its C=O double bond because of the electronegative effect of the neighboring OR group and has its analogy in ketones, the C=O frequency of which is also only slightly affected by ordinary hydrogen bonds.[5] The 1662 and 1614 cm.$^{-1}$ bands (Randall, *et al.*,[2] give 1661 and 1618 cm.$^{-1}$) seem therefore to stem from a splitting of the carbamic N–H group bending frequency because of the presence of two such hydrogen atoms here, the corresponding frequency in the case of solid primary amides[4] being shown at 1620–1650 cm.$^{-1}$. Such a splitting of a vibration because of a doubling of the vibrating unit on the same atom is very common.[6] In a chloroform solution these bands move to lower frequencies and unite in a broad band centered at about 1590 cm.$^{-1}$. This fact supports the above assignment, for the primary amide N–H band also behaves similarly by moving to about 1600 cm.$^{-1}$ in solution.[4] The Raman band observed for this substance in the melted form[7] at about 1692 cm.$^{-1}$ (besides a band at 1606 cm.$^{-1}$) may be a joint band made up of the bands at about 1728 and 1662 cm.$^{-1}$.

The value of 1714 ± 9 cm.$^{-1}$ found here for the C=O frequency in secondary carbamates agrees with the value of 1706 cm.$^{-1}$ given by Randall, *et al.*,[2] for ethyl N-methylcarbamate and with the value of 1704 cm.$^{-1}$ found by Baker and Joseph[3] in the case of an oil paste of a complex secondary carbamate which contains a hydroxy group in a γ-position to the carbonyl group. The somewhat lower carbonyl frequency in this case, relative to the usual frequency of about 1714 cm.$^{-1}$, as also in the case of compound 6, is probably the result of an internal hydrogen bond between the γ-hydroxy group and the carbonyl group (chelation). The small increase in the C=O frequency of I (no. 8) —1722 cm.$^{-1}$—seems to be due to the strong negative inductive effect of the chlorocarboxy group on the carbamic C=O group polarization. The even higher frequencies of this group observed by Randall, *et al.*,[2] in various substituted carbamates (*e.g.*, ethyl methoxycarbamate (methoxyurethan), 1727 cm.$^{-1}$; ethyl N-α-toluylcarbamate (phenacetylurethan), 1748 cm.$^{-1}$) must also be explained similarly, the effect of the substituents being here stronger because of their direct bond to the nitrogen atom. The frequencies of 1727 and 1745 cm.$^{-1}$ observed[3b] for the C=O group (in the undiluted phase) of ethyl N-trifluoromethylcarbamate and ethyl N-heptafluoropropylcarbamate, respectively, are probably fully analogous.

Thus it is clear that the C=O frequency of simple secondary carbamates appears at about 1715 cm.$^{-1}$ both in solution in chloroform and in the solid phase. This value contradicts the figures of 1735 and 7000 (probably a misprint for 1700) cm.$^{-1}$ reported by Thompson, *et al.*,[1b] for the C=O band in secondary urethans in chloroform solution and the liquid or solid phase, respectively (without giving any actual value). The values given by Thompson, *et al.*,[1b] for the C=O absorption of primary and tertiary urethans in chloroform solution are, however, in good agreement (1728 and 1690 cm.$^{-1}$, respectively) with the results reported above. Their value of 1690 cm.$^{-1}$ for undiluted primary urethans seems again to be due to non-resolution of the broad bands at about 1725 and 1660 cm.$^{-1}$.

The NH bending frequency appeared at 1530 cm.$^{-1}$ in an oil paste of compound 5 (Thompson, *et al.*,[1b] give 1540 cm.$^{-1}$ for a N–H bending in the solid or liquid phase of secondary urethans; see also ref. 3a) and at 1512 cm.$^{-1}$ in chloroform solution (Thompson, *et al.*, 1530). Compound 6 showed this band in carbon tetrachloride solution at 1516 cm.$^{-1}$, compound 7 showed a broad N–H bending absorption at 1514 cm.$^{-1}$ in $CHCl_3$ (both an amidic and a carbamic band) and compound 8 showed it (in $CHCl_3$) at 1509 cm.$^{-1}$. The corresponding amidic band appears[9] in solution at 1550–1510 cm.$^{-1}$ and in the solid phase at 1570–1515 cm.$^{-1}$.

The value of 1687 ± 4 cm.$^{-1}$ for the frequency of the tertiary carbamates means that while the first alkyl group introduced into the primary carbamate molecule decreases its frequency by about 10 cm.$^{-1}$ only, the second alkyl group decreases it by about 25 cm.$^{-1}$. The same phenomenon is also shown by amides in dilute solution as can be judged from the values of 1690 (primary), 1680 (secondary) and 1650 cm.$^{-1}$ (tertiary).[4] The reason for this behavior is difficult to see but may be connected with the direction of the positive inductive effect of the alkyl groups (which increases the contribution of the polar form VI to the actual structure of the carbamate molecule). Thus, because of the pyramidal form of the trivalent nitrogen atom[10] (with the lone pair of electrons above it), this effect is directed, in monoalkyl carbamates, not toward the N–CO bond but at an angle to it, while in dialkylcarbamates the resultant of the effects of the two alkyl groups is (taking in account its projection on the basal plane) in this direction and is therefore much more efficient in increasing the contribution of the resonating structure VI to the structure of the tertiary carbamates.

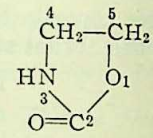
If the results for the linear carbamates which contain a cyclic nitrogen atom are examined, it can be seen that their C=O frequency reflects clearly the electronic effects of their substituents, especially those in the 2-position of the oxazolidine ring. Thus, N-carboethoxy-1,3-oxazolidine, which bears no substituent in this position, absorbs at 1706 cm.$^{-1}$ while its 2-pentamethylene derivative (as also the similar compound 14) absorbs at 1678 cm.$^{-1}$. This decrease in frequency is probably the result of the positive inductive effect of the 5 methylene groups, attached in the latter case to the 2-carbon atom, which strengthens the polarization of the carbonyl group. The reason for the value of 1706 cm.$^{-1}$ for N-carboethoxy-oxazolidine itself which is higher than that of ordinary tertiary carbamates (1687) seems to be its $-CH_2O-$ group, attached to the nitrogen atom, which probably does not possess a positive inductive effect. This compound should therefore be looked at, in this respect, as a secondary, rather than tertiary, carbamate which absorbs in this region.

In the case of the N-carboalkoxy-2-oxazolidones, the substituent in the 2-position (the oxygen atom) has a strong negative inductive effect, and therefore an increase of their carbamate carbonyl frequency must be expected. Indeed, all the oxazolidonic carbamates measured (no. 15–21) show this band in the higher frequency range of 1718–1731 cm.$^{-1}$. This value may be compared with the value of 1736 cm.$^{-1}$ obtained by Randall, *et al.*,[2] for the carbamic C=O frequency of the somewhat similar ethyl methylbenzoylcarbamate. It is interesting to note that the highest frequency is observed with the *p*-nitrobenzyl ester where there exists an appreciable electron attraction away from the carbamic C=O group. This attraction would of course tend to increase the bond strength of this carbonyl group.

The 2-Oxazolidone C=O Absorption.—If the carbamic ester grouping is part of a five-membered ring, *e.g.* in 2-oxazolidones, then an additional factor must be taken into account when its C=O frequency is considered. This factor is the strain of such a five-membered ring which as a rule increases its exocyclic stretching frequencies.[11] This strain is apparent in the C=O frequency of γ-lactones which rises to about 1770 cm.$^{-1}$ as compared with the value of about 1740 cm.$^{-1}$ in the case of esters and six-membered lactones.[12] The C=O frequency of oxazolones is also very high,[13] at about 1820 cm.$^{-1}$, partly because of this strain. Thus the C=O frequency of simple 2-oxazolidones would already be expected to be quite high, while in N-acetylated oxazolidones this frequency would be expected to rise even more. Table II shows that this is really the case.

TABLE II

THE FREQUENCY OF THE 2-OXAZOLIDONE C=O STRETCHING VIBRATION



Material	Concn. g. + 1 ml. $CHCl_3$[a]	Frequency, cm.$^{-1}$	Bands in 1100–1000 cm.$^{-1}$ region
2-Oxazolidone	0.056	1760(broad)	1085, 1029
4-Dimethyl-	.034	1748	1043
N-Methyl-	.05	1746	1049
N-Phenyl-	.031	1753	1053
N-Acetyl-	.056	1785[b]	1057, 1038
N-Benzoyl-	.050	1793[c]	1100, 1041
N-Carboethoxy-	.050	1798	1079, 1043
N-Carbopropoxy-	.042	1795	Not measured
N-Carboallyloxy-	.050	1805	Not measured
N-Carbobenzyloxy-	.073	1810	1085, 1039
N-Carbo-*p*-nitro benzyloxy-	.036	1798	Not measured
4,5-Tetramethyleno-2-oxazolidones			
N-Benzoyl-	0.048[e]	1791[d]	1099, 1059
N-Carbobenzyloxy-*cis*- (IV)	.095	1807	1073, 1033
N-Carbobenzyloxy-*trans*- (V)	.070	1807	1090, 1037

[a] Unless otherwise stated. [b] The amidic CO group absorbs at 1695 cm.$^{-1}$. [c] The amidic CO group absorbs at 1679 cm.$^{-1}$. [d] The amidic CO group absorbs at 1677 cm.$^{-1}$. [e] 1 ml. CCl_4.

It is interesting to note that N-methyloxazolidone absorbs at a lower frequency than oxazolidone (1746 as compared with 1760 cm.$^{-1}$) as can be expected from the inductive effect of the N-methyl group. The high polarization of N-methyloxazolidone, as evidenced by its high electric moment,[14] would also suggest that its CO frequency is not relatively high. This decrease in frequency is especially remarkable because of the stable hydrogen bonded dimer form of 2-oxazolidone (VII) which persists even in dilute solution,[14] since such a structure would probably diminish considerably the

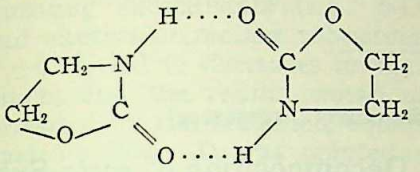
C=O frequency of oxazolidone from its "free" value. It must be added that when methyl oxazolidone was measured in a carbon tetrachloride solution and not in chloroform (which is known to



VII

decrease the C=O frequency of the materials dissolved in it[15]), it showed this band at about 1760 cm.$^{-1}$.

The value of 1724 cm.$^{-1}$ is reported in the literature[16] for the CO frequency of 2-oxazolidone in the solid phase.

The case of 4-dimethyloxazolidone seems to be similar and here also a stable dimer must be expected with an accompanying decrease in the C=O frequency. The further decrease of this frequency in this case (1748 as compared with 1760 cm.$^{-1}$ for oxazolidone) probably is due to the positive inductive effect of the two neighboring methyl groups on the nitrogen atom, in analogy to the effect of the pentamethylene group in the case of carbamates 13 and 14 (see above).

The relatively low C=O frequency of N-phenyloxazolidone (1753 cm.$^{-1}$) is also remarkable, especially since in anilides the phenyl ring has an opposite effect.[1a] In N-phenyl carbamates, however, the C=O frequency observed in the solid phase was also relatively low (1690–1720 cm.$^{-1}$).[3a]

In comparison with the oxazolidonic C=O frequency, that of 2-pyrrolidone and N-methyl-2-pyrrolidone was also measured. Pyrrolidone showed the CO band in carbon tetrachloride solution (0.046 g. + 1 ml.) at 1678 cm.$^{-1}$ and N-methylpyrrolidone, in chloroform, at 1688 cm.$^{-1}$. 2-Pyrrolidone is known to form hydrogen bonded dimers even in dilute solutions[17] and its lower frequency is therefore understandable. Mecke and Mecke[16] give the value of 1690 cm.$^{-1}$ for this frequency in the liquid phase and 1706 cm.$^{-1}$ for a 0.05–0.1 mole per liter solution in CCl_4. The last value seems to be due to the "free" molecule which is probably present in this dilution. The much lower frequency of N-methylpyrrolidone, relative to that of N-methyloxazolidone (1746 cm.$^{-1}$), seems to suggest a much larger ionic character in the former case as is the case in amides in general. This assumption, however, is at variance with the present view[14,18] based on electric moment measurements. It must also be pointed out that in going over from an open structure to a five-membered ring the tertiary carbamates suffer the biggest increase in the CO frequency. Thus the increase in this case is about 60 cm.$^{-1}$ as compared with about 45 cm.$^{-1}$ for secondary carbamates, 40 cm.$^{-1}$ for tertiary amides and 30 cm.$^{-1}$ for saturated esters.

The acyl groups can again be observed, in Table II, to increase appreciably the C=O frequency, this effect being highest in the case of the aromatic acyl derivatives (*e.g.*, N-benzoyl-oxazolidone, 33 cm.$^{-1}$), maybe because of the higher polarization of the acylic C=O group in this case. The still higher oxazolidonic C=O range (1795–1810 cm.$^{-1}$) of the N-carboalkoxy-oxazolidones is to be expected in the light of the increased electron attraction power of the carboalkoxy group.

Apart from the oxazolidone C=O frequency another band seems to be characteristic for the oxazolidonic ring. This medium-strong band appears at 1029–1059 cm.$^{-1}$ in all the measured compounds containing such a ring, as can be seen from Table II. Sometimes this band is split into two branches. These bands seem to be due to the C–OC(O) ring stretching vibrations in analogy to the antisymmetrical ring stretching band of tetrahydrofuran[19] at about 1080 cm.$^{-1}$ and to the N–C–O stretching bands at about 1160, 1130 and 1100 cm.$^{-1}$ of oxazolidines.[20] The Raman band found in solid primary carbamates[7] at about 1120 cm.$^{-1}$ may be the counterpart of this band in the case of the open NC(O)O–C group. The decrease in the stretching frequency of the C–OR bond when this is part of a strained ring is then the usual behavior of such (endocyclic) bonds.[11]

Experimental

The infrared absorption measurements were carried out with a Perkin–Elmer, model 12C, infrared spectrometer equipped with a sodium chloride prism. The synthesis of most of the materials used in this investigation has already been described by Ben-Ishai.[21] The rest of them were either of commercial origin or synthesized according to the literature.

Ethyl carbamate, showed (in solution) also bands at: 3370, 1589, 1468, 1403, 1373, 1324, 1237, 1170, 1061, 985, 956, 889 and 849 cm.

2-Aminoethyl carbamate hydrobromide showed (in an oil paste) the NH_3^+ bands at 1970 and 1920 cm.$^{-1}$ (besides a band at about 3200 cm.$^{-1}$.

2-(Carboethoxyamino)-ethanol showed (in CCl_4 solution) also bands at 3360, 2930, 1516, 1379, 1330, 1248, 1081 and 1036 cm.$^{-1}$.

Carbobenzyloxyglycine-(2-chloroethyl)-amide showed also bands (in $CHCl_3$) at 1514, 1452, 1355, 1261, 1049 and 981 cm.$^{-1}$.

N-Carboethoxy-2-pentamethyleno-1,3-oxazolidine showed (in $CHCl_3$) also bands at 1425, 1379, 1349, 1330, 1277, 1175, 1139, 1073, 1037, 973, 946, 910 and 844 cm.$^{-1}$.

N-Carbopropoxy-2-pentamethyleno-1,3-oxazolidine showed (in $CHCl_3$) also bands at 1452, 1419, 1363, 1341, 1324, 1280, 1237, 1132, 1072, 1024, 978, 942, 910 and 843 cm.$^{-1}$.

N-Carboethoxy-2-oxazolidone showed (in $CHCl_3$) also bands at 1477, 1385, 1307, 1184, 1079 and 1043 cm.$^{-1}$.

N-Carbobenzyloxy-2-oxazolidone showed (in $CHCl_3$) also bands at 3475, 2925, 1590, 1462, 1386, 1315, 1085, 1039, 981 and 908 cm.$^{-1}$.

2-Oxazolidone showed (in $CHCl_3$) bands also at 3440, 3290, 3160, 2925, 1484, 1399, 1332, 1320, 1246, 1085, 1029, 960 and 924 cm.$^{-1}$.

4-Dimethyl-2-oxazolidone showed (in $CHCl_3$) bands also at 3440, 3240, 1466, 1377, 1294, 1235, 1043, 986 and 937 cm.$^{-1}$.

N-Phenyloxazolidone showed (in $CHCl_3$) bands also at 2930, 1599, 1487, 1406, 1309, 1130, 1053, 991, 955 and 899 cm.$^{-1}$.

N-Acetyloxazolidone showed also (in $CHCl_3$) bands at 3465, 3160, 2925, 1482, 1383, 1315, 1240, 1146, 1057, 1038 and 956 cm.$^{-1}$.

Polar Factors in Radical Dissociations. Kinetics of Decomposition of *meta*-Substituted Phenylazotriphenylmethanes[1a]

BY STANLEY SOLOMON, CHI HUA WANG AND SAUL G. COHEN[1b]

RECEIVED JANUARY 9, 1957

meta-Substituted phenylazotriphenylmethanes, m-X—C_6H_4N=NC$(C_6H_5)_3$, X = CH_3, Br, NO_2, (H), have been prepared and decomposed in toluene at two temperatures. The decompositions showed first-order kinetics with activation energies in the range 26–30 kcal. mole^{-1}. The substituent CH_3 led to increased rates, the substituents Br and NO_2 to decreased rates of decomposition, the effects being quite similar to those of p-substituents studied previously. The results for m-substituents were correlated by the Hammett equation, ρ −0.85, and indicated that phenyl radicals may be rendered less stable by electron withdrawal. Factors affecting homolytic dissociation processes are discussed. Decomposition of phenylazotriphenylmethane in acetic acid led to benzene (>40% yield), to biphenyl (10% yield) and to no succinic acid. The origin of the products is discussed.

As part of our study of the effects of structure on the homolytic dissociation of organic compounds, which lead to the formation of free radicals, we have been examining the effects of substituents in the phenyl group of phenylazotriphenylmethanes on the kinetics of their decomposition. The ease with which homolytic dissociation occurs, or the strength of the bond or bonds concerned may be considered in terms of steric effects, polar factors, and the difference in the resonance stabilization of the ground states and transition states.

The decomposition of substituted ethanes[2] R_3–C–C–R_3 shows marked increase in rates and decrease in activation energies as the alkyl groups R are made more complex or are changed to aryl groups, the variations resulting from steric factors, which affect the central carbon–carbon bond, and resonance stabilization of the radicals. Azo-bis-alkanes and azo-bis-arylalkanes R_3C—N=N—CR_3 are related materials, in which the azo linkage facilitates decomposition while reducing steric effects. Substitution of α-alkyl and aryl groups for hydrogen in the parent compound azomethane, R = H, leads to successive and approximately additive increase in rate and decrease in activation energy, which have been interpreted in terms of resonance stabilization of the radicals,[3] and hence of the transition states. Steric effects have also been observed in the decomposition of certain azo compounds, largely due to β-substituents.[4]

Substituents in the nuclei of hexaarylethanes, whether electron attracting or electron donating, increase the extent of their dissociation, the large effects of o-substituents commonly being attributed to steric and resonance factors, and the effects of p-substituents, to resonance.[5] The effect of m-substituents, often attributed to steric factors, may result largely from the charge (+ or −) which they impose upon the aromatic rings to which they are attached, leading, in symmetrically substituted ethanes, to electrostatic repulsions between the two halves and weakening of the central bond. That the effect of m-substituents is comparable to and frequently greater than that of p-substituents indicates that this polar factor may be of importance in the latter case also.

In the decomposition of substituted benzoyl peroxides,[6] electron-donating substituents were found to increase the rates, electron-attracting substituents, (except nitro) to decrease them, and the data fitted the Hammett equation fairly well, ρ −0.38. This was interpreted[6a] in terms of the effects of the substituents on the size of the negative ends of the dipoles, postulated to exist at the central oxygen–oxygen bond and thus on repulsive forces operating between the two halves of the molecules. Similar effects of substituents were observed in the decomposition of t-butyl perbenzoates.[7] Also, in the dissociation of five symmetrically substituted 1,1,4,4-tetraphenyl-2,3-dibenzoyltetrazanes,[8] in which the phenyl substituents were CH_3, H and Br, the equilibrium constants were correlated with the Hammett equation, ρ −1.52. This was interpreted as resulting from stabilization by electron-donating substituents of the positive charge on the α-nitrogen in one of the resonance forms of the hydrazyl radicals. Further study of the dissociation of these tetrazanes indicated that the Hammett equation success-

fully correlated the rates of both the dissociation and the recombination.[9]

In the decompositions of *p*-substituted phenylazotriphenylmethanes[10] we observed that both electron-donating substituents (*e.g.*, *p*-CH_3O, σ −0.27) and electron-attracting substituents (*e.g.*, *p*-NO_2, σ +0.78) led to decreases in the rates of decomposition, and the results would of course not be correlated by the Hammett equation with conventional σ-values. It was pointed out that both types of substituents could increase the resonance stabilization of the ground state by increasing conjugation of the phenyl and azo groups and strengthen the phenyl–nitrogen bond. It was suggested that this effect might be modified by the effects of the substituents on the stability of the phenyl radical and thus on the stabilization of the transition states, with electron-donating substituents stabilizing the radicals and partly counteracting the stabilization of the ground states. Alternatively the observed order could be interpreted in terms merely of the inductive effect, −I substituents decreasing the stability of phenyl radicals. In order to minimize the effect of the substituent on the conjugation of the azo linkage with the phenyl group and to isolate the effect of the substituent on the phenyl radical, it seemed desirable to study some *m*-substituted phenylazotriphenylmethanes. The compounds *m*-X—C_6H_4-N=NC(C_6H_5)$_3$, X = CH_3, Br, NO_2 and (H) were each synthesized by (1) preparation of the substituted phenylhydrazine hydrochloride, (2) condensation of the hydrazine salts with triphenylmethyl chloride to form the hydrazo compounds, *m*-X-C_6H_4-NH-NH-C(C_6H_5)$_3$, and oxidation of the latter to the azo compounds. The unsubstituted hydrazo compound autoxidized during purification leading directly to the azo compound. The *m*-nitro compound was resistant to oxidation, treatment with amyl nitrite finally proving effective. This reagent was used to oxidize the *m*-bromo and *m*-methyl compounds, the reaction in the latter case being quite vigorous. We were unfortunately unable to prepare *m*-methoxyphenylhydrazine and *m*-acetaminophenylhydrazine.

The rates of decomposition of the azo compounds in *ca.* 0.01 *M* solution in toluene were determined under oxygen-free nitrogen at two temperatures by measurement of the volume of evolved nitrogen (V_t) as a function of time, essentially as described previously.[10] Several runs were made at each temperature. Small induction periods (*ca.* 5 minutes) were observed, and zero time readings were obtained by linear extrapolation of a zero-order plot for the first 10% of the reaction back to zero time. These values were used in calculation of V_∞. Linear plots of ln $V_\infty/(V_\infty - V_t)$ *vs.* time were obtained, indicating that the decompositions were first order. Typical plots are given in Fig. 1. One compound, X = *m*-Br, was decomposed at 0.02 mole/l. and at 0.007 mole/l. concentration with no change in rate constant. Rate constants were determined from the slopes, activation energies from the Arrhenius equation and entropies of

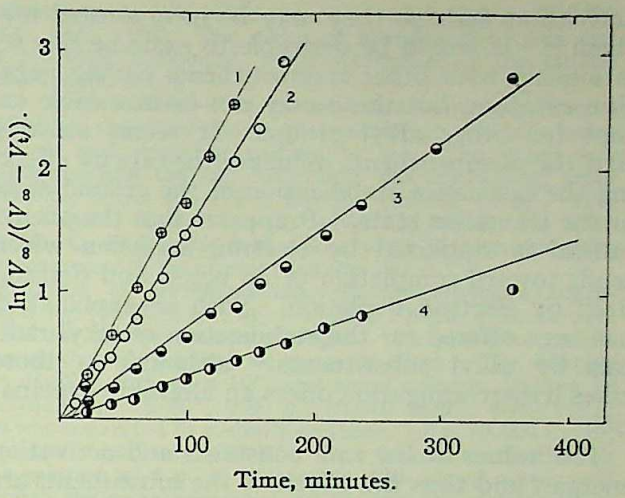

Fig. 1.—Decomposition of *m*-XC_6H_4—N=NC(C_6H_5)$_3$ in toluene, 53.80°: curve 1, X = CH_3; curve 2, X = H; curve 3, X = Br; curve 4, X = NO_2.

activation according to the transition state theory. The data are summarized in Table I.

TABLE I

DECOMPOSITION OF SUBSTITUTED PHENYLAZOTRIPHENYLMETHANES, *m*-X—C_6H_4N=NC(C_6H_5)$_3$

m-X	*T*, °C. ±0.05	No. of runs	$k_1 \times 10^4$ sec.$^{-1}$	E, kcal., mole^{-1}	$\Delta S^\pm$, cal. mole^{-1} deg.$^{-1}$
CH_3	53.80	7	2.77 ± 0.10	27.2 ± 1.5	6 ± 4
CH_3	43.80	3	0.74 ± 0.02		
H	53.80	8	2.40	27.6	7
H	43.80	3	0.63		
Br	53.80	4	1.14	29.9	13
Br	64.00	2	4.58		
NO_2	53.80	4	0.58	26.5	1
NO_2	64.00	3	1.99		

The CH_3 substituent increased the rate of decomposition slightly while the groups Br and NO_2 led to decreased rates. The results are correlated satisfactorily by the Hammett equation (Fig. 2),

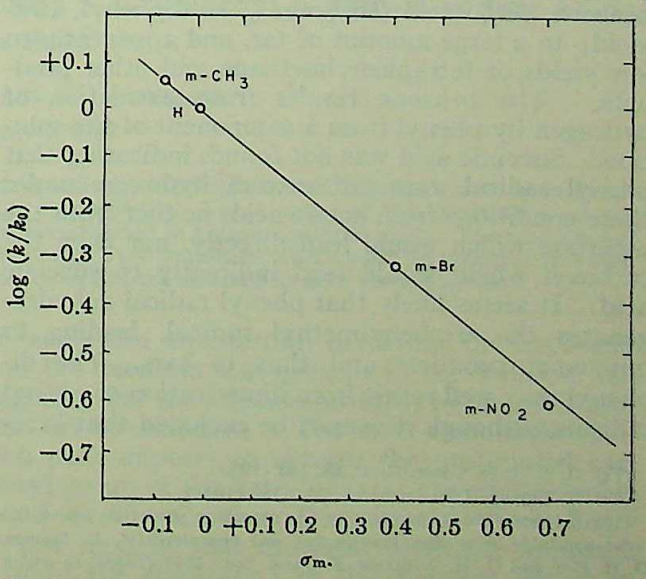

Fig. 2.—ρ–σ plot for decomposition rate constants, *m*-X—C_6H_4N=NC(C_6H_5)$_3$, in toluene at 53.80°.

ρ −0.85; σ CH_3, Br, NO_2: −0.07, +0.39, +0.71, respectively. The entropies of activation are not constant, but since they change with the energies of

activation perhaps they may be incorporated into them.[11] It would be desirable to examine this relationship with other *m*-substituents having negative σ-values, but these may not be accessible except for other alkyl groups. It seems unlikely that the *m*-substituents influence the rate by affecting the resonance stabilization of the ground state or the transition state. It appears that the phenyl radical is stabilized by electron accession which tends toward completion of an octet, and destabilized by electron depletion. Such an explanation has been offered for the stabilization of alkyl radicals by alkyl substituents,[12] although in those cases hyperconjugation offers an alternate explanation.

The values of the rate constants and activation energies and thus the effects of the substituents are quite similar for the *m*-substituted and for the *p*-substituted compounds in the cases in which we can make comparisons. (It may be noted that *m*- and *p*-substituents show similar effects in the dissociation of hexaarylethanes.) Indeed, if log k/k_0 for the *p*-substituted phenylazotriphenylmethanes[10] (CH_3, CH_3O, HO, Br, NO_2) is plotted against *meta* σ-values, the points, with the exception of *p*-methoxyl, lie fairly close to the line drawn through the *m*-values. Whether this is fortuitous, the *p*-effects being the resultant of the several factors discussed above, or whether the effect of *p*-substituents arises in similar fashion to the *m*-effects, possibly from electrostatic effects on the phenyl radicals, is not clear.[13]

Products of Decomposition.—Previous studies of the products of decomposition of phenylazotriphenylmethane have indicated that benzene[14a] was formed in low yield, but that diphenyl was not found except when the decomposition was carried out in benzene,[14b] the solvent contributing one phenyl group to this product, which was formed in low yield. In our work, decomposition of phenylazotriphenylmethane in acetic acid led to benzene, 40% yield (58% cor.); to diphenyl, 10% yield; to a large amount of tar, and apparently to low yields of tetraphenylmethane and other products. The benzene results from extraction of hydrogen by phenyl from a component of the solution. Succinic acid was not found, indicating that phenyl radical does not extract hydrogen under these conditions from acetic acid, neither from the α-carbon which would lead directly, nor from the carboxyl which would lead indirectly to succinic acid. It seems likely that phenyl radical dehydrogenates the triphenylmethyl radical, leading to quinonoid products and thus to tars. The diphenyl may well result from dimerization of phenyl radicals, although it cannot be excluded that it results from substitution by phenyl radical into the benzene which is formed in low concentration during the course of the reaction.

Experimental[15]

m-**Nitrophenylhydrazine Hydrochloride.**[16]—A solution of 10 g. (0.145 mole) of sodium nitrite in 70 ml. of water was added dropwise to a solution of 20 g. (0.145 mole) of *m*-nitroaniline (Fisher) in 200 ml. of concentrated hydrochloric acid at 0–5°. The solution was stirred at room temperature for one hour and recooled, and to it was added slowly a solution of 65 g. (0.29 mole) of $SnCl_2 \cdot 2H_2O$ in 65 g. of concentrated hydrochloric acid. A tan precipitate was collected and crystallized from absolute ethanol, m.p. 208–210°, 16.8 g., 61% yield. *Anal.* Calcd. for $C_6H_8N_3O_2Cl$: C, 38.02; H, 4.24. Found: C, 38.50; H, 4.54.

m-**Bromophenylhydrazine Hydrochloride.**[17]—A solution of 20 g. (0.116 mole) of *m*-bromoaniline (Eastman Kodak Co.) in 200 ml. of hydrochloric acid was treated at 0–5° first with a solution of 8.0 g. (0.116 mole) of sodium nitrite in 16 ml. of water for 0.5 hour, and then with a solution of 52 g. (0.23 mole) of $SnCl_2\ 2H_2O$ in 52.5 g. of hydrochloric acid. A white precipitate was collected, dissolved in 250 ml. of boiling water, neutralized with 3 *N* sodium hydroxide, cooled and extracted with ether. The extract was dried over calcium chloride and treated with dry hydrogen chloride leading to a precipitate which was crystallized from 2-propanol, m.p. 225°, 8.4 g., 32% yield. *Anal.* Calcd. for $C_6H_8N_2BrCl$: C, 32.24; H, 3.60. Found: C, 32.04; H, 3.96.

m-**Tolylhydrazine Hydrochloride.**[18]—A solution of 20 g. (0.19 mole) of *m*-toluidine (Eastman Kodak Co.) in 200 ml. of hydrochloric acid was treated at 0.5° with a solution of 13 g. (0.19 mole) of sodium nitrite in 50 ml. of water, stirred at room temperature for 0.5 hour, recooled and treated with 84 g. (0.37 mole) of $SnCl_2\ 2H_2O$ in 84 ml. of hydrochloric acid. The product was collected, dissolved in hot water, saturated with hydrogen sulfide, filtered, made slightly alkaline with 3 *N* sodium hydroxide, cooled and extracted with ether. The extract was dried, treated with dry hydrogen chloride until precipitation was complete. Excess hydrogen chloride led to decomposition. The product was crystallized from 2-propanol, m.p. 168–170°, 8.6 g., 32% yield. *Anal.* Calcd. for $C_7H_{11}N_2Cl$: C, 52.99; H, 6.99. Found: C, 52.34; H, 6.99.

Toward a-*m*-**Methoxyphenylhydrazine and** *m*-**Acetaminophenylhydrazine.**—A. *m*-Aminophenol, 1.0 mole, was converted to *m*-hydroxyacetanilide, 0.87 mole, m.p. 149°, reported[19] 148°. This product, 0.73 mole, treated with methyl sulfate. led to *m*-methoxyacetanilide, 0.30 mole, m.p. 79–80°, reported[19] 80–81°. This was hydrolyzed with dilute hydrochloric acid, leading to *m*-anisidine, b.p. 249°, reported 251°.[20] Attempts to diazotize the amine and reduce the diazonium compound led to a product which decomposed at room temperature.

b. An unsuccessful attempt was made to prepare *m*-acetaminophenylhydrazine by treatment of a solution of 5 g. (0.27 mole) of *m*-aminoacetanilide hydrochloride in 200 ml. of hydrochloric acid with 1.85 g. (0.027 mole) of sodium nitrite in 15 ml. of water, followed by treatment with 12 g. (0.053 mole) of $SnCl_2$ in 12 g. of hydrochloric acid. No precipitate formed and treatment with alkali, extraction with ether and treatment with dry hydrogen chloride led to a dark oil.

m-**X-Phenylazotriphenylmethanes.**—Equimolar quantities of the substituted phenylhydrazine hydrochloride and triphenylmethyl chloride were allowed to react in dried pyridine at 20° with stirring for three hours. Quantities of materials used are summarized in Table II.

Pyridine hydrochloride was filtered off and washed with cold pyridine and the filtrates were diluted with water. The precipitates were collected and worked up along with ether extracts of the diluted filtrates.

a. X = H.—The hydrazo compound was partially oxidized during evaporation of the ether, leading to a yellow solid. This was dissolved in 600 ml. of absolute ethanol and concentrated in vacuum below room temperature leading to 14.7 g. (0.0425 mole), 77% yield, of crude azo compound, m.p. 107–108° dec., reported 111°.[21] Decomposition of a sample at 100° in decalin led to 67% of the theoretical yield of nitrogen. The nitrogen was swept with carbon dioxide and collected over 50% potassium hydroxide. Four additional crystallizations from absolute ethanol led to a product melting at 110–112° which, when decomposed, led to 96% yield of nitrogen.

TABLE II

REACTION OF TRIPHENYLMETHYL CHLORIDE WITH PHENYLHYDRAZINE

X	m-X-$C_6H_4NHNH_2HCl$, g.	$(C_6H_5)_3CCl$, g.	C_5H_5N, ml.
H	8.0	16.0	120
NO_2	9.7	14.1	130
Br	5.0	6.2	80
CH_3	4.1	8.0	80

b. X = m-NO_2.—The crude hydrazo product melted at 140–150° and was somewhat difficult to oxidize. It was not affected by treatment in ether solution at room temperature with 35% hydrogen peroxide in the presence and absence of sodium bicarbonate. It was oxidized slowly by hydrogen peroxide in acetone. It was apparently oxidized by nitrogen dioxide in acetic acid, but the results were not consistent. Amyl nitrite led to satisfactory results and was used in subsequent syntheses. The hydrazo compound, 2.32 g., was suspended in anhydrous ether and treated with two molar equivalents of amyl nitrite and a few drops of acetyl chloride, a clear yellow solution resulting. The solution was filtered and evaporated in vacuum and the azo compound was crystallized from methanol, m.p. 111–112°, reported[17] 111–112°.

c. X = m-Br.—The crude hydrazo product was suspended in ether and oxidized as described above. The ether was evaporated and the product was washed with methanol, m.p. 108–109°, reported[17] 110°, 3.9 g. (0.0091 mole), 41% yield. The yields of nitrogen from this and the preceding compound, when determined in the kinetic runs were 100 ± 3%.

d. X = m-CH_3.—The crude hydrazo compound was oxidized as described above, the reaction in this case being vigorous and requiring cooling in ice. The ether was evaporated and the azo compound was crystallized from methanol, m.p. 108–109°, 6.0 g., (0.0165 mole), 64% yield. *Anal.* Calcd. for $C_{26}H_{22}N_2$: C, 86.15; H, 6.12. Found: C, 84.88; H, 6.16. The yield of nitrogen from this compound in the kinetic runs was 100 ± 2%.

Products of Decomposition.—Phenylazotriphenylmethane, 8.6 g. (0.025 mole), was heated in 100 ml. of acetic acid at 63° for 24 hours under nitrogen. Air was then passed through the solution with no apparent effect. The solution was distilled through a 10″ glass spiral column, leading to benzene, b.p. 78–80°, 0.80 g., (0.010 mole), 40% yield; this was converted to m-dinitrobenzene. 1.5 g. (0.009 mole), m.p. and mixed m.p. 88–89°. In a blank run distillation of a solution of 1 g. of benzene in 100 ml. of acetic acid through the same apparatus led to recovery of benzene in 70% yield. The remainder of the acetic acid was distilled off and the residue was extracted with 40 ml. of hot water. Concentration of the aqueous extract to dryness led to no succinic acid.

The residue was further extracted with 80 ml. of hot ethanol, leading to an insoluble tar; a suspended solid, 0.025 g., m.p. 270°, apparently tetraphenylmethane, 0.3% yield, reported[21] m.p. 267°; and the alcoholic extract. The latter was cooled, leading to a tar; a solid, 0.5 g., m.p. 120–140°, from which, after recrystallization from alcohol there was obtained a product, 0.030 g., m.p. 146°, possibly hexaphenylethane 0.5% yield, reported[22] m.p. 145–147°; and the alcohol solution. The latter was steam distilled, leading to biphenyl, 0.2 g. (0.0013 mole), 10% yield, m.p. and mixed m.p. 68–69°. Extraction of the tars with hot benzene led to an impure solid, 0.42 g., m.p. 80–92, which was not worked up further.

The Kinetics of Ring Closure of Alkyl-substituted 3,3-Dimethyl-5-keto-hexanoic Acids by Sulfuric Acid

BY W. E. SILBERMANN AND T. HENSHALL[1]

RECEIVED JANUARY 4, 1957

Acid-catalyzed ring-closures of 3,3-dimethyl-5-keto-hexanoic acid and of 6-alkyl-substituted homologs have been found to give dimedone and 3,3-dimethyl-6-alkyl-cyclohexanediones-1,5, respectively. The kinetics of the cyclizations of the hexanoic acid and of four alkyl-substituted derivatives have been investigated in aqueous sulfuric acid. The reaction has also been followed in acetic acid–sulfuric acid solution. The kinetic results are consistent with a reaction sequence in which the rate-controlling stage is electrophilic attack by C_1^+ on the double bond of the enolized form of the keto-acid.

The results of preliminary experiments on the cyclization of 3,3-dimethyl-5-keto-hexanoic acid (III, R = H) to dimedone by aqueous sulfuric acid already have been reported.[2] In further work on this reaction, the range of acid concentrations has been extended, and it has been observed that the activation energy for the process is markedly dependent on the acidity of the solvent, decreasing as the concentration of sulfuric acid increases (Table II). This effect is interpreted in terms of an acid–base equilibrium involving the keto-acid and the oxonium ions present in the solution and suggests that the reaction proceeds by way of a protonated intermediate. The most reasonable reaction path appears to involve the protonated carboxyl group of the keto-acid and the enolic double bond at C_5=C_6 (see Discussion). Accordingly it was thought that the most profitable approach toward the elucidation of this reaction lay in an investigation of the effects of substituent groups with definite electronic properties on the π-electrons of the enol form. The choice of suitable substituents, is, however, strictly limited both by the ease of preparation by synthesis and by the stability

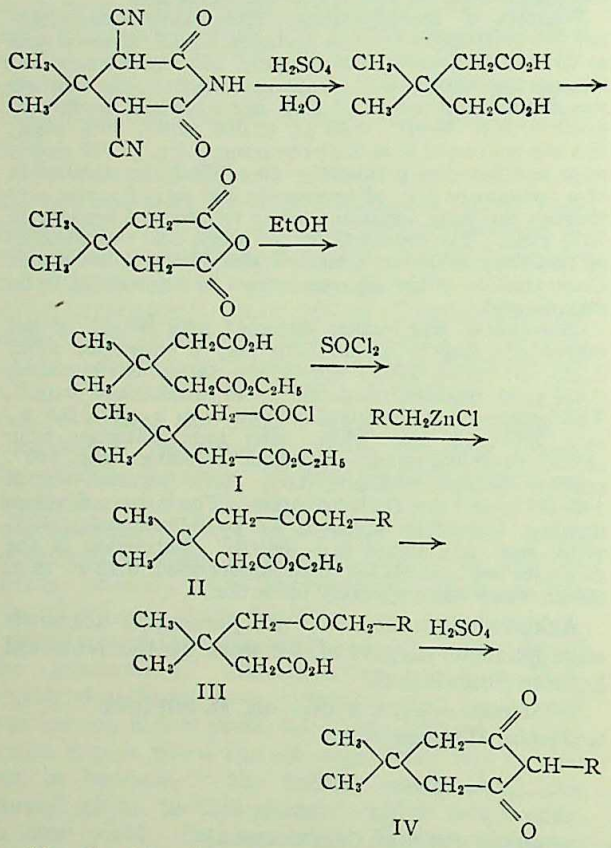
of such groups to the reaction medium. A start has been made with those keto-acids substituted on C_6[3] by methyl, ethyl, *n*-propyl and isopropyl groups. These were prepared by the route outlined below, in which α,α'dicyano-β,β-dimethylglutarimide, obtained from acetone and cyanoacetic ester by Guareschi's method, is converted successively into β,β-dimethylglutaric acid, anhydride, half-ester, ester chloride, keto-ester and keto-



acid. In kinetic measurements on these acids, only the trimethyloctanoic acid (III, R = isopropyl) showed any departure from simple kinetic order, an effect which may arise from the bulky nature of the isopropyl group. The activation energies for ring closure of the substituted acids were found to be significantly lower than for the parent compound, and the same dependence of activation energy on sulfuric acid concentration of the medium was observed also for the heptanoic, octanoic and nonanoic acids. The curves of E_a against "% H_2SO_4" are roughly parallel (see figure) corresponding to a differential heat, ΔH, of the order of 2 kcal. mole^{-1} over the range of investigation.

Additional evidence in support of the proposed mechanism has been obtained from kinetic measurements in acetic acid–sulfuric acid mixtures; in the presence of high concentrations of sulfuric acid the kinetics in this medium are much more complicated than those in aqueous solution, but good first-order rate constants are obtained from measurements in acetic acid containing small proportions of sulfuric acid. Rates similar to those obtained in aqueous solutions were induced by these relatively smaller amounts of the mineral acid, indicating the probability of easier proton transfer from the acetoxonium ion to the basic centers of the keto-acid molecule. The activation energies in acetic acid solution were also much lower than in water. Traces of water added to the acetic acid–sulfuric acid solvent had only slight effects on the total rate but raised the energy of activation and correspondingly reduced the entropy of activation. Small quantities of acetic anhydride apparently inhibited the reaction rate in acetic acid–sulfuric acid solution, and in the presence of sufficient anhydride (up to 5%) the reaction was completely suppressed. Also there was no measurable reaction in pure acetic acid or in "moist" acetic acid free of mineral acid.

A correlation of reaction rate of the substituted acids with the Hammett acidity function H_0 and with stoichiometric acid concentration $C_{H_2SO_4}$ has been attempted. The results are similar to those for the hexanoic acid, *i.e.*, plots of log k_{100}[4] against H_0 were slightly curved (except for the heptanoic acid) and the average slopes lie between 0.42 and 0.47, while the linear plots of log k_{100} against log $C_{H_2SO_4}$ show gradients of 4.0, 4.8 and 5.0 for the heptanoic, octanoic and nonanoic acids, respectively. There is apparently no simplification of these relationships in aqueous perchloric acid solution; for preliminary experiments with the heptanoic acid gave

$$\delta(\log k)/\delta(\log C_{HClO_4}) \doteqdot 5 \text{ and } -\delta(\log k)/\delta(H_0) \doteqdot 0.5$$

and the investigations in these solutions were not pursued further.

It is proposed to extend the study of the cyclization reactions and especially to determine the influence of substituents on C_2 and of different groups on C_3 of the keto-acids; the results of such experiments will be communicated.

Experimental

Preparation and Purification of Materials. 3,3-Dimethyl-5-keto-hexanoic acid was prepared and purified as described previously.[2] δ-Keto-acids of

general formula $(CH_3)_2C(CH_2COCH_2R)(CH_2CO_2H)$ (III, R = alkyl)

Ethyl hydrogen β,β-dimethylglutarate was obtained by heating β,β-dimethylglutaric anhydride[5] (0.84 mole) on the steam-bath for 29 hr. with 300 ml. of absolute ethanol. The excess of alcohol was removed and the residue fractionally distilled, the main fraction (b.p. 148–150° (2.5 mm.)) being collected very slowly. The distillate failed to crystallize at −12°; it was freed of about 9 g. of the acid anhydride. The colorless oily half-ester was obtained in 82% yield (equivalent weight found 186.2, calcd. for $C_9H_{16}O_4$, 188.2).

Acid Chloride I, Keto-esters II and Keto-acids III.—The acid chloride I was prepared as required by treating 20- to 30-g. portions of the half-ester with twice the theoretical quantity of thionyl chloride (b.p. 76–78°) for 1.5 to 1.8 hr. at room temperature and then for 0.5 hr. at 40°. The excess of thionyl chloride was removed and the residual liquid immediately distilled. The acid chloride was col-

(3) The 3,3-dimethyl-5-keto-acids are numbered conventionally; abbreviated names: hexanoic acid, heptanoic acid, octanoic acid, trimethyloctanoic acid and nonanoic acid occasionally used in the subsequent text all refer to keto-acids of type III (R = H, CH_3, C_2H_5, iso-C_3H_7, *n*-C_3H_7, respectively.) In order that each carbon atom shall retain the same number, the cyclic products IV will be named as 3,3-dimethyl-6-alkyl-cyclohexane-1,5-diones.

(4) k_{100} is the first-order rate constant at 100.0° on the scale of the Anschütz standard thermometer.

lected (70–85% yield) between 115° (13 mm.) and 121° (16 mm.).[6]

Ethyl esters II of the required keto-acids were prepared by reaction of the ester acid chloride I with alkyl zinc chlorides, RCH_2ZnCl. The latter reagents were prepared in the usual way[7] from the Grignard reagent, RCH_2MgBr, and freshly fused and ground anhydrous zinc chloride in dry ether. Most of the ether was replaced by dry benzene before the acid chloride, dissolved in dry benzene, was gradually added to the alkyl zinc chloride reagent. The well-stirred reaction mixture was heated under gentle reflux (temp. in liquid, 62°) for about 3 hr. after all the acid chloride had been added, then cooled in ice-water and decomposed by cold water containing some hydrochloric acid. The organic liquid layer was separated, combined with a benzene washing of the aqueous layer, dried ($MgSO_4$) and the solvent removed. The residual liquid was fractionally distilled. Yields of the colorless oily keto-esters were between 67 and 85% based on the acid chloride.

Ethyl ester	B.p., °C.	Mm.
3,3-Dimethyl-5-keto-heptanoate	95	2
3,3-Dimethyl-5-keto-octanoate	104–105	3
3,3-Dimethyl-5-keto-nonanoate	129.5–131	1
3,3,7-Trimethyl-5-keto-octanoate	123–125	3.5

Hydrolysis of the esters with concentrated aqueous alcoholic potassium hydroxide gave the corresponding δ-keto-acids III, which were collected by means of ether and purified by distillation. (It is noteworthy that hydrolysis of ethyl 3,3-dimethyl-5-keto-heptanoate by aqueous alcoholic potash gave also about 15% of the cyclized product, 3,3,6-trimethylcyclohexanedione-1,5.) The colorless or faintly yellow oily acids did not crystallize at −12°; they were freed of any traces of solid and stored in the desiccator.

The δ-keto-acids III had the following properties:

R = CH_3: b.p. 129.5° (0.7 mm.); equiv. wt. found 176.3, calcd. for $C_9H_{16}O_3$ 172.2; $n^{18}D$ 1.4490[8a]; ultraviolet spectrum of Na salt: λ_{max} 294 mμ, ε 560; semicarbazone, m.p. 137.5–138°.[8b]

R = C_2H_5[8c]: b.p. 146–147° (2 mm.); equiv. wt. found 189.3, calcd. for $C_{10}H_{18}O_3$ 186.3; $n^{22}D$ 1.4463; ultraviolet spectrum of Na salt: λ_{max} 294 mμ, ε 163; semicarbazone, m.p. 132° dec. Found: C, 54.4, 54.75; H, 8.6, 8.7; N, 17.4. Calcd. for $C_{11}H_{21}O_3N_3$: C, 54.3; H, 8.7; N, 17.3.

R = iso-C_3H_7: b.p. 142.5–143° (1.3 mm.); equiv. wt. found 199.0 and 198.5, $C_{11}H_{20}O_3$ requires 200.3; $n^{22}D$ 1.4444; ultraviolet spectrum of Na salt: λ_{max} 288 mμ, ε 54; semicarbazone, m.p. 156.5–157.5° dec. Found: C, 55.9, 55.9; H, 9.2, 9.0; N, 16.5. $C_{12}H_{23}O_3N_3$ requires: C, 56.0; H, 9.0; N, 16.3.

R = n-C_3H_7: b.p. 170–171° (0.9 mm.). The distilled acid was dissolved in 150 ml. of 5 N (pure) sodium hydroxide solution, and after 50 hr. at room temperature the solution was cooled in ice-water and carefully acidified to congo red by hydrochloric acid. The oily keto-acid was collected by means of pure ether, and the ether was completely removed under low pressure (with agitation of the liquid by dry air), any last traces of solvent being removed by heating *in vacuo* for 10 min. at 100°; equiv. wt. 193.2, $n^{22}D$ 1.4476; ultraviolet spectrum of Na salt; λ_{max} 294 mμ, ε 173; semicarbazone, m.p. 132° dec. Found: C, 56.2; H, 8.9; N, 16.8.

Sulfuric acid solutions for the kinetic runs were prepared by weighing colorless, concentrated sulfuric acid (May & Baker, 99%), and the acid content was checked by alkali titration.

Acetic acid for use as solvent in the kinetic runs was purified by distilling AnalaR glacial acetic acid through a 50 × 1.5 cm. Fenske column. The purified acid melted at 16.52–16.55° (three-quarters melted)—16.60° (last crystals); this indicated a purity of 99.9$_5$%.[9]

Cyclization of the δ-Keto-acids to 3,3-Dimethyl-6-alkylcyclohexanediones-1,5.—A sample of each of the keto-acids was heated in aqueous sulfuric acid solution (10 ml.), and the reaction mixture was cooled and poured into water. After cooling in ice-water the solid product was filtered off and dried *in vacuo* over concentrated sulfuric acid.

The 3,3-dimethyl-5-keto-heptanoic acid (0.9 g.) (72% H_2SO_4, 132°, 1 hr.) gave 0.8 g. of crude white 3,3,6-trimethylcyclohexanedione-1,5 (m. range 152–162°); the dione was recrystallized from aqueous alcohol and dried *in vacuo* and finally had m.p. 163–165.5°[10] (flat white needles),[11a] equiv. wt. found 153.5, calcd. for $C_9H_{14}O_2$ 154.1.

The 3,3-dimethyl-5-keto-octanoic acid (0.9 g.) (72% H_2SO_4, 130°, 1.3 hr.) gave 0.7 g. of crude 3,3-dimethyl-6-ethylcyclohexanedione-1,5, (m. range 154–158°); the recrystallized product had m.p. 156–157.5° (colorless crystals)[11b]; equiv. wt. found 167.5, calcd. for $C_{10}H_{16}O_2$ 168.1.

The 3,3,7-trimethyl-5-keto-octanoic acid (1.1 g.) (79% H_2SO_4, 100°, 3.3 hr.) gave 0.55 g. of 3,3-dimethyl-6-isopropylcyclohexanedione-1,5; m.p. of recrystallized dione, 167° (softening from 155°).[11c] Found: C, 72.9; H, 10.05; equiv. wt., 178, 180.5. Calcd. for $C_{11}H_{18}O_2$: C, 72.5; H, 9.96; equiv. wt., 182.2.

The 3,3-dimethyl-5-keto-nonanoic acid (0.75 g.) (63% H_2SO_4, 130°, 1.5 hr.) gave 0.62 g. of 3,3-dimethyl-6-n-propylcyclohexanedione-1,5, m.p. (recrystallized) 161.5–163° (colorless lustrous plates and needles).[11d] Found: C, 72.3; H, 9.7; equiv. wt., 180.5.

Kinetic Studies. (a) The Analytical Method.—The cyclic reaction products were estimated by means of the ultraviolet absorption spectra of their sodium enolates, as previously indicated for dimedone. Samples of the hot reaction mixtures were taken with a calibrated 1-ml. pipet, and each sample was mixed with 500 ml. of 0.1 N NaOH solution. The optical density of each alkaline solution was measured, at the wave length for maximum absorption, by comparison with a standard blank solution containing identical amounts of NaOH and sulfuric acid.

Ultraviolet spectra of the diones were recorded on freshly prepared and purified samples in 0.1 N aqueous NaOH. Measurements on two series of standard alkaline solutions of each dione showed that Beer's law was accurately obeyed in every case. Measurements were made in 10.0 mm. quartz cells, using a Unicam SP500 spectrophotometer.

	$\lambda_{max}^{(enol\ ion)}$ mμ	ε
3,3,6-Trimethylcyclohexanedione-1,5[12]	294.5	24300
3,3-Dimethyl-6-ethylcyclohexanedione-1,5	295	24050
3,3-Dimethyl-6-isopropylcyclohexanedione-1,5	295	23450
3,3-Dimethyl-6-n-propylcyclohexanedione-1,5	295.5	23250

(b) Rate Measurements.—A vapor-bath thermostat, with pure liquids boiling under atmospheric pressure, was again used; temperature constancy to within ±0.1–0.15° generally was obtained without difficulty. All runs were started by adding a weighed sample of the keto-acid in a small glass thimble to the solvent after the temperature had become quite steady and then shaking rapidly.

(c) The Reaction in Aqueous Solution. (i) Order of Reaction with Respect to the Keto-acids.—Ring-closures of the heptanoic, octanoic and nonanoic acids followed simple first-order kinetics over all ranges of reaction; very satisfactory reproducibility of the rate constants was observed. The cyclization of the trimethyloctanoic acid did not quite conform to the simple first-order law, the value of $2.303 \log (C_0/C_t) \div t$ declining by about 10–15% from time $t = 0$ to later stages of the reaction, but no evidence was found for any marked reversibility of this ring closure. Rate

(6) A. J. Birch and R. Robinson, *J. Chem. Soc.*, 488 (1942), give 110° (10 mm.).

(7) R. Adams, Ed., "Organic Reactions," Vol. VIII, John Wiley & Sons, Inc., New York, 1954, Ch. 2.

(8) R. D. Desai, *J. Chem. Soc.*, 1079 (1932), gives: (a) 1.4492; (b) 138°; (c) describes preparation of this acid ambiguously and gives $n^{22}D$ 1.4491, semicarbazone m.p. 137°.

(9) G. L. Foster, *ibid.*, 2788 (1954).

(10) The m.p.'s of the diones appear to depend somewhat on the conditions of heating; values recorded here are for samples immersed in a Thiele tube at about 20° below the m.p. and then heated at a normally slow rate.

(11) R. D. Desai, ref. 8, gives m.p.'s: (a) 163°, (b) 153°, (c) 156°, (d) 162°.

(12) E. G. Meek, J. H. Turnbull and W. Wilson, *J. Chem Soc.*, 2891 (1952), report ε 24000 at 295 mμ in 94200 in aqueous ethanolic NaOH.

constants for the latter acid were derived from careful estimates of the initial rate.

(ii) Activation Energy.—First-order rate constants were measured at three or more temperatures in each of a number of sulfuric acid solutions. Activation energies were obtained from the linear plots of $5 + \log k$ against $1/T$. Reaction temperatures were indicated by a sensitive mercury thermometer kept liquid-immersed next to the reaction tube. When two thermometers were both used in the measurement of an activation energy, these were compared directly and appropriate correction was made to the reading of one.

[a] This corrects a computation error in the earlier communication.[2]

(ii) The ring-closures were found to be of simple first order with respect to the keto-acid in acetic acid solutions containing not too large amounts of sulfuric acid. The solvent mixtures were prepared by direct weighing of the pure acetic acid and of 100% sulfuric acid, prepared by mixing 99% H_2SO_4 and oleum (20% SO_3) (repeated gravimetric and volumetric analyses gave results all between 100.0 and 100.7% H_2SO_4), and were kept for at least 12 hr. before being used for kinetic experiments. The kinetic and analytical procedures were essentially as for the experiments in aqueous solutions. First-order rate constants for the ring-closures in acetic acid solution are given in Table III.

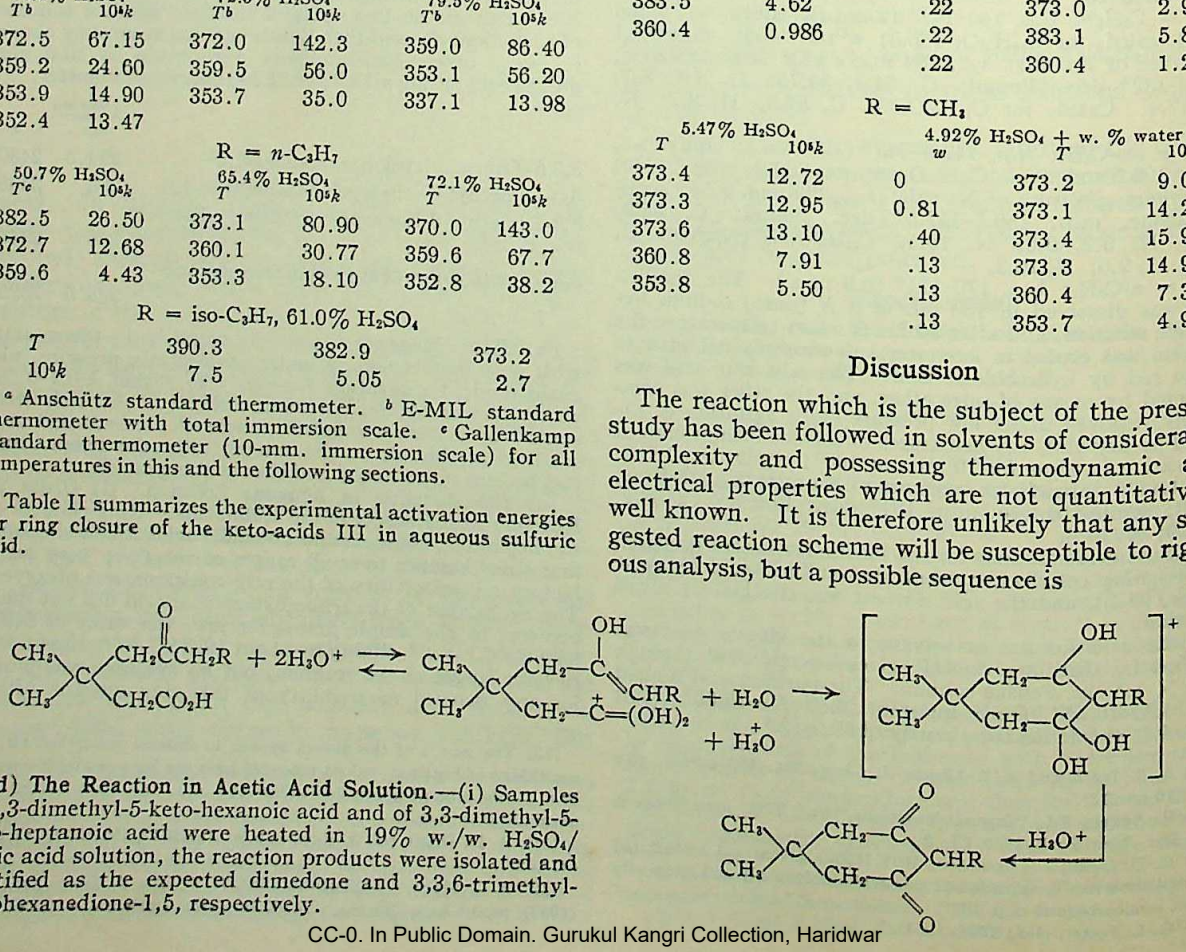
Discussion

The reaction which is the subject of the present study has been followed in solvents of considerable complexity and possessing thermodynamic and electrical properties which are not quantitatively well known. It is therefore unlikely that any suggested reaction scheme will be susceptible to rigorous analysis, but a possible sequence is



(d) The Reaction in Acetic Acid Solution.—(i) Samples of 3,3-dimethyl-5-keto-hexanoic acid and of 3,3-dimethyl-5-keto-heptanoic acid were heated in 19% w./w. H_2SO_4/acetic acid solution, the reaction products were isolated and identified as the expected dimedone and 3,3,6-trimethylcyclohexanedione-1,5, respectively.

Enolization of keto-methylene groups in acid solutions is well known, and there is good evidence for the protonation of carboxylic acid groups in the presence of sulfuric acid.[13,14] For each keto-acid there is approximately the same change of activation energy corresponding to a given variation of solvent composition (see Fig. 1); this suggests that at least two terms contribute to the experimental activation energy, one a true activation energy for the rate-determining stage involving the transition state and the other a heat change depending on the solvent. In nearly anhydrous solvents proton transfers may be rate-controlling,[15] but in aqueous solution proton transfer to a basic oxygen atom is invariably rapid and leads to an equilibrium concentration of the conjugate acid. Ionization of a molecule of the keto-acid may then be represented by

$$A + 2H_3O^+ \underset{}{\overset{\text{fast}}{\rightleftharpoons}} AH_2^{++} + 2H_2O \qquad (1)$$

If the trend of the curves of $E_a \sim \%\ H_2SO_4$ is continued to very high sulfuric acid concentrations (at which accurate kinetic measurements cannot be made), a lower limiting value of the activation energy tends to be approached (see especially results for the octanoic acid); this should be the true activation energy for the rate-determining stage. Under those conditions the equilibrium 1 is presumably displaced much more completely to the right, and so the energy change involved ceases to contribute significantly to the measured activation energy. Heat changes occurring on proton transfer to basic oxygen atoms under the conditions of these experiments have not been independently determined, but increments of E_a from the lower limiting values to values measured in the less acid solvents are consistent with rapid attainment of the pre-equilibrium 1.

Both ketones and carboxylic acids are completely protonated in anhydrous sulfuric acid, but in the aqueous acid solution the base strength of ketones apparently is greater than that of structurally similar carboxylic acids.[14] Since rather high concentrations of sulfuric acid are required for measurable rates of cyclization and since enolization of keto-methylene groups is known to be a reasonably facile process in much less strongly acid solution, the addition of another proton to the carboxylic acid group would appear to be a necessary prerequisite for ring-closure. The carbon atom of the $-CO_2H$ group can approach close to the terminal methylene group, and when the former bears a partial positive charge while C_6 is attached by an enolic double bond, the situation is favorable to cyclization

The rapid and reversible proton transfers may be simultaneous with each other and with any other fast stages preceding the rate-controlling process. The reaction rate may then be determined by rate of conversion to enol or, more probably, by the rate of (unimolecular) ring-closure of the enolized intermediate $^+A'H$; in each case the rate equation would be of first order in keto-acid.

If the rate of enolization were rate-determining, the over-all reaction rate would be that for the process[16]

$$^+AH + H_2O \longrightarrow A'\text{ (enol)} + H_3O^+$$

Data recorded for aliphatic ketones show that an alkyl substituent on the α-carbon tends to accelerate acid-catalyzed enolization because of hyperconjugative electron release,[17] but this effect appears to be very much smaller than the increase in the rate of ring closure which has been found to result from substitution on C_6 of the 5-keto-acid by alkyl groups.

TABLE IV

C_6-Substituent	H	CH_3	C_2H_5	n-C_3H_7	iso-C_3H_7
Relative rate[a]	1.00 (ref.)	38	14.5	18.7	1

[a] From rate constants at 100.0° in 61% H_2SO_4. The probable reason for the slow reaction of the iso-C_3H_7 compound will be discussed.

Further, from the large amount of kinetic data available, especially that of Zucker and Hammett,[18] it is clear that rates of enolization of (aromatic) ketones become very great in highly acid solutions, and rates for the aliphatic ketones appear generally to be even greater.[19] Also, activation energies for acid-catalyzed enolization of (aromatic) ketones have normally large values,[20] and so it may be rea-

sonably supposed that at the higher temperatures, as well as high acidities, required for the ring closure, the enolization must be a very fast process which cannot be rate-determining. Therefore the kinetics of the cyclization are best represented by an initial reversible addition of two protons to the keto-acid molecule, with enolization of the keto-methylene group being followed by ring closure of the unstable intermediate $^{+}A'H$.

$$A + 2H_3O^{+} \rightleftharpoons {}^{++}AH_2 \text{ (keto)} + 2H_2O \qquad K_1\text{, equil.}$$

$${}^{++}AH_2 + H_2O \rightleftharpoons {}^{+}A'H + H^{+}{}_3O \qquad K_2\text{, rate-controlling}$$

$$\downarrow (k)$$

$$\text{product} \longleftarrow \text{(intermediates)}$$

$$\text{Reaction rate } v = k[{}^{+}A'H] = kK_2K_1[A][H^{+}{}_3O]/[H_2O]$$
$$= kK[A]$$

($K = K_1K_2[H^{+}{}_3O]/[H_2O]$; $[H^{+}{}_3O]$ and $[H_2O]$ in large excess and constant in any one solvent)

The observed rate constant will be $k_{obs} = kK$, where k is the specific rate of the slow stage and the value of K varies with the solvent composition. It follows that $E_a = E_{a(true)} + \Delta H$; $E_{a(true)}$ is the true activation energy for the rate-determining stage and ΔH is a heat change term depending on the value of K, *i.e.*, on the nature of the solvent. This conforms to the suggestion already made to account for the change of E_a with acidity. Some part of the variation of rate with acidity might possibly be due to changes in the dielectric constant of the medium, but this possibility cannot be tested at present.

For this reaction sequence the rate equation is (f_T = the activity coefficient of the transition

$$v = k[{}^{+}A'H]f_{{}^{+}A'H}/f_T$$

state) and on insertion of the equilibrium constants in terms of activities thus gives

$$\text{specific rate } k_0 = kK_2K_1[H^{+}{}_3O] \times \frac{1}{a_{H_2O}} \times \frac{f_A f_{H^{+}{}_3O}}{f_T} \quad (2)$$

This expression would reduce to the form

$$\text{specific rate} = \text{(constant)}\,[H^{+}{}_3O] \times \frac{1}{a_{H_2O}} \times \frac{f_A f_{H^{+}{}_3O}}{f_T} = ca_{H^{+}}\frac{f_A}{f_T}$$

only provided that K_2 and K_1 are constant.

It may be justifiable to assume the ratio of activity coefficients constant in equation 2 because of the constitutional similarity of the transition state and the intermediate $^{+}A'H$, which is a keto-acid molecule plus a proton; but the value of K_1 probably increases with the acidity of the solvent. For aqueous sulfuric acid at 25° between 50 and 79% w./w. H_2SO_4, the data[21] show that $(a_{H_2O})^{-1}$ is not a simple function of $[H_3O^{+}]$, but on applying the simple relationship $(a_{H_2O})^{-1} = \alpha[H_3O^{+}]^n$ to the upper and lower ends of the range, values of n between 2.5 and 13 are indicated. If $[H_3O^{+}]$ is measured by the stoichiometric acid concentration, $C_{H_2SO_4}$, it appears from equation 2 that the dependence of rate of ring closure on acidity should be of much higher order than the first. Linear plots of log k_{100} against log $C_{H_2SO_4}$ show that in fact: specific rate = const. $(C_{H_2SO_4})^m$, the values of m being 4.6, 4.0, 4.8 and 5.0 for the hexanoic, heptanoic, octanoic and nonanoic acid, respectively.

The effect of varying acidity on rates of ring-closure is almost wholly through its influence on the activation energy. Results summarized in Table V show that entropies of activation vary little and in no significantly regular manner with the sulfuric acid content of the solution. Therefore the effect on rate of the mineral acid strength apparently is connected principally with the variable pre-equilibrium.

TABLE V

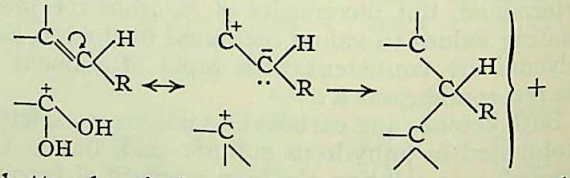
STANDARD ENTROPIES OF ACTIVATION, $\Delta S°$, AT 100.0°[22]

Keto-acid (III) R =	H_2SO_4, % 42.8	44.8	50.7	61.0	72.3–72.5
H			−15.5	−16.6	−15.7
CH_3		−18.6	−19.4	−20.6	
C_2H_5	−19.8		−20.3	−20.6	−20.5
n-C_3H_7			−21.5	−21.7	−20.9
i-C_3H_7				−35.5	

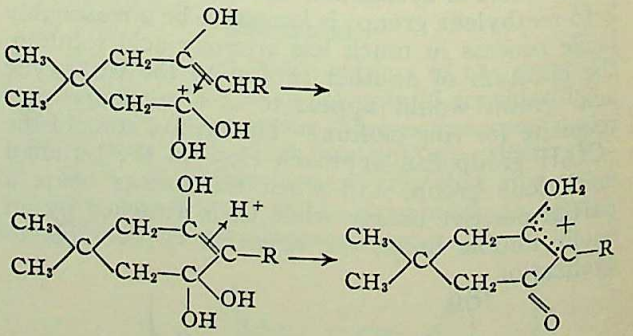
($\Delta S° = 2.303 \times 1.987$ (log PZ − log kT/h) − 1.987; log PZ = log $k + E_a/2.303RT$, where E_a is the "smoothed" value of E_a read from the graph. An error of 0.3 kcal. in E_a would change $\Delta S°$ by 0.8 e.u.)

The largely negative values of $\Delta S°$ are consistent with the rate-determining process being the formation of a cyclic transition state from a non-cyclic intermediate (*cf.* later discussion of solvent effects.)

Formation of the transition state in the ring-closure may be classically represented as electrophilic attack by C_1^{+} on the enolic double bond



A better description of this step would seem to be the creation of a molecular bond[23] by donation of the π-electrons of the double bond to the vacant bonding orbital of C_1^{+}, according to the scheme



Further, a notable feature of the reaction is the lowering of activation energy by alkyl substituents on C_6 and the concomitant reduction in the frequency factor (expressed logarithmically by the entropy of activation). The electron-releasing

alkyl groups must tend to reduce the electron affinity of the double bond which they flank, *i.e.*, they lower the ionization potential of the π-electrons. Consequently the energy needed to make these electrons available for donation to the vacant orbital of the acceptor atom C_1^+ is diminished. This is consistent with the activation energy for electrophilic attack by C_1^+ on the double bond of the enol form, as the postulated rate-determining stage, being reduced by alkyl substitution on C_6 of the keto-acid. The effect would be expected to increase with higher tendency for electron release by the substituent, *i.e.*, primary alkyl < $-CH(CH_3)_2$ if inductive electron release only is considered. Some contribution by first-order hyperconjugation may account for the methyl group being a little more effective than the ethyl.

Inspection of models indicates that whereas in the keto-acid molecule there is likely to be little restriction on the positions of any of the alkyl substituents, in a cyclic transition state the isopropyl substituent at C_6 can be accommodated only in a narrowly defined range of configurations, whilst the positions of the ethyl and *n*-propyl groups appear to be less severely limited and that of the methyl group hardly at all. Thus the relative restriction in numbers of favorable configurations as between transition state and keto-acid molecule would be predicted to increase in the order shown, and entropies of activation are found to fall in this order.

$$H < CH_3 < C_2H_5 \sim n\text{-}C_3H_5 \ll -CH(CH_3)_2$$

ΔS° decreases →

slightly.....sharply

(The change of ΔS° on substitution with methyl, ethyl and *n*-propyl might perhaps be explicable on general statistical grounds,[24] the primary effect of structural modification being on the activation energy. The bulky isopropyl group, however, exerts a direct spatial effect.)

The *gem*-dimethyl groups on C_3 of the keto-acid must greatly facilitate ring-closure by constraining the molecule to adopt a configuration in which the potential reaction centers are fairly close together; in the absence of these groups or of one of them it seems likely that the molecule would exist preferentially in an extended form. It has in fact been observed that 3-phenyl-5-keto-hexanoic acid and 5-keto-hexanoic acid do not cyclize measurably under conditions like those used for the 3,3-dimethyl compounds. This point is being investigated.

The Ring-closure in Non-aqueous Solution.—Proton transfer to a keto-acid molecule in anhydrous sulfuric acid–acetic acid solvent must be represented by

$$2CH_3\overset{+}{C}O_2H_2 + A \rightleftharpoons \overset{++}{A}H_2 + 2CH_3CO_2H$$

or

$$2H_2SO_4 + A \rightleftharpoons \overset{++}{A}H_2 + 2HSO_4^-$$

Since acetic acid is a much weaker base than water, the first equilibrium should lie much more completely to the right than that for the corresponding proton transfer between oxonium ion and keto-acid, while the second reaction is not subject to competition from possible proton transfers to a base other than keto-acid A. Thus the acid-catalyzed ring-closure would here be expected to be very much faster than that in aqueous solution, or for corresponding rates a much smaller amount of sulfuric acid should be necessary. In fact, stoichiometric quantities of sulfuric acid about one-fifth as large as those required in aqueous solution gave conveniently measurable rates of cyclization in acetic acid. The reaction in acetic acid has not been studied in presence of large amounts of sulfuric acid; good first-order kinetics apparently cease to be followed if certain though fairly small mineral acid concentrations are exceeded. Under conditions leading to reaction rates similar to those observed in the aqueous solutions, the reactions in acetic acid show much smaller activation energies and also lower entropies of activation.

TABLE VI

Acid	Catalyst	E_a, cal. mole^{-1}	ΔS°	ΔG°, cal. mole^{-1}[a]
3,3-Dimethyl-5-keto-hexanoic	8.94% w./w. H_2SO_4 (anhydrous)	18300	−33.1	29900
	10.05% w./w. H_2SO_4 + 0.2% water	18900	−30.9	29750
3,3-Dimethyl-5-keto-heptanoic	5.47% w./w. H_2SO_4 (anhydrous)	11450	−48.0	28600
	4.92% w./w. H_2SO_4 + 0.13% water	14900	−38.5	28450

[a] ΔG° = free energy of activation.

Because of the very low dielectric constant of acetic acid,[25] electrostatic orientation effects are probably very much less important in this solvent than in aqueous solution. Formation of the cyclic transition state from the intermediate $^+A'H$ involves a decrease in polarity, and it might thus be expected that solvation of the reactant is more effective (relative to that of the transition complex) in the solvent of high dielectric constant (water). Since greater solvation of the reactant may lead to increased activation energies due to the inclusion of a "heat of solvation" term,[26] the observed lowering of activation energy when acetic acid is substituted for water as reaction solvent is consistent with the assumptions made about the polar nature of the reactant species and of the transition complex. Also, if solvent orientation tends to diminish when the transition state is formed, the entropy of activation should be least in the solvent of lowest dielectric constant. Thus, if the fundamental entropy change is $-X$ in a solvent of low dielectric constant in which the solvation change associated with formation of the transition state is perhaps negligible, then in another solvent with higher dielectric constant the release of molecules from solvation

may contribute a degree of "disordering," *i.e.*, an entropy term $+Y$. The entropy of activation in the latter solvent then becomes $-X + Y$, which is less negative than $-X$. ($\Delta S°$ for the hexanoic acid: in water, $\doteqdot -16$, in acetic acid, $\doteqdot -33$, and similarly for the heptanoic acid.)

When small amounts of water are added, the solvent system obviously becomes very complicated; the water may promote ionization of the sulfuric acid, which is otherwise very incomplete[27]

$$CH_3CO_2H + H_2SO_4 \rightleftharpoons CH_3\overset{+}{C}(OH)_2 + HSO_4^-$$

Also, owing to the low polarity of the acetic acid, water molecules or oxonium ions may become partially segregated in the neighborhood of the keto-acid molecules; in that case the environment of the reactant will be unlike that in anhydrous acetic acid and may tend toward conditions prevailing in aqueous solutions. This would account for the reaction parameters in "wet" acetic acid having values between those observed in the anhydrous solvent and those in aqueous solution. Inhibition of the ring-closure by acetic anhydride is believed to be due to the presence of acetylium ion, $CH_3\overset{+}{C}O$;[28] the latter must function as a strong acid and electrophilic reagent and may attack the basic centers of the keto-acid or the enolic double bond.

Reactions of Nitrous Acid with *p*-Hydroxycinnamic Acid and its Derivatives[1]

BY CHRISTINE ZIOUDROU,[2] WILLIAM L. MEYER AND JOSEPH S. FRUTON

RECEIVED MARCH 21, 1957

p-Hydroxycinnamic acid reacts with HNO_2 in dilute aqueous solution to form *p*-hydroxymandelaldehyde. With derivatives of *p*-hydroxycinnamic acid in which the carboxyl group is substituted (*e.g.*, the methyl ester), the predominant reaction is a nitration *ortho* to the phenolic hydroxyl. Because of the production of nitrite by the nitrate reductase of plants, the possibility exists that reactions of HNO_2 with *p*-hydroxycinnamic acid and its derivatives may occur in plant tissues.

Previous studies in this Laboratory[3,4] have led to the finding that N-acetyldehydrotyrosine (N-acetamino-*p*-hydroxycinnamic acid) is readily converted by dilute HNO_2 to N-acetyl-*p*-hydroxymandelic acid amide. This conversion was first observed[3] upon acidification of suspensions of *Escherichia coli* grown in a culture medium supplemented with acetyldehydrotyrosine. Subsequent studies[4] showed that the role of the bacteria is to reduce nitrate (a component of the basal medium[5]) to nitrite, presumably by the action of nitrate reductase[6]; upon acidification of the culture filtrate to *p*H 4 or less, a rapid non-enzymic reaction between HNO_2 and acetyldehydrotyrosine ensues. Because of the widespread occurrence, among plants, of nitrate reductase and of *p*-hydroxycinnamic acid (*p*-coumaric acid) and its derivatives (*e.g.*, caffeic acid, coniferyl alcohol), the new reaction merited further study in relation to several problems of plant metabolism.

Reaction of *p*-Hydroxycinnamic Acid with HNO_2.—In analogy with the action of HNO_2 on acetyldehydrotyrosine, the expected product of the reaction with *p*-hydroxycinnamic acid is *p*-hydroxymandelaldehyde, which does not appear to have been described previously; the isomeric 1,4′-dihydroxyacetophenone was prepared by Robinson.[7] Upon treatment of *p*-hydroxycinnamic acid with 2 equivalents of HNO_2 at *p*H 2, CO_2 is evolved with the formation of a product whose strong reducing properties, absorption spectrum, elementary analysis, and derivatives (2,4-dinitrophenylhydrazone, semicarbazone, phenylosazone) support its identification as *p*-hydroxymandelaldehyde. On treatment with 2.5 moles of $NaIO_4$ per mole of product, the expected amount of formic acid was released, and *p*-hydroxybenzaldehyde (identified as its phenylhydrazone) was formed. However, with a 1:1 molar ratio of periodate to product, 50% of the expected formic acid was released more rapidly than the rest, suggesting that the *p*-hydroxymandelaldehyde is present in aqueous solution as a dimer that is slowly cleaved during the reaction with periodate. This possibility is supported by the fact that the semicarbazone isolated from aqueous solution gave an elementary analysis in agreement with the values calculated for a derivative of a dimer.

The rate of the reaction of *p*-hydroxycinnamic acid with nitrite is markedly dependent on *p*H. At 30°, in the presence of 0.11 *M* citric acid–sodium citrate buffer containing 4×10^{-3} *M* nitrite (introduced as sodium nitrite) the apparent first-order rate constants (in min.$^{-1}$) for the disappearance of *p*-hydroxycinnamic acid (initial concentration, 4×10^{-4} *M*) were found to be: *p*H 5.1, 0.0010; *p*H 4.1, 0.0068; *p*H 2.9, 0.092. At lower *p*H

values, the rate was too rapid to be measured accurately with the available equipment. These rate constants were determined by observation of the decrease in the absorbance at the wave length corresponding to the maximum absorption of *p*-hydroxycinnamic acid; these maxima were (molar absorbance values being given in parentheses): *p*H 5.1, 286 mμ (19,600); *p*H 4.1, 305 mμ (19,200), *p*H 2.9, 308 mμ (21,600). The absorption spectrum of *p*-hydroxymandelaldehyde at acidic *p*H values has a maximum at 273 mμ (molar absorbance, 2620); near 300 mμ, the molar absorbance is about 950 (*cf.* Fig. 1). Beer's law was assumed to hold under the conditions of these experiments.

The effect of *p*H on the rate of the disappearance of *p*-hydroxycinnamic acid indicates that the reactive species is HNO_2 (pK' *ca.* 3.4) or a substance derived from it in acid solution. Although insufficient kinetic data are available for their use in the formulation of a mechanism of the reaction, the results are consistent with the hypothesis advanced previously[4] that the reaction involves an attack by the nitrosonium ion (NO^+), which may arise from nitrous acid by the reaction $HNO_2 + H^+ \rightarrow NO^+ + H_2O$.[8]

Reaction of Caffeic Acid with HNO_2.—When caffeic acid (3,4-dihydroxycinnamic acid) was treated with 2 equivalents of nitrous acid at *p*H 2, CO_2 was evolved, and an orange-colored solution resulted, from which no well-defined product could be isolated. The conversion of the initial product (possibly 3,4-dihydroxymandelaldehyde) to other substances is indicated by spectrophotometric observations. In acid solution, caffeic acid exhibits maximal absorption at 315 mμ (molar absorbance, 21,500). Two minutes after treatment with HNO_2 at room temperature, the absorption spectrum of the reaction mixture had changed to one exhibiting maximal absorption at 347 mμ, with a lesser peak at 284 mμ. During the succeeding 2 hours, the peak at 315 mμ gradually diminished, but the other peak was retained. From the reaction mixture (after 2 hours), there was obtained a brown amorphous material that is soluble in water, acetone and alcohol; it is insoluble in hydrochloric acid but dissolves in NaOH to give a dark red solution.

Nitration of *p*-Hydroxycinnamic Acid Derivatives by HNO_2.—It has long been known that phenols can be nitrated by means of nitrous acid (*e.g.*, salicylic acid is converted to 5-nitrosalicylic acid). Presumably, the initial attack by NO^+ at the position *ortho* to the phenolic hydroxyl gives rise to the nitroso compound, which is oxidized to the nitro derivative.[9] It is of interest therefore that, in the reaction of *p*-hydroxycinnamic acid or of its α-acetamido derivative with HNO_2 under the conditions described above, no evidence was obtained of nitration. This suggests that the α-carbon of *p*-hydroxycinnamic acid is more reactive toward an electrophilic reagent such as NO^+ than is the carbon *ortho* to the phenolic hydroxyl group. However, when the methyl ester of *p*-hydroxycinnamic acid was treated with one equivalent of HNO_2 in dioxane–water (*p*H *ca.* 2), the principal product was 3-nitro-4-hydroxycinnamic acid methyl ester, indicating a preferential attack of the ring by the nitrosonium ion. In this case, decarboxylation cannot occur, as with *p*-hydroxycinnamic acid, thus removing from the over-all process a strongly exergonic reaction that may be expected to favor nitrosation of the α-carbon. A similar situation appears to apply in the action of HNO_2 on derivatives of benzalacetophenone such as 4,4′-dihydroxychalcone; from the reaction mixture in dioxane–water a product was obtained which, on alkaline degradation, gave 3-nitro-4-hydroxybenzoic acid. Studies on the action of nitrous acid on hydroxychalcones will be reported in a subsequent communication from this Laboratory.

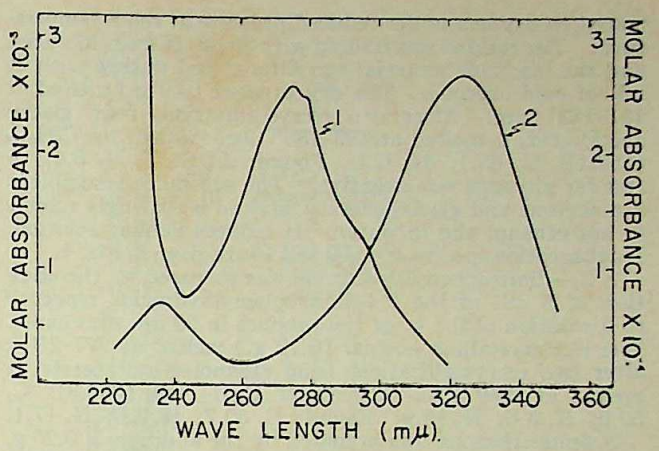

Fig. 1.—Absorption spectra of *p*-hydroxymandelaldehyde at *p*H 2 (curve 1, ordinate at left) and at *p*H 10 (curve 2, ordinate at right).

Discussion.—The extensive studies of Freudenberg[10] and others have drawn renewed attention to the possibility that the biosynthesis of lignin involves the oxidation and polymerization of phenylpropane derivatives. This view is supported by isotope experiments indicating the utilization of *p*-hydroxyphenylpyruvic acid for lignin formation.[11] Although speculation about the role of nitrite in lignin formation would be premature at present, the reactions described in the present communication, when considered in relation to the widespread occurrence of nitrate reductase in plants, suggest that consideration be given to the possibility that *p*-hydroxycinnamic acid derivatives may be oxidized in plant tissues, not only in the H_2O_2-dependent reactions already examined,[12] but also in reactions that involve HNO_2 as the oxidant.

Experimental

Formation of *p*-Hydroxymandelaldehyde.—To a solution of *p*-hydroxycinnamic acid (3 g., 0.0182 mole) in 50 ml. of freshly distilled dioxane was added a solution of sodium nitrite (2.45 g., 0.036 mole) in 50 ml. of water; the mixture was adjusted to *p*H 2 by the addition of about 4 ml. of 5 *N* hydrochloric acid. The resulting yellow solution was shaken for 1.5 hours at room temperature, and then was concentrated to dryness under reduced pressure at 40°. The residue was extracted 8 times with 50-ml. portions of hot acetone, and the combined acetone extracts were concen-

trated to dryness under reduced pressure at room temperature. The residue was treated with 80 ml. of ice-cold water, and the insoluble material was filtered and washed with 20 ml. of cold acetone. The dry product (0.9 g.) melted at 181–183° dec. After two recrystallizations from glacial acetic acid, it melted at 183–185° dec. Calcd. for $C_8H_8O_3$ (152.1): C, 63.1; H, 5.3. Found: C, 62.5; H, 5.4. A test for nitrogen was negative. The substance is soluble in hot acetone and glacial acetic acid, and is sparingly soluble in hot ethanol and in water. It reduces Fehling solution. Its absorption spectra at *p*H 2 and 10 are given in Fig. 1.

A 2,4-dinitrophenylhydrazone was prepared by the addition of 5 ml. of the 2,4-dinitrophenylhydrazine reagent[13] to a solution of 0.1 g. of the product in 20 ml. of ethanol. The red crystalline powder (0.12 g.) melted at 277–280°; after two recrystallizations from ethanol–ethyl acetate, it melted at 280° dec. Calcd. for $C_{14}H_{12}N_4O_6$ (332.3): C, 50.6; H, 3.6; N, 16.9. Found: C, 50.7; H, 3.8; N, 17.1.

A semicarbazone was prepared by the addition of 0.25 g. of semicarbazide hydrochloride to a hot solution of 0.2 g. of the product in 10 ml. of water containing 0.6 g. of sodium acetate. The mixture was heated for 5 minutes on the steam-bath and chilled; the resulting crystalline product (0.2 g.) melted at 165° dec. After 3 recrystallizations from water it melted at 168° dec. Calcd. for a semicarbazone of a dimer, $C_{17}H_{19}N_3O_6$ (361.35): C, 56.5; H, 5.2; N, 11.6. Found: C, 56.4; H, 5.4; N, 11.6.

An osazone was prepared by the addition of 0.6 g. of phenylhydrazine hydrochloride and of 0.5 ml. of saturated sodium bisulfite solution (to prevent the formation of tarry products) to a hot solution of 0.2 g. of the product in 10 ml. of water containing 1.1 g. of sodium acetate. The mixture was heated for about 20 minutes on the steam-bath and chilled; the resulting yellow product (0.25 g.) melted at 190°. After 5 recrystallizations from ethanol–water it melted at 198–199°. Calcd. for $C_{20}H_{18}N_4O$ (330.3): C, 72.7; H, 5.45; N, 16.9. Found: C, 72.3; H, 5.6; N, 16.7.

For the oxidation of the product with periodate, 600 mg. (2.6 millimoles) of $NaIO_4$ was added to a solution of 200 mg. (1.3 millimoles) of *p*-hydroxymandelaldehyde in 300 ml. of water. The mixture was allowed to stand overnight at room temperature, extracted 10 times with 50-ml. portions of ether, and the combined ether extracts were concentrated to dryness. The residue was dissolved in 5 ml. of ethanol; 2 ml. of glacial acetic acid and 0.5 ml. of phenylhydrazine were added. The resulting phenylhydrazone melted at 176°. A mixed melting point with an authentic sample of the phenylhydrazone of *p*-hydroxybenzaldehyde showed no depression.

The quantitative determination of the formic acid produced on oxidation with periodate was performed in the manner described by Potter and Hassid.[14] When 100 mg. (0.65 millimole) of *p*-hydroxymandelaldehyde in 150 ml. of water was treated with 140 mg. (0.65 millimole) of $NaIO_4$, only 14.3 mg. (0.31 millimole) of formic acid was released. However, upon treatment of same amount of the aldehyde with 350 mg. of $NaIO_4$, the expected amount (30.3 mg., 0.66 millimole) of formic acid was released.

Reaction of *p*-Hydroxycinnamic Acid Methyl Ester with HNO_2.—To a solution of the ester (1 g., 0.0056 mole) in 15 ml. of dioxane was added a solution of $NaNO_2$ (0.4 g., 0.0056 mole) in 15 ml. of water; the mixture was acidified with 5 *N* hydrochloric acid to *p*H 2. Upon standing at room temperature for 4 hours, a yellow precipitate (0.65 g., yield 58%) separated. After recrystallization from ethanol, the product melted at 148°. Calcd. for $C_{10}H_9O_5N$ (223.2): C, 53.8; H, 4.1; N, 6.3. Found: C, 53.6; H, 3.8; N, 6.4. The same product was obtained when 0.2 g. of the ester was treated with 0.1 g. of $NaNO_2$ in 300 ml. of dilute aqueous hydrochloric acid (*p*H 2). Saponification of the product with 2 *N* alcoholic KOH gave an acid which melted at 223–225° after recrystallization from ethanol. Calcd. for $C_9H_7O_5N$ (209.1): N, 6.7. Found: N, 6.7. Johnson and Kohmann[15] prepared 3-nitro-4-hydroxycinnamic acid and reported a melting point of 223° for the compound; they also reported a melting point of 142–144° for the methyl ester.

Heats of Hydrogenation. I. Apparatus and the Heats of Hydrogenation of Bicyclo[2,2,1]heptene, Bicyclo[2,2,1]heptadiene, Bicyclo[2,2,2]octene and Bicyclo[2,2,2]octadiene

BY RICHARD B. TURNER, W. R. MEADOR AND R. E. WINKLER

RECEIVED FEBRUARY 25, 1957

A calorimeter for the measurement of heats of catalytic hydrogenation in solution is described together with the results obtained for hydrogenations of bicyclo[2,2,1]heptene (−33.1 kcal./mole), bicyclo[2,2,1]heptadiene (−68.1 kcal./mole), bicyclo[2,2,2]octene (−28.3 kcal./mole) and bicyclo[2,2,2]octadiene (−56.2 kcal./mole) in acetic acid at 25°.

Some years ago Kistiakowsky[1] and his associates measured the heats of catalytic hydrogenation of a variety of unsaturated organic substances in the gas phase at 82°. The results obtained for the fifty-one compounds that were included in this investigation, have had important theoretical consequences of continuing interest. Since the gas phase technique is applicable only to substances possessing appreciable volatility, extension of the method to the liquid phase (29°) was undertaken in the Harvard laboratories by Williams,[2] and the heats of hydrogenation of nine additional compounds were determined by the latter procedure in 1942. Since that time no further experiments involving direct measurements of heats of hydrogenation have been reported, and in view of the considerable potential of the method, a continuation of this study appeared to be most desirable. The present paper constitutes the first report of work carried out in this Laboratory with the object of examining heat changes involved in reactions of the type

$$X(\text{dissolved}) + H_2(\text{gas}) \longrightarrow Y(\text{dissolved})$$

conducted in acetic acid solution at 25°.

Method.—Determination of the heats of hydrogenation of compounds included in the present series was carried out by measuring the change in temperature of the calorimeter and its contents due to simultaneous hydrogenation of the compound in question and of the platinum oxide catalyst. At the end of each hydrogenation run the calorimeter was cooled and was calibrated electrically over the temperature range and time interval recorded in the hydrogenation experiment. Correction of observed temperature changes, expressed in ohms, for the heating effects of stirring and for heat exchange between the calorimeter and its surroundings was made by application of an improved form of the Regnault-Pfaundler equation.[3] The results were further corrected for heat dissipation in the heater leads during electric calibration and for small heat changes within the calorimeter accompanying condensation of acetic acid from the vapor phase during hydrogenation. The heat of hydrogenation was calculated finally as the difference between the total heat evolved and that associated with reduction of the catalyst, the latter quantity being determined separately.

Apparatus.—The calorimeter (Fig. 1), which is based on the Williams design,[2] consists of a silvered Dewar flask of approximately 450 ml. capacity with a recessed 34/45 ground glass joint at the top, through which the calorimeter head is introduced. Two 19/38 recessed joints also pass through the top of the calorimeter and carry vacuum-jacketed glass tubes—of which one (A) is shown—for the support of ampoules (B) of catalyst and of the test substance. One of these tubes extends a few millimeters below the solvent surface and terminates at its upper end in a 14/20 ground glass joint equipped with a stopcock (C) through which hydrogen can be admitted in order to displace air from the calorimeter and solvent prior to a run (see Procedure).[4] The second tube (not shown) is cut off just below the recessed joint and is closed at the upper end by a ground glass stopper.

The calorimeter head is constructed of a 34/45 ground glass joint, closed at each end and evacuated, through which pass the stirrer shaft housing and connecting tubes to the thermometer and heater wells (D and E, respectively). The stirrer shaft housing is joined to the hydrogen inlet tube (F) which makes connection through a 10/30 ground glass joint and manifold to an open end manometer, a jacketed, mercury-filled measuring buret that serves as the hydrogen reservoir and a pump for evacuating the system.

Stirring is accomplished by means of a glass propeller and shaft (G) which passes through loose-fitting Teflon guides (H) to one member of a magnetic coupling[5] enclosed in a vacuum tight glass housing, of which the cover (J) provides the bearing surface for the stirrer. The stirring assembly is driven by a variable speed, thyratron-controlled, d.c. motor[6] coupled to the driving magnet through a right angle gear box and universal joints to permit flexibility of alignment. Tests of the motor and control system established that the variation in speed at any given setting is less than 1%.

The thermometer is a Western Electric 14-B thermistor, temperature coefficient of resistance at 25°, −3.9% per degree C., nominal resistance at 25°, 2000 ohms. This unit was stabilized by heating to 105° for two months prior to use[7] and has proved to be entirely reliable. The thermistor has been compared periodically against a Beckmann thermometer and no significant variations in the temperature response of the element have been observed.

Resistance changes are measured with a conventional Wheatstone bridge circuit employing a Shallcross No. 817-B decade box (total resistance 1111.1 ohms) and a Leeds and Northrup No. 2430 d.c. galvanometer. Variation of the voltage across the bridge provides a sensitivity adjustment, which is normally set so that a temperature change of 0.001°, corresponding to a resistance change of about 0.1 ohm, produces a galvanometer deflection of 2–3 mm.

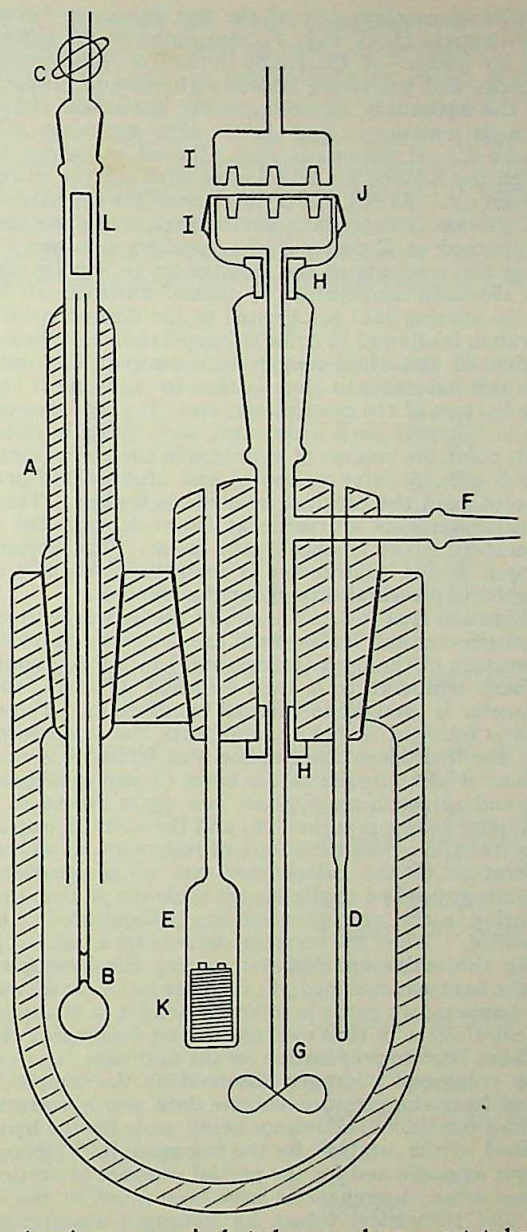

Fig. 1.—A, vacuum-jacketed ampoule support tube; B, evacuated ampoule; C, stopcock to hydrogen cylinder; D, thermometer well; E, heater well; F, connection to buret system and manometer; G, stirrer; H, Teflon guides; I, magnetic coupling; J, stirrer bearing surface; K, heater; L, magnet. Shaded portions are evacuated.

The electric heater (K) consists of 8.4 ft. of enameled manganin wire (B. and S. 36, total resistance 96 ohms) wound on a Teflon form and immersed in mineral oil in the well E. Leads from the heater and from the resistance thermometer pass out through the connecting tubes to terminals mounted on the calorimeter head. Power dissipation in the heating element is determined in the usual way[8] by means of a potential divider, a standard resistance (10 ohms) and a potentiometer.

During operation the calorimeter is immersed to a point just above the hydrogen inlet tube F in a thermostat bath held constant at 24.6 ± 0.004°. The parts of the assembly that project above the surface of the bath are surrounded by a copper can, to which a coil of copper tubing is soldered. Thermostat water is circulated through the coil and through the jacket of the gas-measuring buret.

Procedure.—Hydrogenation Run.—The calorimeter containing 225 ml. of acetic acid is assembled with evacuated

ampoules of catalyst and of the test substance,[9] wired to small magnets (L of Fig. 1), suspended in the supporting tubes by means of externally mounted Alnico magnets. Stopcocks and joints are sealed with apiezon grease, and, after the apparatus has been tested for leaks, the entire system is evacuated and filled with hydrogen through stopcock C. Hydrogen is then allowed to bubble slowly through the solvent for 10 minutes with stirring to remove dissolved air. At the end of this period the evacuation and filling process is repeated several times, and the system is finally closed at C under 3 mm. positive pressure. After heating the contents of the calorimeter to a point slightly above the bath temperature by means of the electric heater (K), the stirring rate is adjusted to the desired speed, and the system is allowed to come to equilibrium as indicated by linearity of the time–temperature curve. The ampoule of the test substance is then broken by allowing it to drop to the bottom of the calorimeter, and the time–temperature curve is followed until a constant slope is again obtained. At this point the volume of hydrogen in the buret (measured under 3 mm. positive pressure) and atmospheric pressure are noted, and the catalyst ampoule is broken. Temperature measurements are made at intervals until the time–temperature curve is once again linear. The pressure of hydrogen in the calorimeter is maintained slightly above atmospheric pressure throughout the reaction.

Calibration Run.[10]—At the end of the hydrogenation run, the calorimeter and its contents are cooled by allowing the temperature of the bath (refrigerated) to fall to about 18°. The bath temperature is then returned to 24.6°, and the calorimeter is brought to thermal equilibrium. The rating period is followed as before, and when the temperature at which the hydrogenation reaction was initiated is reached, the volume of hydrogen in the buret (3 mm. positive pressure) and atmospheric pressure are again recorded. The calorimeter heater is turned on, and the voltage drop across the heater and across the standard resistance, as well as the temperature of the calorimeter, are noted at intervals. The voltage applied to the heater is chosen so that the rate of heating in the hydrogenation run is duplicated as nearly as possible. When the temperature reaches a point approximating the maximum achieved during the hydrogenation run, the heater is switched off, the time being noted, and the time–temperature curve is followed until it is finally linear. The calorimeter is then dismantled and thoroughly cleaned with aqua regia in preparation for the next run.

The volume of hydrogen absorbed by the sample is calculated from the pressure–volume data and is corrected to standard conditions, allowance being made for the hydrogen absorbed by the catalyst, for the free space in the evacuated catalyst ampoule and for the partial pressure of acetic acid. In cases where discrepancies have been noted in the calculated and theoretical values for hydrogen absorption, the heats of hydrogenation reported are based upon hydrogen uptake. This procedure avoids possible complications resulting from losses of trace amounts of sample through retention in the ampoule stem or through evaporation and provides partial compensation for the presence of small amounts of impurities. In the few runs where discrepancies in hydrogen uptake of more than 1% have been observed (for example, see Paper IV), a special effort has been made to ascertain the nature of the impurities.

Tests of the Calorimeter.—Several preliminary tests were carried out for the purpose of assessing the precision and accuracy of results given by the calorimeter. It was first determined that the energy equivalent of the calorimeter, expressed in cal./ohm,[11] is independent of the rate of heat input over a given temperature interval. The results of a typical test run, in which the rate of stirring was the same as that employed in the hydrogenation experiments, are recorded in Table I. Since the resistance–temperature response of the thermistor may not be treated as linear over resistance intervals greater than 10 ohms (approximately 0.112°), the energy equivalent as a function of resistance is dependent to some degree upon the total resistance change. The difference in this value for successive hydrogenation and calibration runs can, however, easily be held to less than 2 ohms, and hence no significant error is introduced by extrapolation of the calibration data to the resistance interval of the hydrogenation run.

(9) *Approximately 100 mg. of platinum oxide is used in each run. Organic samples of a size sufficient to absorb 1 to 5 mmoles of hydrogen are employed.*

(10) *Each hydrogenation run is calibrated individually.*

(11) *The calorie employed throughout this investigation is defined as 4.1833 International Joules.*

	Energy input, cal./min.	Energy equivalent, cal./ohm
1	2.624	1.708
2	5.823	1.716
3	9.813	1.707
	Average	1.710 ± 0.004[a]

[a] Standard deviation.

No attempt has been made in the present investigation to obtain resistance readings with a precision exceeding 0.05) ohm (~0.0005°). The major part of the deviation (0.23%) recorded in Table I can thus be attributed to this source. Somewhat less precise results are expected for the hydrogenation runs (Tables II, III and IV), but in only a few cases has the experimental variation been appreciably greater than ±0.5%, and in many instances it has been significantly less.

Of the compounds that have been examined in this Laboratory thus far, five were included in the earlier investigations. An estimate of the accuracy of the present data can therefore be made by comparison of our results with those obtained previously (Table II). The experimental value reported by

TABLE II

HEATS OF HYDROGENATION OF FIVE REFERENCE COMPOUNDS

	ΔH, kcal./mole	
	This investigation	Previous results
Diethyl fumarate	−28.94 ± 0.05	−29.08 ± 0.15[a]

Cycloheptene	−25.85 ± .09	−26.52 ± .02[c]
cis-Cycloöctene	−22.98 ± .10[d]	−23.53 ± .04[e]
Cycloheptatriene	−70.49 ± .39	−72.85 ± .01[a]

[a] Data of R. B. Williams (ref. 2) corrected for the heat of solution of diethyl fumarate. [b] Gas phase data (82°) of Kistiakowsky (ref. 2c). [c] Gas phase data (82°) of Kistiakowsky (ref. 2g). [d] R. B. Turner and W. R. Meador, THIS JOURNAL, 79, 4133 (1957).

Williams[2] for the heat of the reaction

diethyl fumarate(liq.) + H_2(gas) ⟶ diethyl succinate (dissolved)

is −28.98 ± 0.15 kcal./mole. When this figure is corrected for the heat of solution of diethyl fumarate in acetic acid (~100 cal./mole) a value of −29.08 ± 0.15 kcal./mole is obtained, which agrees with our result within experimental error. Since Williams' instrument was compared with the Kistiakowsky gas phase calorimeter by measurement of the heat of hydrogenation of heptene-1 and appropriate correction of the liquid phase results to the gas phase at 82°, it may be concluded that all three calorimeters give concordant values, although the actual measurements apply to different conditions of state. A direct comparison of our results for the heats of hydrogenation of cyclohexene, cycloheptene and *cis*-cycloöctene with the Kistiakowsky values is unfortunately not possible in the absence of the requisite thermodynamic data. It will be observed, however, that the solution measurements on these monoölefins run about 0.5 to 1.5 kcal./mole lower than the corresponding gas phase values, as compared with a difference of about 0.5 kcal. between liquid phase and gas phase results for heptene-1 noted by Williams.[2] A somewhat larger correction term would be expected for cycloheptatriene with three double bonds,[12] and in this case a rough comparison of the solution and gas phase data can be made in the following manner. Calculation of the "resonance energy" of cycloheptatriene from the heat of hydrogenation of this substance and three

(12) See the discussion commencing on p. 1399 of reference 2.

Digitized by Arya Samaj Foundation Chennai and eGangotri

times the heat of hydrogenation of cycloheptene gives, for the gas phase, a value of 6.7 kcal./mole. A corresponding calculation employing the solution data furnishes a value of 7.1 kcal./mole. The agreement is closer than might have been expected in view of complications that may arise in solution work from solvent–solute interactions. It would appear, however, that such effects are small in the case of relatively non-polar molecules, and it seems unlikely that the over-all error in our results is greater than about 1%. With regard to precision and accuracy, the present calorimeter is therefore comparable to that described by Williams, who used somewhat larger quantities of material than were employed in this work.

Materials.—The platinum oxide catalyst was obtained in a single batch from Baker and Co., Newark, N. J., and was thoroughly mixed and equilibrated with air at constant humidity prior to weighing. X-Ray examination of this material, carried out through the courtesy of Dr. J. Waser, revealed the presence of small amounts of free platinum mixed with the platinum oxide.

Acetic acid employed as the solvent was J. T. Baker Chemical Co. reagent grade, which was stirred with platinum in a hydrogen atmosphere and distilled before use. The solvent was prepared in large batches to ensure uniformity in any given series of experiments. Periodic calibration of the catalyst in various solvent samples, however, showed no significant variation in heat evolved.

Electrolytic hydrogen was supplied from a cylinder through a Deoxo purifier (Baker and Co., Newark, N. J.).

Diethyl fumarate, Eastman Kodak Co. product, was twice distilled at atmospheric pressure, b.p. 213–214°, n^{20}D 1.4412. **The cyclohexene** employed in this investigation was obtained from the American Petroleum Institute, sample No. 522-5S, impurity, 0.023 ± 0.02%. **Cycloheptene**, b.p. 113°, n^{25}D 1.4562, was made available through the courtesy of Dr. W. von E. Doering. The sample was prepared by acid-catalyzed dehydration of cycloheptanol and was purified by distillation through a 4-ft., 50-plate column packed with glass helices. **Cycloheptatriene** (tropilidene), n^{20}D 1.5239, was prepared by F. L. Detert, Hickrill Chemical Research Foundation, from benzene and diazomethane according to the procedure of Doering and Knox.[13a] The material used for hydrogenation was part of the same sample employed in the thermodynamic studies of Waddington and his associates,[13b] who report a m.p. of −75.24° and a purity of 99.986 mole % for this substance. This specimen is therefore purer than the sample, m.p. −79.5°, used by Kistiakowsky.[2g] **Bicyclo[2,2,1]heptene**, purified by passage through a Perkin–Elmer vapor fractometer, was also provided by Dr. Doering. We are further indebted to Drs. S. J. Cristol and J. Hine for samples of **bicyclo[2,2,1]heptadiene**, b.p. 82.1–82.3°, n^{20}D 1.4700, and of **bicyclo[2,2,2]octene**, m.p. 114–115°. **Bicyclo[2,2,2]octadiene**, m.p. 57°, was prepared especially for the hydrogenation work through the courtesy of Dr. C. A. Grob.[14] At Dr. Grob's suggestion the material was subjected to vapor phase chromatography and was found to be entirely homogeneous.

Results and Discussion

The values obtained for the heats of hydrogenation of the platinum oxide catalyst and of the various olefins are given in Tables III and IV, respectively. The heat evolved in reduction of the catalyst is expressed as cal./100.0 mg. and that for the olefins as kcal./mole. The averages of individual determinations on the various compounds are listed together with the corresponding standard deviations. Since the heats of hydrogenation of the olefins were uniformly determined as the difference between the total heat evolved and that associated with reduction of the catalyst, the uncertainty in the latter value is included as an appropriate term in the deviations reported for the unsaturated compounds.

The progress of hydrogenation was followed volumetrically as well as calorimetrically. The reactions are initially fast owing to rapid reduction of the platinum oxide, which is complete in less than two minutes. The subsequent rates of reduction exhibit considerable variation from compound to compound and are generally higher for those substances showing a high heat of hydrogenation per double bond than for those for which the heat of hydrogenation per double bond is low.

With reference to recent discussions of the phenomenon of "homoallylic resonance,"[15] the question of the existence or absence of homoallylic stabilization (*cf.* structure IV) in bicyclo[2,2,1]-heptadiene (I) is one of considerable interest. This substance has been shown by Winstein[16] to

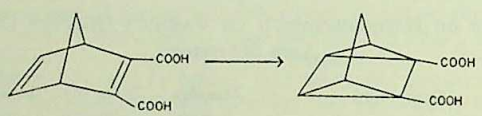
undergo bromination with double bond participation to give, among other products, *cis*-3,5-dibromomonortricyclene (V).[17] Bridging in the bicycloheptadiene system also has been observed by Cristol and Snell,[18] who showed that bicyclo[2,2,1]-heptadiene-2,3-dicarboxylic acid (VI) is readily converted into tetracyclo[2,2,1,$0^{2,6}0^{3,5}$]heptane-2,-3-dicarboxylic acid (VII) on irradiation with ultra-



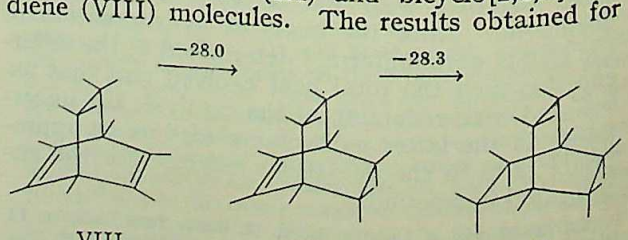
violet light. The formation of bridged products in these reactions, however, does not demonstrate the existence of homoallylic resonance in the resting bicycloheptadiene and bicycloheptadienedicarboxylic acid molecules, since bridging in these cases may be conditioned by attack of an electrophilic reagent or by radiation induced excitation. In this connection it should be noted that the shifts observed in the spectra of 2,5-dihydroacetophenone[19] and of various bicycloheptadiene and bicyclooctadiene derivatives[20] are subject to similar restrictions of interpretation. In any event it is clear that homoallylic resonance, if present in these systems, must be small since the orientation of the π-orbitals involved is not favorable for efficient overlap.[21]

A quantitative investigation of this problem by the hydrogenation method has now been undertaken. Although interpretation of the data is unfortunately complicated by uncertainties in the magnitudes of certain steric interactions and strain effects, the results indicate that structures of type IV make no important contribution to the energy of the bicycloheptadiene molecule.

The heats of hydrogenation of bicyclo[2,2,1]-heptene (II) and of bicyclo[2,2,1]heptadiene (I) are −33.13 ± 0.21 and −68.11 ± 0.41 kcal./mole, respectively. As a basis for estimating "homoallylic resonance energy" in the diene system, twice the bicycloheptene value, or −66.26 ±0.42 kcal./mole, has been taken as a point of reference. If, in accordance with the procedure adopted by Kistiakowsky,[16] "resonance energy" in the diene is defined as the difference between the heat of hydrogenation observed for this substance and that calculated for the "non-resonating" reference model, the "resonance energy" estimated for bicycloheptadiene is *negative* and equal to −1.9 kcal./mole. An alternate, but entirely equivalent, approach involves comparison of the heat change calculated for hydrogenation of the diene to olefin (−35.0 kcal./mole) with that observed for reduction of the olefin to the corresponding paraffin (−33.1 kcal./mole). Now hydrogenation of the first double bond of bicycloheptadiene results in the introduction of two hydrogen atoms (a and b of II) that do not encounter the steric repulsions a → c and b → d (*cf.* III) introduced on hydrogenation of bicycloheptene. Since an increase in steric compression in the reduction product will be reflected in a relative decrease in the heat of hydrogenation, the heat change calculated for reduction of "non-resonating" bicycloheptadiene from twice the figure for bicycloheptene will be too low. The apparent value for "resonance energy" must therefore be revised upwards to correct for this effect. The magnitude of the correction term is difficult to assess, but in view of the value assigned to the rotational barrier in ethane (2.8 kcal./mole),[22] it seems unlikely that the interactions in question can involve more than about one kcal. To the extent that this approximation is valid, and within the limits of experimental error, it would appear that bicycloheptadiene is devoid of homoallylic stabilization.

A further obvious complication in the treatment of the bicycloheptene–bicycloheptadiene system arises from the high degree of strain associated with these molecules. The heat of hydrogenation of bicycloheptene is one of the highest yet recorded, being 6 kcal. higher than that of cyclohexene, and the heat developed in the conversion of bicycloheptadiene into bicycloheptene is surpassed only by the heat of hydrogenation of *cis*-di-*t*-butylethylene.[23] Clearly, if the strain energy in bicycloheptadiene is more than twice that of the corresponding monoölefin, calculations of the type indicated above can lead to an apparent negative resonance energy.

In an effort to limit the uncertainties attending the strain problem, we have investigated the heats of hydrogenation of the relatively unstrained bicyclo[2,2,2]octene (IX) and bicyclo[2,2,2]octadiene (VIII) molecules. The results obtained for



(17) Similar attempts on the part of van Tamelen (reference 15b) to demonstrate participation in reactions of 1,4-cyclohexadiene were unsuccessful.

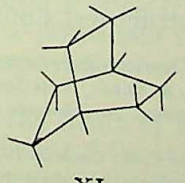
these substances are -28.25 ± 0.02 and -56.21 ± 0.10 kcal./mole, respectively. Since the heat change calculated for the process VIII → IX (−28.0 kcal./mole) is, within experimental error, essentially identical with that observed for the transformation IX → X, the "resonance energy" of bicycloöctadiene must be equated to the correction terms that are applied. As in the case of bicycloheptadiene, account must be taken of the discrepancy introduced by the appearance of two additional 1:3 hydrogen–hydrogen repulsions in the second step of the hydrogenation sequence VIII → XI → X. Assuming for these interactions the arbitrary figure taken in the bicycloheptadiene treatment, the stabilization energy in bicycloöctadiene is estimated to have a maximum value of the order of one kcal. However, in the light of arguments presented in the following paragraphs, there is reason to believe that the steric repulsion correction for bicycloöctadiene should be less than that for bicycloheptadiene. Thus, although a definitive statement regarding homoallylic resonance in bicycloöctadiene cannot be made, the present results suggest that stabilization of this sort is minimal.

The heat of hydrogenation of bicycloöctene to bicycloöctane (−28.3 kcal./mole) is surprisingly high in view of the number of 1:2- and 1:3- eclipsed interactions that appear in the latter product. Cyclohexene, which affords a reduction product possessing a staggered conformation, has a heat of hydrogenation of −27.1 kcal./mole. One would therefore anticipate that the heat of hydrogenation of bicycloöctene would lie somewhat below this value. A consistent argument based upon conformational properties can be advanced in explanation of this apparent anomaly. The conformation of bicycloöctane shown in structure X is totally eclipsed and possesses six 1:2- and six 1:3- opposed hydrogen–hydrogen interactions, as well as three pairs of opposed carbon–carbon bond repulsions. This arrangement represents an energy maximum for non-bonded interactions, which can be relieved considerably by twisting about the central axis to give a partially eclipsed conformation XI. Examination of molecular models indicates that



XI

twisting amounting to about 10° can be accommodated without distortion of bond angles. Similar twisting in bicycloheptane is restricted by the presence of one-carbon bridging. Since a small reduction in each of the interactions noted above can account for a relatively large total energy change, the high heat of hydrogenation of bicycloöctene can be attributed to heat evolution accompanying the conformational transition X → XI. As an alternative to this suggestion it will be noted that if twisting in bicycloöctene is also permitted, the accompanying increase in torsional strain of the double bond will be reflected in a corresponding increase in the heat of hydrogenation of this substance.

Although a final decision between these alternatives cannot be made at the present time, we prefer the second explanation for the following reasons. The heat change accompanying hydrogenation of bicycloöctadiene to bicycloöctene, a process that results in the introduction of two 1:2- and two 1:3- opposed hydrogen–hydrogen interactions,[24] is also abnormally high (−28.0 kcal./mole) when compared with the cyclohexene value. This result is difficult to explain in terms of a totally eclipsed conformation for bicycloöctene but can be rationalized if bicycloöctene possesses a twisted structure.

Comparison of the heats of hydrogenation of cyclopentene and cyclohexene with those of bicycloheptene and bicycloöctene provides an interesting illustration of the relative importance of angle strain and non-bonded repulsions in these systems. The heat evolved in the hydrogenation of cyclopentene[26] is 1.7 kcal. *less* than that produced in the hydrogenation of cyclohexene, despite the fact that bond angles in the former substance must deviate from the normal values. Since in five-membered carbocycles departures from planarity are relatively small,[25] the hydrogen atoms of cyclopentane are all eclipsed, or nearly so, whereas the hydrogen atoms of cyclohexane ("chair" form) adopt a staggered arrangement. In this case it is clear that steric repulsion effects predominate.

The situation with respect to bicycloheptene and bicycloöctene differs from that found in the monocyclic compounds and can best be deduced from inspection of models. It is observed that, apart from certain minor differences, the same numbers of interactions—*e.g.*, two 1,2- and four 1,3-hydrogen–hydrogen repulsions—are introduced in the hydrogenation of both olefins. Whereas bicycloöctane, and probably also bicycloöctene, can twist off from the position of maximum eclipsing, a similar adjustment in the bicycloheptane–bicycloheptene system is not possible, and steric factors would hence be expected to raise the heat of hydrogenation of bicycloöctene relative to that of bicycloheptene. The fact that the heat of hydrogenation of bicycloöctene is almost 5 kcal. lower than that of bicycloheptene must therefore be attributed to angle strain in bicycloheptene, which is more severe than in the case of cyclopentene owing to geometric requirements of the bridged system.

Acknowledgment.—We are indebted to the Eli Lilly Co., Indianapolis, for generous support of this work and to Professor G. B. Kistiakowsky for his invaluable advice and encouragement. It is a pleasure to acknowledge also the assistance that has been rendered us by Professor W. O. Milligan in connection with a variety of problems arising in the course of this investigation.

Heats of Hydrogenation. II. Heats of Hydrogenation and the Acid-catalyzed Isomerization of Some Unsaturated Steroids[1]

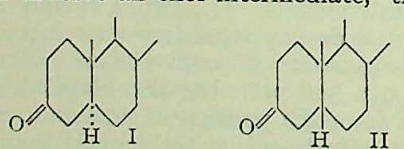
BY RICHARD B. TURNER, W. R. MEADOR AND R. E. WINKLER

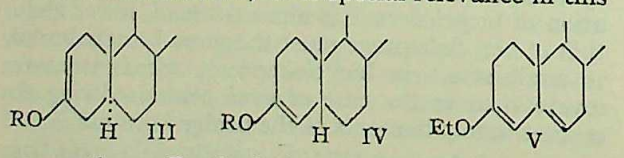
RECEIVED FEBRUARY 25, 1957

The heats of hydrogenation of cholest-1-ene, cholest-2-ene, cholest-3-ene, cholest-5-ene, cholest-6-ene and of 3α-hydroxy-Δ^{11}-cholenic acid have been determined and correlated with conformational properties of these molecules. The observed stability order—$\Delta^2 \simeq \Delta^5 > \Delta^1 \simeq \Delta^6 > \Delta^3 > \Delta^{11}$—is consistent with various observations made in connection with a study of acid-catalyzed double bond migration in these systems.

In connection with a general program dealing with measurements of heats of catalytic hydrogenation in solution, the heats of hydrogenation of several steroid olefins have been determined. The results provide a quantitative measure of stability relationships among olefins possessing double bonds at various positions in a fused ring system. The experimental procedure employed in this investigation has been described in the first paper of this series[2] and requires no further discussion. As a supplement to the hydrogenation experiments, a study of the isomerization of steroid olefins under conditions of acid catalysis also was undertaken. The results of these two lines of investigation are reported in the present communication.

It has been known for many years that monobromination of cholestan-3-one (I) furnishes mainly 2-bromocholestan-3-one, whereas monobromination of coprostan-3-one (II) yields 4-bromocoprostan-3-one as the only isolable product.[3] Similar directional specificity is encountered in sulfonation of the two ketones[4] and in various other allied reactions. Since the bromination reaction has been shown to involve an enol intermediate,[5] the demonstration that cholestan-3-one furnishes enol derivatives (ethers and esters) of structure III, whereas coprostan-3-one yields analogous derivatives of structure IV,[6] is of special relevance in this connection. Particularly noteworthy is the fact that partial catalytic hydrogenation of cholestenone enol ether (V) yields III (R = C_2H_5) with double bond migration rather than the expected Δ^3-isomer.[6b] It may therefore be concluded that a double bond at the 2,3-position of the cholestane nucleus is energetically favored over a double bond at the 3,4-position and that the converse is true for the corresponding olefins of the coprostane series.





Examination of molecular models of coprost-2-ene and of coprost-3-ene reveals a severe steric compression of the 4α- and 7α-hydrogen atoms in coprost-2-ene, which has no counterpart in the Δ^3-isomer and which may be expected to contribute to the thermodynamic instability of the Δ^2-olefin. Other conformational aspects of the coprostene problem have been discussed by Taylor[7] in terms of properties of the *cis*-octalins. The origins of the apparent energy difference between cholest-2-ene and cholest-3-ene recently have been dealt with by Corey and Sneen[8] and are considered further from a slightly different point of view in a later section of this paper.

Directional specificity of the type noted above also has been observed in various derivatives of *cis*- and *trans*-decalin. Thus, dehydration of *trans*-2-decalol over potassium bisulfate yields almost pure *trans*-2-octalin, whereas similar treatment of *cis*-2-decalol affords a mixture in which *cis*-1-octalin represents the major component.[9] Substitution reactions of *trans*-2-decalone occur mainly at the 3-position, but the situation with respect to *cis*-2-decalone is less well defined. Chlorination of this substance gives, in low yield, a product that has been formulated as a 3-chloro derivative.[10] Great caution must therefore be exercised in extrapolating stability relationships from one series of compounds to another, in spite of the existence of close structural similarities.[11,12]

(10) The observation of J. W. Cook and C. A. Lawrence, *J. Chem. Soc.*, 817 (1937), that condensation of *cis*-2-decalone with ethyl oxalate occurs at the 3-position can be explained in terms of product equilibrium and is hence not relevant to the present discussion; *cf.* G. Stork and R. K. Hill, THIS JOURNAL, 79, 495 (1957).

(11) *Cf.* G. Stork and A. W. Burgstahler, THIS JOURNAL, 77, 5068 (1955).

(12) With reference to the structural analogy drawn between coprostan-3-one and *cis*-2-decalone, it will be noted that whereas the steroid ring system is relatively rigid, owing to constraints imposed by the *trans* fusion between rings B and C, the conformational mobility of *cis*-2-decalone is not thus restricted. The entropy contribution to free energy will thus assume greater importance in the *cis*-decalin than in the coprostane series, while this differentiation between *trans*-decalin derivatives and cholestane derivatives should be less marked. Arguments based solely on steric interactions that have been advanced in connection with the coprostanone problem will not necessarily hold with equal force for *cis*-2-decalone, particularly since relief of steric strains could be attained more easily in the more flexible molecule.

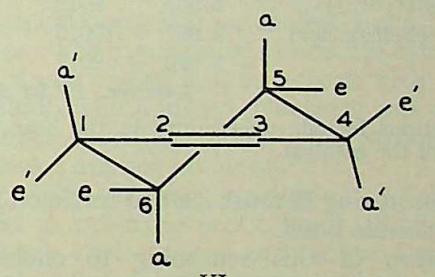
Hydrogenation Data.—The values for the heats of hydrogenation (acetic acid solution, 25°) of six steroid olefins are given in Table I. The precision of the results obtained in this series was limited by the amounts of material that could be employed in view of the relatively low solubility of these substances and of the reduction product, cholestane, in acetic acid. Cholest-4-ene was not included in this investigation, since catalytic hydrogenation of this derivative yields a mixture of stereoisomers.

All of the substances in question possess an olefinic double bond in a six-membered ring, and, with the exception of cholest-5-ene, all are of the *cis*-disubstituted type. The relatively large differences in heat content observed in this series—3 kcal. in the case of compounds 2 and 6—are therefore of considerable interest. In this connection it should be noted that the resonance energy calculated for butadiene from hydrogenation data is 3.5 kcal./mole[13] and that resonance coupling of the benzene ring and vinyl group in styrene results in additional stabilization of only 1.6 kcal./mole.[14] It is evident that steric effects of a rather subtle nature may often overshadow the resonance effect.

The lowest heats of hydrogenation, and hence maximum thermodynamic stabilities, are encountered in the Δ^2- and Δ^5-cholestenes, the values obtained for these substances being indistinguishable within the limits of experimental error. Catalytic hydrogenation of 5:6-unsaturated steroids is known to yield mainly A/B *trans*-fused products, but small amounts (2–4%) of the corresponding A/B *cis* derivatives have been obtained in isolated instances.[15] However, since the energy difference between cholestane (A/B *trans*) and coprostane (A/B *cis*) is small (~ 0.8 kcal./mole),[16] the formation of a few per cent. of coprostane in the reduction of cholest-5-ene should not compromise comparison of the heat of hydrogenation of this substance with that of cholest-2-ene, which yields only cholestane. On the basis of the substitution effect, cholest-5-ene (trisubstituted) should be more stable than cholest-2-ene (disubstituted) by about 1.5 kcal./mole.[17] The 5:6-double bond is, however, exocyclic to ring A, and it is clear from the hydrogenation data that a positional effect of approximately the same magnitude must operate in favor of cholest-2-ene.

The difference in the heats of hydrogenation of cholest-2-ene and cholest-3-ene is 2.1 kcal./mole. The direction of the energy difference establishes the fact that cholest-2-ene is the more stable isomer, and the magnitude of the effect provides an adequate basis for interpretation of the directional specificity observed in the various enol reactions noted previously. The discrepancy between the result obtained for cholest-2-ene (−25.9 kcal./mole) and the heat of hydrogenation of cyclohexene (−27.1 kcal./mole)[2] is presumably attributable in large part to interactions of the axial C.10 methyl group of cholestane with axial hydrogen atoms, which interactions are replaced by hydrogen–hydrogen repulsions in the case of cyclohexane.[18]

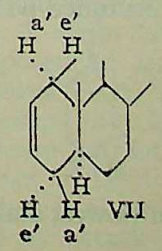
The stability difference between cholest-2-ene and cholest-3-ene has been ascribed by Corey and Sneen[8] to a reduction of the distance separating the C.10 methyl group and the C.6 β-hydrogen atom in the latter compound. An equivalent, but less detailed, treatment of the problem can be given as follows. The preferred conformation adopted by cyclohexene is now generally regarded as the "half-chair" conformation VI, in which carbon atoms 1, 2, 3 and 4 lie in a single plane.[19] The substituent groups attached to carbon atoms 5 and 6 are staggered with respect to each other and are hence considered to have the axial and equatorial properties associated with similarly situated substituents in cyclohexane.



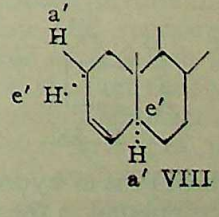
VI

On the other hand, distortion of the molecule necessitated by the planar arrangement of carbon atoms 1–4 forces the substituents on carbon atoms 1 and 4 into partial eclipse with those on carbons 6 and 5, respectively. Atoms or groups attached to carbon atoms adjacent to a double bond are hence neither truly axial nor truly equatorial and are termed quasi-axial (a′) and quasi-equatorial (e′) as the case may be.

With reference to cholest-2-ene (VII), the a′,e′ bonds are all attached to hydrogen, and as a consequence the conformation of ring B is essentially unaffected. On the other hand, in cholest-3-ene (VIII) the 5:6-bond must be quasi-equatorial with respect to ring A if the double bond is planar, and ring B is therefore forced into a deformed "chair" conformation with resultant increase in strain.



VII



a′ VIII

Conversely, restoration of the most favored con-

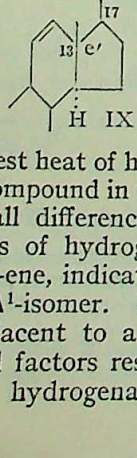
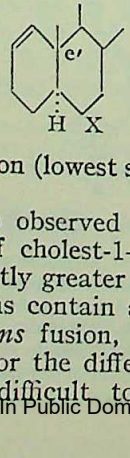
[a] Deviations include uncertainty in the heat of hydrogenation of the catalyst.

formation in ring B must lead to torsional strain in the 3:4-double bond.

Extension of this reasoning to cholest-6-ene, which possesses a double bond adjacent to two *trans* fusions, would suggest that this substance should be thermodynamically less stable than cholest-3-ene, in which only one *trans* fusion is directly involved. Comparison of the heats of hydrogenation of these compounds, however, indicates that cholest-6-ene is more stable than cholest-3-ene by a small, but experimentally significant, amount. A rationalization of this apparent anomaly can be derived from examination of the cholest-6-ene model. In this substance the deformation of ring C, brought about by the presence of a planar olefinic linkage at the 6:7-position, is such that the transoid character of the C/D fusion is somewhat reduced. In the case of 3α-hydroxy-Δ^{11}-cholenic acid (IX), however, introduction of a quasi-equatorial bond at the 13:17-position increases the transoid character of the C/D fusion with resultant increase in strain, and this substance possesses



IX



X

the highest heat of hydrogenation (lowest stability) of any compound in the series.

A small difference was also observed between the heats of hydrogenation of cholest-1-ene and cholest-3-ene, indicating a slightly greater stability for the Δ^1-isomer. Both olefins contain a double bond adjacent to a single *trans* fusion, and the structural factors responsible for the difference in heats of hydrogenation are difficult to assess. It may be noted, however, that in cholest-1-ene the bulky C.10 methyl group possesses an a′-orientation and that in this molecule, but not in cholest-3-ene, conformational effects associated with ring A are directly transmitted to ring C through a quasi-equatorial bond (*cf.* X).

No mention has thus far been made of the part that hyperconjugation may play in determining stability relationships in this series. Since the relative abilities of a′ and e′ hydrogen atoms to participate in hyperconjugation have not been established,[20] any consideration of the hyperconjugative phenomenon is subject to considerable uncertainty. Although it is clear from the data of Table II that more hydrogens are available for possible hyperconjugation in the most stable, than in the least stable, olefins, we do not feel that any useful generalization of this information can be made at the present time.

TABLE II

STABILITY ORDER AND α-HYDROGEN BOND TYPE

Stability order	$\Delta^2 \simeq \Delta^5$	>	$\Delta^1 \simeq \Delta^6$	>	Δ^3	>	Δ^{11}
No. of a′ hydrogens	2	2	1	2	2	1	
No. of e′ hydrogens	2	2	1	0	1	0	

In 1954, Henbest, Meakins and Wood[21] reported a stability order ($\Delta^2 > \Delta^3 \simeq \Delta^1 > \Delta^6 > \Delta^{11}$) for the cholestenes based upon examination of the infrared spectra of these compounds in the olefinic stretching and C–H out-of-plane bending regions. The principal difference between the order proposed by the British investigators and that derived from the hydrogenation data (Table II) lies in the position assigned to cholest-3-ene. Now the strain introduced in these molecules by the presence of unsaturation will be distributed over torsional strain in the olefinic linkages, angle strain in tetrahedral and trigonal bonds and steric strain associated with non-bonded repulsive interactions in such a way that the total energies of the molecules will be minimized. It is not surprising, therefore, that heat of hydrogenation differences, which as a first approximation reflect total energy differences, should give a stability order at variance with the infrared measurements, which are concerned mainly with strain in the double bonds.

Acid-catalyzed Isomerizations.—In addition to the hydrogenation experiments discussed in preceding paragraphs, the behavior of various cholestenes in the presence of acid has been investigated. This work was originally undertaken in the hope that equilibria could be established, which would furnish quantitative data on free energy relationships in this series. However, owing to the intervention of skeletal rearrangement, this hope was realized only for the cholest-4-ene–cholest-5-ene system, and the information that has been obtained is therefore of qualitative rather than of quantitative interest.

When cholest-5-ene is treated with *p*-toluenesulfonic acid in a refluxing mixture of acetic acid

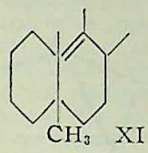
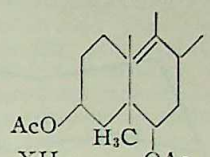
and cyclohexane (85°), it is rapidly converted into an oily mixture containing both cholest-5-ene and cholest-4-ene as indicated by infrared analysis. No other components, for example acetate esters or other double bond isomers, are spectrophotometrically detectable, and the specific rotation of the product (−17.5°) suggests the presence in the mixture of approximately 55% of cholest-4-ene and 45% of cholest-5-ene, corresponding to a free energy difference of only 0.1 kcal./mole. The infrared spectrum of a synthetic mixture of this composition is indistinguishable from that of the isomerization product. Similar treatment of cholest-4-ene affords identical material, and since no further change is effected by prolonged heating with acid under the conditions specified above, the isomerization product is regarded as an equilibrium mixture.

Treatment of the equilibrium mixture, or of either pure olefin, with *p*-toluenesulfonic acid in refluxing acetic acid for 2.5 hr., results in the formation of a colorless oil, which has resisted all attempts at crystallization. Although this product appears to be chromatographically homogeneous, it is not unlikely that the material represents a mixture of two or more substances. Unsaturation was demonstrated by the tetranitromethane test, and examination of the ultraviolet spectrum of the tetranitromethane treated material indicated the presence of a tetrasubstituted double bond.[22] Support for this conclusion is derived from the failure of the product to undergo catalytic hydrogenation under normal conditions. Hydrogenation can, however, be accomplished under forcing conditions,[23] and the oily product obtained in this way proved to be saturated in the tetranitromethane test.

In intact cholestane or coprostane structures only three positions, 8:9, 8:14 and 17:20, can accommodate a tetrasubstituted double bond. The 17:20-position is unlikely in view of the general difficulty encountered in the introduction of a tetrasubstituted double bond in this position[24] and would further appear to be excluded by the observation that both cholest-7-ene and cholest-8:14-ene furnish a different isomerization product. Examination of the infrared spectrum of the reduced material revealed no detectable amounts of cholestane or coprostane. Since forced hydrogenation of 8:9- and of 8:14-cholestene and coprostene derivatives leads to the formation of the corresponding cholestanes and coprostanes, respectively,[23,25] it follows that the tetrasubstituted olefin described above must be formed by skeletal rearrangement. The most reasonable suggestion that can be made regarding the structure of this material is that it represents the product of Wagner–Meerwein rearrangement (XI) involving intermediate formation of a C.5 carbonium ion followed by migration of the C.10-methyl group. The resulting 9:10-olefin can, of course, equilibrate the corresponding 8:9- and 8:14-unsaturated derivatives. An analogy for such a rearrangement is available in the observation that cholestane-3β,5α,6β-triol 3,6-diacetate



XI



XII

undergoes rearrangement on acid-catalyzed dehydration to yield a substance for which structure XII has been established with reasonable certainty.[26]

Cholest-1-ene, cholest-2-ene, cholest-3-ene and cholest-6-ene, on treatment with *p*-toluenesulfonic acid in acetic acid-cyclohexane at 85°, are unaffected apart from the appearance of small amounts of acetate esters formed by addition of acetic acid to the double bonds. These observations are consistent with the fact that secondary carbonium ions, obtained by proton addition to the four olefins noted above, are less stable than the tertiary carbonium ion derived from cholest-4-ene and cholest-5-ene. The appearance of acetate ester in the absence of isomerization is in accord with the suggestion that olefin addition reactions can occur by a mechanism in which conventional carbonium ion intermediates are not involved.[27]

Under more vigorous conditions (*p*-toluenesulfonic acid in refluxing acetic acid), cholest-1-ene, cholest-2-ene, cholest-3-ene and cholest-6-ene are all slowly transformed into material which, after removal of acetate esters, shows infrared absorption characteristics identical with those of product XI. Interruption of the cholest-1-ene and cholest-3-ene isomerizations at an intermediate stage gives, after removal of esters, material consisting very largely of cholest-2-ene, as indicated by infrared analysis. The predominance of cholest-2-ene in these cases is consistent with the results of the hydrogenation experiments, which establish that this olefin is more stable than the Δ^1- and Δ^3-isomers by 1.5 and 2.1 kcal./mole, respectively. It is of interest to note that cholest-3-ene is converted into XI with prior isomerization into cholest-2-ene, rather than directly through cholest-4-ene.

The rearrangement of cholest-6-ene into product XI is regarded as proceeding through cholest-5-ene as an intermediate. The particular point of interest that arises in this connection is the preference of the Δ^6-olefin for isomerization in this direction as opposed to isomerization and rearrangement *via* cholest-7-ene. A possible explanation for this observation may be found in the fact that the C.7 carbonium ion, formed by proton addition at C.6, possesses a 1,3-diaxial methyl–hydrogen interaction that is absent in the C.6 carbonium ion, obtained by attack at C.7. As a corollary to this argument, it will be observed that proton addition (a) in the axial sense at C.6 (see XIII) is sterically

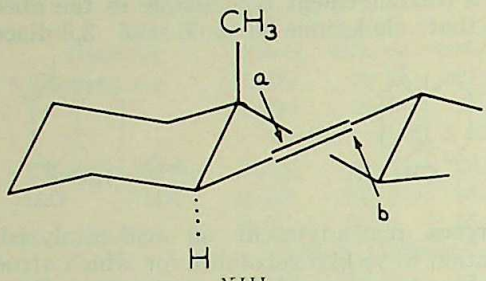
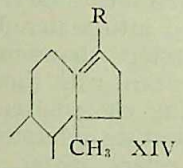
hindered by the C.10 methyl group, whereas approach of a proton as in (b) is unencumbered.[28]



XIII

Treatment of cholest-7-ene with *p*-toluenesulfonic acid in acetic acid–cyclohexane at 85° results in rapid conversion of this compound into a noncrystalline mixture in which cholest-8:14-ene predominates. Prolonged treatment of the mixture, or of pure cholest-8:14-ene, under these conditions furnishes an unsaturated oil with infrared absorption characteristics differing from those of the starting materials and of product XI. As in the case of XI, the material possesses a tetrasubstituted double bond,[22] and on forced hydrogenation it furnishes a saturated, amorphous substance in which the presence of traces of cholestane can be detected by infrared measurements. However, since cholestane is a minor constituent of the reduction product, it seems reasonable to assume that the tetrasubstituted olefin consists mainly of rearrangement products of type XIV.



XIV

Double bond isomerizations in the steroid series, particularly those involving the 7:8-, 8:9-, 8:14 and 14:15-positions are well known and are conventionally brought about by saturated solutions of hydrogen chloride in chloroform.[29] In no previous case, however, has the problem of skeletal rearrangement received attention, and the observations that have been made in connection with this investigation may be taken as a warning that such rearrangements occur under relatively mild conditions. It seems probable that the poor yields encountered in hydrogen chloride–chloroform isomerizations that are not conducted at low temperature may be attributed to this phenomenon.

Experimental[30]

Materials.—**Cholest-1-ene**, m.p. 68–69°, $[\alpha]_D$ +12° (*c* 1.5, chloroform) was prepared from cholest-1-en-3-one by a procedure developed by Henbest.[31] The conjugated ketone was reduced with lithium aluminum hydride, and the resulting unsaturated alcohol was converted into the corresponding 3-chloro derivative by treatment with thionyl chloride. Reductive removal of chlorine with lithium aluminum hydride furnished a crude sample of the desired olefin. Final purification was accomplished by recrystallization of the dibromide, m.p. 134–136°, from which pure cholest-1-ene was obtained by the action of zinc dust in acetic acid.

Cholest-2-ene was prepared by the method of Fieser and Dominguez.[32] The crude olefin was purified through the dibromide, m.p. 124–125°, from which cholest-2-ene, m.p. 74–75°, $[\alpha]_D$ +69.7° (*c* 0.9, chloroform), was regenerated by treatment with zinc and ethanol.

Preparation of **cholest-3-ene** was carried out according to the procedure of Lardelli and Jeger.[33] The product obtained in this way, after purification through the dibromide, m.p. 123–124°, melted at 73.5–74.5°, $[\alpha]_D$ +58.2° (*c* 0.9, chloroform): literature values, 72–73°, $[\alpha]_D$ +65° (chloroform)[33]; 72–72.5°, $[\alpha]_D$ +57° (chloroform).[34]

Cholest-4-ene, m.p. 80–83°, $[\alpha]_D$ +66° (*c* 1.0, chloroform) was synthesized as described by Barton and Rosenfelder.[34]

Cholest-5-ene was obtained by sodium–alcohol reduction of cholesteryl chloride as described by Mauthner and Suida.[35] Crystallization of the crude product from ether–methanol afforded material melting at 92–94°, $[\alpha]_D$ −55.0° (*c* 1.5, chloroform).

The preparation of **cholest-6-ene** was accomplished by a modification of the procedure reported by Cremlyn and Shoppee.[36] A solution of 80.0 g. of 7-ketocholesteryl acetate in 2 l. of benzene containing 80.0 g. of *p*-toluenesulfonic acid was heated under reflux in a nitrogen atmosphere for 7 hr. The solution was then cooled, diluted with ether and washed successively with water, dilute sodium carbonate solution, water and a saturated solution of sodium chloride. After drying over magnesium sulfate and removing the solvents, the residual material was crystallized, first from ethanol and then from acetone. Fifty grams of cholesta-3,5-dien-7-one, m.p. 112–114°, was obtained in this way.

A solution of 20.0 g. of dienone in 200 ml. of ether and 250 ml. of acetic acid was stirred with 2.0 g. of platinum oxide catalyst in an atmosphere of hydrogen for 14 hr., at the end of which time the absorption of hydrogen had ceased. The catalyst was removed by filtration, and the filtrate was diluted with ether and washed with water and dilute sodium hydroxide solution. After drying, the solvent was removed under reduced pressure, and the residual material was chromatographed on alumina. Cholestan-7α-ol (4.4 g.), m.p. 90–94°, was obtained from the petroleum ether–benzene eluates.[37] Two recrystallizations from acetone afforded 3.4 g. of pure material melting at 95–97°. Benzoylation furnished 2.9 g. of the corresponding benzoate as long needles, m.p. 158–160°. A further 940 mg., m.p. 155–158°, was obtained as a second crop.

Pyrolysis of the benzoate (2.47 g.) was carried out under reduced pressure at a bath temperature of 400°. The total crude product, after removal of the benzoic acid, was chromatographed on alumina, whereupon 1.43 g. of pure cholest-6-ene, m.p. 84–85°, $[\alpha]_D$ −84.3° (*c* 1.56, chloroform) was obtained.

Cholest-7-ene has been prepared by Cremlyn and Shoppee[36] by chromatography of the *p*-toluenesulfonyl derivative of cholestan-7β-ol on neutral or alkaline alumina. Four grams of cholestan-7β-ol, m.p. 110–113.5°, obtained in the preceding experiment, was converted into the corresponding tosylate and passed through a column of neutral alumina. The hydrocarbon fraction was reserved for subsequent purification, and the cholestan-7α-ol formed simultaneously was removed from the column and recycled, either by oxidation to cholestan-7-one followed by sodium–alcohol reduction or by epimerization with sodium butylate.[36]

(28) Mechanisms for double bond migration other than the one pictured here can also be formulated, *e.g.*, isomerization through bridged ion intermediates and concerted isomerization–rearrangement processes. The carbonium ion mechanism is employed for illustrative purposes for reasons of simplicity.

The total olefin obtained in this way, after recrystallization from acetone and from ether–methanol, melted at 85.8–87°, $[\alpha]_D$ +6°. The infrared spectrum indicated contamination by small amounts of cholest-6-ene, which could not be removed by repeated crystallization.[33] The product was finally rechromatographed on alkaline alumina and, after several passes, a sample, m.p. 86–87°, $[\alpha]_D$ +11.7°, free of cholest-6-ene was obtained.

Cholest-8:14-ene, m.p. 53.5–55°, $[\alpha]_D$ +20° (*c* 1.0, chloroform) was prepared from cholest-7-ene by isomerization over palladium (hydrogenation conditions) as described by Eck and Hollingsworth.[25]

The 3α-hydroxy-Δ^{11}-cholenic acid employed in this investigation was a purified sample, m.p. 165–166°, of material prepared some years ago at the laboratories of Merck and Co., Rahway, N. J.

Acid Isomerization at 85°.—A solution of the olefin and an equal weight of *p*-toluenesulfonic acid in a mixture of acetic acid and cyclohexane (4:1, 6 ml. of solvent for 30 mg. of olefin) was heated to reflux temperature in an electrically heated oil-bath in a flask fitted with a thermometer extending below the surface of the solution. At the end of the selected heating period, the solution was poured into dilute sodium hydroxide, and the aqueous layer was extracted three times with petroleum ether. The combined organic fractions were then washed with dilute alkali, water, saturated sodium chloride and filtered through anhydrous magnesium sulfate. After evaporation of the solvent, the product was twice dissolved in carbon disulfide and taken to dryness in order to ensure removal of the last traces of hydrocarbon solvent prior to infrared analysis.

(38) Cremlyn and Shoppee obtained pure cholest-7-ene directly from the alumina column.

Acid Isomerization at 120°.—The procedure employed for isomerizations at the higher temperature resembled that described above, except that after the reflux temperature had been reached, about 30% of the solvent was distilled off. The cyclohexane and water passed over as an azeotrope, and the temperature of the solution rose to about 120°. When reactions were carried out in acetic acid alone, without removal of small amounts of water that are present under these conditions, the results obtained were erratic. At the end of the reaction period, the products were isolated as before, and the acetate esters were removed by chromatography on alumina before infrared analysis of the hydrocarbon fractions.

Hydrogenation of Product XI.—A sample of product XI was dissolved in 40 ml. of acetic acid–cyclohexane (4:1) and stirred in a hydrogen atmosphere with pre-reduced platinum oxide catalyst. No hydrogen was absorbed, and the recovered material proved to be unsaturated in the tetranitromethane test. The experiment was then repeated with 200 mg. of XI in 35 ml. of acetic acid–cyclohexane (4:1), to which 4 drops of 12 *N* hydrochloric acid was added. After 42 hr. at 60°, 110% of the calculated amount of hydrogen had been absorbed, and the product gave no reaction with tetranitromethane. The infrared absorption spectra of the reduced material showed no detectable amounts of cholestane or of coprostane.

Hydrogenation of Product XIV.—Hydrogenation was carried out at 60° with added hydrochloric acid as described in the preceding experiment. The reaction product showed a negative tetranitromethane test for unsaturation, and the infrared spectrum gave evidence of the presence of small amounts of cholestane.

Heats of Hydrogenation. III. Hydrogenation of Cycloöctatetraene and of Some Seven-membered Non-benzenoid Aromatic Compounds[1]

BY RICHARD B. TURNER, W. R. MEADOR, W. VON E. DOERING, L. H. KNOX, J. R. MAYER AND D. W. WILEY

RECEIVED FEBRUARY 25, 1957

The heats of hydrogenation of several potentially aromatic substances have been measured in solution, and resonance energies have been estimated by comparison of the heats of hydrogenation of these compounds with heats calculated for reasonable models. The compounds that have been examined together with the ΔH values and calculated resonance energies are as follows: cycloöctatetraene ($-\Delta H$ 97.96 ± 0.05 kcal./mole, R.E. 2.4 kcal./mole), 1,3,5-cycloöctatriene ($-\Delta H$ 72.36 ± 0.26 kcal./mole, R.E. 0.9 kcal./mole), azulene ($-\Delta H$ 98.98 ± 0.13 kcal./mole, R.E. 28 kcal./mole), heptafulvene ($-\Delta H$ 92.63 ± 0.41 kcal./mole, R.E. 13 kcal./mole), heptafulvalene ($-\Delta H$ 130.77 ± 0.31 kcal./mole for six molar equivalents of hydrogen, R.E. 28 kcal./mole), dihydroheptafulvalene ($-\Delta H$ 138.81 ± 0.20 kcal./mole) and tropone ($-\Delta H$ 67.58 ± 0.30 kcal./mole to cycloheptanone).

Since the heats of hydrogenation of benzene, and of various related substances including styrene, hydrindene and furan, were measured by Kistiakowsky and his associates[2] some twenty years ago, no further studies of heats of hydrogenation in the aromatic series have been reported. In the meantime several potentially aromatic compounds of considerable theoretical interest have been prepared in sufficiently pure condition for hydrogenation studies. Of these substances cycloöctatetraene, azulene, methylenecycloheptatriene (heptafulvene), cycloheptatrienylidenecycloheptatriene (heptafulvalene), 7-(7′-cycloheptatrienyl)-cycloheptatriene (dihydroheptafulvalene) and cycloheptatrienylium oxide (tropone) have now been examined in the hydrogenation calorimeter.

Experimental

The technique for measurement of heats of hydrogenation in solution described in Paper I[3] was employed in the present investigation with the following modifications. In the cases of heptafulvene and heptafulvalene, Diethylcarbitol was used as the solvent, since these substances are subject to rapid polymerization in acetic acid. Despite extensive purification of the Diethylcarbitol, reduction of the platinum oxide catalyst gave higher heat values in this solvent (−32.94 ± 0.21 cal./100.0 mg.) than in acetic acid (−30.95 ± 0.13 cal./100.0 mg.) and consumed one cc. more hydrogen (*e.g.*, 16.25 cc./100.0 mg. in 275 cc. of Diethylcarbitol *vs.* 15.12 cc./100.0 mg. in 225 cc. of acetic acid). The results were nevertheless consistent, and no discrepancies traceable to the solvent have been noted. All reductions in

Diethylcarbitol were carried out in volumes of 275 ml.; hydrogenations in acetic acid were conducted in 225 ml. of solvent.

The hydrogenation of tropone over platinum-in-acetic acid proceeded with the absorption of 92% of the theoretical amount of hydrogen, calculated on the basis of 4 molar equivalents. However, the clean absorption of 3 molar equivalents of hydrogen was observed over palladium supported on barium sulfate, and the results reported for tropone were obtained in acetic acid with this catalyst. All runs in which palladium was used were carried out in the following manner. The calorimeter containing the solvent, catalyst and an evacuated ampoule containing tropone was flushed with hydrogen according to the previously described procedure.[3] After absorption of hydrogen by the catalyst was complete and thermal equilibrium had been established, the hydrogenation reaction was initiated by breaking the ampoule of tropone. The final results were corrected for the heat of solution of tropone (-0.14 ± 0.01 kcal./mole), which was determined separately, and thus are referable to the dissolved state.

Materials.—A sample of **cycloöctatetraene** obtained from the General Aniline and Film Corp. was purified by conversion into the silver nitrate complex, m.p. 173° dec., as described by Cope and Hochstein.[4] Regeneration and fractionation afforded a sample boiling at 141–141.5° (19 mm.), $n^{25}D$ 1.5350. Examination of the infrared spectrum of this material for the styrene band at 11.08 μ gave no evidence for contamination by the latter substance.

1,3,5-Cycloöctatriene was prepared by the procedure of Cope and Hochstein[4]; $n^{24}D$ 1.5248.

Azulene was synthesized as described by Doering, Mayer and DePuy.[5] The sample employed for hydrogenation, m.p. 99–100°, was purified by chromatography on alumina.

Solutions of **heptafulvene** in Diethylcarbitol were freshly prepared for each run by the method of Wiley.[6] The heptafulvene was collected in a trap containing small amounts of Diethylcarbitol cooled to −40°. The resulting solutions were then made up to 275 ml. and were hydrogenated at once. The stability of heptafulvene in Diethylcarbitol was established by the negligible decrease of the extinction coefficient of the absorption band at 405 mμ over a period of 24 hr. at room temperature.

Heptafulvalene, m.p. 121–122°, was prepared by the method of Mayer.[7]

Dihydroheptafulvalene, m.p. 61°, was obtained by the procedure of Doering and Knox.[8]

Tropone was synthesized as described by Doering and Detert[9] and was purified by recrystallization and evaporative distillation; $n^{25}D$ 1.6155, m.p. −5°.

For reductions in Diethylcarbitol (diethylene glycol diethyl ether) the solvent was purified by (a) distillation at 10 mm. (b.p. 85–86°), (b) treatment with lithium aluminum hydride at 50° for 4 days and distillation at 2–3 mm. (b.p. 65–66°) and (c) distillation through a 24-inch helix-packed column under nitrogen at 37 mm. (b.p. 100°). The product was collected in 350-ml. fractions which were sealed at once under nitrogen in Pyrex flasks, m.p. −46 to −45°.

Results and Discussion

The results obtained in the present investigation are given in Table I. For the evaluation of resonance energies[10] from heats of hydrogenation, the measurements should ideally be carried out in the gas phase. The fact that the values reported here were obtained in solution therefore constitutes an obvious disadvantage, since corrections for solvent–solute interactions involving both the unsaturated derivatives and the hydrogenation products require thermodynamic data that are not generally available. The uncertainties that are introduced by the solvation problem, however, would appear to be small in view of evidence that has been cited previously.[3] Thus calculation of the resonance energy of cycloheptatriene from the gas phase data of Kistiakowsky[11] gives a value of 6.7 kcal./mole, based on a reference standard equal to three times the heat of hydrogenation of cycloheptene. The same method of calculation applied to the measurements made in acetic acid furnishes a comparison value of 7.1 kcal./mole. In any event, ambiguities that arise from uncertainties in the formulation of appropriate "non-resonating" models undoubtedly constitute a more important source of difficulty than do solvent–solute interactions, at least in the case of relatively non-polar molecules.

TABLE I

HEATS OF HYDROGENATION IN SOLUTION[a]

Compound	Mmoles	Catalyst, mg.	$-\Delta H(25°)$, kcal./mole
Cycloöctatetraene	1.259	100.2	97.96
	1.307	100.0	97.96
		Average	97.96 ± 0.05[b]
1,3,5-Cycloöctatriene	1.553	100.2	72.63
	1.315	98.8	72.06
	1.648	98.8	72.39
		Average	72.36 ± 0.26
Azulene	0.8103	99.8	98.75
	0.8007	99.7	99.20
		Average	98.98 ± 0.13
Heptafulvene[c]	1.614	100.2	93.24
	1.560	100.5	92.08
	1.555	100.5	92.56
		Average	92.63 ± 0.41
Heptafulvalene[c]	4.176[d]	110.0	130.86[e]
	4.189[d]	100.5	130.68[e]
		Average	130.77 ± 0.13[e]
Dihydroheptafulvalene	0.7347	99.0	138.90
	0.7593	99.3	138.72
		Average	138.81 ± 0.20
Tropone[f]	0.9813	Pd–$BaSO_4$	67.75
	0.8417	Pd–$BaSO_4$	67.89
	1.938	Pd–$BaSO_4$	67.09
		Average	67.58 ± 0.30

[a] Except in the cases indicated, all hydrogenations were carried out in acetic acid with a platinum oxide catalyst. [b] Deviations include uncertainty in the heat of hydrogenation of the platinum oxide. [c] Hydrogenations of heptafulvene and of heptafulvalene were carried out with Diethylcarbitol as the solvent. [d] Millimoles of *hydrogen* absorbed. [e] These values are based upon the absorption of 6 molar equivalents of hydrogen (see Discussion). [f] Tropone was reduced over 1.0-g. samples of a 5% palladium-on-barium sulfate catalyst. In these experiments the catalyst was equilibrated with hydrogen, and the hydrogenation reaction was initiated by solution of the tropone. The results are corrected for the heat of solution of tropone in acetic acid.

Cycloöctatetraene.—Cycloöctatetraene is one of the earliest molecules to derive its importance from a potential bearing on the theory of aromatic

(10) As used throughout this paper, "resonance energy" is defined as the difference between the measured heat of hydrogenation (reaction) of a given compound and that estimated for one or more reasonable models. It should be emphasized that resonance energy is not an intrinsic property of a molecule but that it depends on, and varies with, the choice of the model.

character.[12] The conformation and resonance energy of this substance have been subjects of considerable controversy in recent years. Although a large body of evidence has been variously interpreted in favor of the "tub" structure on the one hand and the "crown" structure on the other,[13] it is now generally agreed that cyclooctatetraene exists in the "tub" form.[14] This structure allows each olefinic linkage to assume a strainless, planar configuration with C=C—C angles approximating 120° but with angles between adjacent double bonds of nearly 90° owing to rotation about the intervening C–C single bonds. Conjugative stabilization in such a non-planar molecule should be largely suppressed, and the resonance energy would therefore be expected to be small.[15] Support for this conclusion is provided by the X-ray analyses of Kaufman, Fankuchen and Mark[16] which show that in the crystal the carbon–carbon bond lengths are alternately 1.54 and 1.34 Å. as in paraffinic and olefinic substances, respectively. This result contrasts with the single value of 1.39 Å. reported for the carbon–carbon distances in benzene.[17]

Following publication of data on the heat of formation of cyclooctatetraene[18] shortly after World War II, Pink and Ubbelohde[19] calculated a resonance energy of 25.3 kcal./mole for this substance. This result is inconsistent with the chemical properties of cyclooctatetraene, in particular with its ready conversion into derivatives of bicyclo-[4,2,0]octadiene,[20] and a considerably lower value was subsequently suggested by Person, Pimentel and Pitzer[14a] on the basis of conventional calculations employing the 1950 combustion data of Prosen, Johnson and Rossini[21] and bond energies (4 C=C, 4 C—C and 8 C—H bonds) given by Pitzer.[22] An alternative method of treatment of the Rossini data, however, furnishes a still lower and, we believe, more reliable result.

The heat of isomerization of cyclooctatetraene into styrene (gas phase) derived from Rossini's results is −36.3 kcal./mole.[21,23] Taking 36.9 kcal./mole as the resonance energy of styrene[24] and 72.5 kcal./mole as the heat of formation of "non-resonating" styrene, calculated by Franklin's method of group equivalents (Table II),[25] the heat of formation of styrene can be expressed as 35.6 kcal./mole.

TABLE II

CALCULATION OF HEATS OF FORMATION (NON-RESONATING STRUCTURES)[25]

Styrene	ΔH_f	Cyclooctatetraene	ΔH_f
2 C=C (*cis*)	37.8	4 C=C (*cis*)	75.5
		Total	75.5
1 C=C	20.2		
1 C=C	15.0	Naphthalene	
		4 C=C (*cis*)	75.5
1 C_6-ring corrn.	−0.5	1 C=C	24.6
		2 C_6-ring corrn.	−1.0
Total	72.5	Total	99.1
Azulene			
3 C=C (*cis*)	56.6		
2 C=C	40.4		
1 C_5-ring corrn.	5.7		
Total	102.7		

From this result and from the isomerization data it follows that the heat of formation of cyclooctatetraene is 71.9 kcal./mole. Calculation of the heat of formation of "non-resonating" cyclooctatetraene by the Franklin method[25] gives a value of 75.5 kcal./mole (Table II), and resonance stabilization of this molecule is hence estimated to be of the order of 3.6 kcal./mole. The result obtained by this procedure is in good agreement with the value of 4.8 kcal./mole recently derived by Springall, White and Cass[26] from heat of combustion data and selected average bond energies.

Since all of the values thus far reported for resonance energy in the cyclooctatetraene system are based upon combustion experiments, determination of this quantity by an independent method seemed most desirable. The heat of hydrogenation of cyclooctatetraene was accordingly measured in acetic acid solution at 25° and was found to be −97.96 ± 0.05 kcal./mole (Table I).

Assuming the superficially reasonable reference standard of four times the heat of hydrogenation

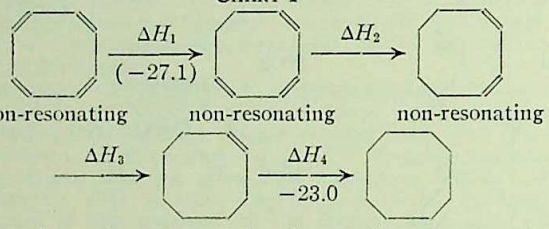
of *cis*-cycloöctene (−22.98 ± 0.10 kcal./mole),[27] the resonance energy calculated for cycloöctatetraene is *negative* and equal to −6.0 kcal./mole. It will be noted, however, that owing to severe repulsions between non-bonded atoms in cycloöctane,[11,27] the heat of hydrogenation of *cis*-cyclooctene is considerably lower than that of cyclohexene (−27.10 kcal./mole),[3] which furnishes a reduction product in which non-bonded interactions are minimized.[28] Since the repulsions that are introduced in the last of the four hypothetical steps in the hydrogenation of "non-resonating" cyclooctatetraene (Chart I) are undoubtedly greater

CHART I



than those introduced in the earlier stages, the use of ΔH_4 to represent the heat of all four steps is a poor choice, which leads to an unreasonably low prediction. In order to correct for this effect, the cyclohexene value (−27.1 kcal./mole) has been assigned to ΔH_1 on the grounds that the heat of hydrogenation of the first double bond of the model should closely approximate that of a representative, *cis*-disubstituted olefin. An average of this figure and that obtained experimentally for ΔH_4 (−23.0 kcal./mole) gives an average heat of hydrogenation for all four double bonds of −25.1 kcal./mole. The resonance energy calculated for cycloöctatetraene on the basis of these assumptions is 2.4 kcal./mole, a result that agrees reasonably well with the lower values derived from combustion data.

As a further check on the magnitude of the cyclooctatetraene resonance, the heat of hydrogenation of cycloöctatetraene has been compared with that of 1,3,5-cycloöctatriene in analogy with the procedure followed by Kistiakowsky and his associates[2a] in their treatment of the resonance energy of benzene. By subtracting the heat of hydrogenation of 1,3-cyclohexadiene to cyclohexane from that of benzene to the same product, the heat of the reaction benzene + H_2 → 1,3-cyclohexadiene can be calculated. This change is *endothermic* to the extent of 5.6 kcal./mole, as compared with the hydrogenation of an unconjugated, *cis*-disubstituted double bond, *exothermic*, −28.6 kcal./mole (gas phase). The reduction in heat evolution of 34.2 kcal./mole observed in this case represents the increase in stabilization resulting from introduction of a third double bond into the 1,3-cyclohexadiene molecule and is defined[10] as the resonance energy of benzene relative to the cyclohexene—1,3-cyclohexadiene model.[29]

Returning now to the question of cycloöctatetraene, it follows that a quantitative measure of the aromatic character of this substance can be gained from the extent to which the heat change for the process cycloöctatetraene + H_2 → 1,3,5-cycloöctatriene deviates from the standard value of −27.1 kcal./mole (solution). The quantity calculated for this transformation from the heats of hydrogenation of cycloöctatetraene and of 1,3,5-cycloöctatriene to cycloöctane is −25.6 kcal./mole. The discrepancy in this case is hence only 1.5 kcal./mole, a value that is comparable in magnitude to the resonance energy of simple conjugated dienes.

With reference to the triene problem it is interesting to note that the heat of hydrogenation of 1,3,5-cycloöctatriene (−72.4 kcal./mole) is *higher* than that of 1,3,5-cycloheptatriene (tropilidene) (−70.5 kcal./mole) despite the fact that the heat of hydrogenation of *cis*-cycloöctene is *lower* than that of cycloheptene by almost 3 kcal.[3,27] The resonance energy of 1,3,5-cycloöctatriene (0.9 kcal./mole) is obtained directly as the difference between the resonance energy of cycloöctatetraene (2.4 kcal./mole) and the contribution of the fourth double bond (1.5 kcal./mole). The stabilization of tropilidene is 9.8 kcal./mole based on Kistiakowsky's data[11] or 9.0 kcal./mole based on the solution data,[3] both figures being referable to a "non-resonating" model in which cyclohexene is used for the first double bond, cycloheptene for the third and an average of the two for the second.

The negligible resonance energy of 1,3,5-cyclooctatriene probably is due to its non-planar structure. By analogy one can assume that a non-planar cycloheptatriene structure for tropilidene would also lead to little or no resonance energy. The fact that tropilidene has a relatively high degree of stabilization is in better accord with a planar conformation.[30] It should be mentioned that such an arrangement involves considerable angular strain, of which no account is taken in formulation of the comparison standard. This inadequacy of the model serves to lower the calculated resonance energy.[31]

Azulene.—In view of widespread interest in the properties of non-benzenoid aromatic compounds, we have measured the heat of hydrogenation of azulene. This substance undergoes rapid reduction in acetic acid with clean absorption of five molar equivalents of hydrogen and furnishes a ΔH value of −98.98 ± 0.13 kcal./mole. Simple calculations based on

(27) R. B. Turner and W. R. Meador, THIS JOURNAL, **79**, 4133 (1957).

(28) In this connection cyclohexene is regarded as a typical unstrained, *cis*-disubstituted olefin, the hydrogenation of which is uncomplicated by the steric repulsion problem. It will be recalled that the gas phase values obtained for cyclohexene and for *cis*-butene (−28.6 kcal./mole) by G. B. Kistiakowsky, J. R. Ruhoff, H. A. Smith and W. E. Vaughan, *ibid.*, **57**, 876 (1935) and **58**, 137 (1936), are identical.

(29) The value of 36.0 kcal./mole for the resonance energy of benzene is based on a model consisting of three molecules of cyclohexene and differs from the figure given above by the resonance energy of 1,3-cyclohexadiene (1.8 kcal./mole).

(30) For additional discussion of this problem see W. von E. Doering, G. Laber, R. Vonderwahl, N. F. Chamberlain and R. B. Williams, THIS JOURNAL, **78**, 5448 (1956). The resonance energy obtained in the present investigation compares favorably with that calculated by Wheland (reference 24, p. 132) for planar cycloheptatriene. The recent suggestion of M. V. Evans and R. C. Lord, "Abstracts of Papers," 130th Meeting, American Chemical Society, Atlantic City, N. J., Sept. 16, 1956, p. 41R, that tropilidene is bicyclo[3,2,0]heptadiene-1,5 is at variance with results of E. Vogel (private communication) which indicate that a synthetic product of this structure is not identical with tropilidene.

(31) A similar problem is encountered in the case of benzene, since the actual molecule possesses compressional energy not found in the cyclohexene model.

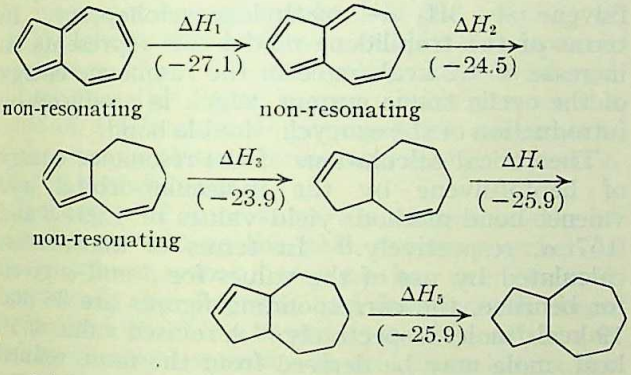
twice the heat of hydrogenation of cyclopentene (−25.9 kcal./mole)[32] and three times the heat of hydrogenation of cycloheptene (−25.9 kcal./mole)[3] give a resonance energy of 30.5 kcal./mole for this substance. Correction for steric repulsion effects is more difficult in this instance than in the cyclooctatetraene case, and the situation is further complicated by the presence in azulene of two trisubstituted double bonds at bridge head positions. The treatment that follows must, therefore, be regarded as a very crude approximation at best.

The heat of hydrogenation of the non-resonating model is again obtained as the summation of heats evolved in a hypothetical reduction process (Chart II). The cyclohexene value (−27.1 kcal./

CHART II



mole) is assumed for ΔH_1, and the cycloheptene and cyclopentene[32] figures have been taken for ΔH_4 and ΔH_5, respectively.[33] The heats of hydrogenation ΔH_2 and ΔH_3 present a special problem, and the values that have been chosen, −24.5 kcal./mole for ΔH_2 and −23.9 kcal./mole for ΔH_3, are based upon averages of the heats of hydrogenation of 1-methylcycloheptene and ethylidenecyclopentane and of 1-methylcyclopentene and methylenecycloheptane,[34] respectively, after correction of the methylenecycloheptane value for the substitution effect.[35] The heat of hydrogenation of the non-resonating model is then −127.3 kcal./mole, and the estimated resonance energy of azulene is 28.3 kcal./mole.[36] Since azulene possesses a dipole moment of approximately 1.0 *D*,[37] solvation energy should be larger in this case than in the case of non-polar molecules. "Resonance energy" calculated from solution data thus includes a factor for solvation.

In 1947, Heilbronner and Wieland[38] reported a value of 46 kcal./mole for the resonance energy of azulene, derived from consideration of: (a) the difference in heats of combustion of the isomer guaiazulene and cadalene (−29.6 ± 2.1 kcal./mole),[39] taken also as the difference in heats of formation of the isomeric pair azulene and naphthalene; (b) the heat of formation of naphthalene (solid state); (c) the heat of sublimation of carbon; (d) the heat of sublimation of azulene and (e) various bond energies given by Pauling.[40]

An equivalent, but more direct, evaluation of the azulene resonance can be made on the basis of the following relationships, in which all quantities refer to the vapor phase.

(1) ΔH_f (non-resonating naphthalene) − R.E. (naphthalene) = ΔH_f (naphthalene)

(2) ΔH_f (naphthalene) + $\Delta H_{isom.}$ (azulene → naphthalene) = ΔH_f (azulene)

(3) ΔH_f (non-resonating azulene) − ΔH_f (azulene) = R.E. (azulene)

(4) R.E. (azulene) = R.E. (naphthalene) + ΔH_f (non-resonating azulene) − ΔH_f (non-resonating naphthalene) − $\Delta H_{isom.}$ (azulene → naphthalene)

The heats of formation (ΔH_f) of non-resonating molecules of azulene and of naphthalene determined by Franklin's method of group equivalents[25] (Table II) are 102.7 and 99.1 kcal./mole, respectively. The heat of isomerization of azulene into naphthalene, corrected for the difference in heats of vaporization of these two substances,[38] is 33.2 kcal./mole, and it follows that R.E. (azulene) = R.E. (naphthalene) −29.6 kcal. Assuming Pauling's value of 75 kcal./mole for the resonance energy of naphthalene,[41] the resonance energy calculated for azulene by this method is 45.6 kcal./mole. However, evidence that has accumulated during the past few years suggests that the Pauling resonance energies are high. Franklin[25] has given a value of 62 kcal./mole for the resonance energy of naphthalene, and values of 60, 61 and 52.6 kcal./mole have resulted from revised calculations by the valence-bond and molecular-orbital methods.[42] A new experimental value recently has been obtained by Linstead and Jackman,[43] who have investigated the heats of *dehydrogenation* of various hydroaromatic systems by tetrachloro-*o*-benzoquinone. By comparison of the heat changes accompanying the conversions of 1,4-cyclohexadiene into benzene and of 1,4-dihydronaphthalene into naphthalene and assumption of Kistiakowsky's value of 36.0 kcal./mole for the benzene resonance, a tentative value of 67.6 ± 2 kcal. has been obtained for the resonance energy of naphthalene.

(32) This solution value for cyclopentene is approximate and was obtained by subtracting 1.0 kcal., an average value for the discrepancy between our solution results and Kistiakowsky's gas phase data (see Table II, reference 3), from the gas phase value for cyclopentene (reference 2b.

(33) The order in which the various double bonds are considered is immaterial to the present argument.

(39) E. Perottet, W. Taub and E. Briner, *ibid.*, **23**, 1260 (1940).

(40) The cadalene employed in the combustion experiments of Perottet, Taub and Briner (ref. 39) is described as an oil, b.p. 155–157° (12 mm.), d^{20}_4 0.9737, $n^{20}D$ 1.5572. The physical state of the guaiazulene was not specified, but it is reasonable to suppose that the data for this compound are also referable to the liquid phase. The heat of formation of azulene (solid state), calculated by Heilbronner and Wieland as the sum of the heats of formation of naphthalene (solid) and the heat of isomerization of guaiazulene into cadalene was not corrected for this discrepancy, and inclusion of an approximate correction term derived from the heats of fusion of azulene and of naphthalene (ref. 38) gives a revised resonance energy value of 44 kcal./mole.

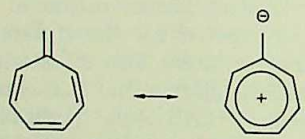
Recalculation of the resonance energy of azulene employing Franklin's result of 62 kcal./mole for stabilization in the naphthalene system gives a value of 32.4 kcal./mole in reasonable agreement with the results obtained in the present investigation. Conversely, the resonance energy derived for azulene from the hydrogenation data provides independent experimental support for a low value (58 to 60 kcal.) for the resonance energy of naphthalene.

In 1955, the heat of combustion of azulene was measured for the first time by Kováts, Günthard and Plattner, from whose results a value of −34.9 kcal./mole can be calculated for the gas phase heat of isomerization of azulene into naphthalene.[44] The use of this figure and the Franklin value of 62 kcal./mole for the naphthalene resonance in equation 4 leads to a resonance energy of 30.7 kcal./mole for azulene. Direct calculation of the azulene resonance from the heat of combustion data by the Franklin-Wheland method[44a] gives a value of 35.8 kcal./mole.

Heptafulvene.—Heptafulvene (I) contains a cyclic system of conjugated double bonds, for which the theoretical treatment of Pullman and Pullman[45] has predicted aromatic properties. Although the

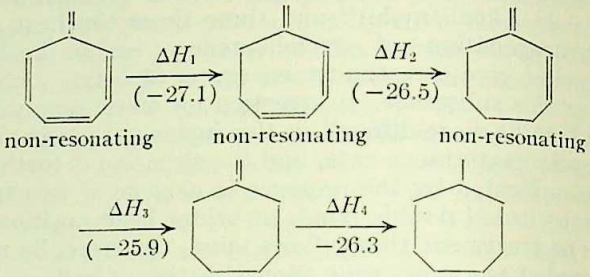


Ia Ib

substance has never been obtained in pure form, owing to its extreme reactivity, solutions of moderate stability have been prepared.[6] The sensitivity of heptafulvene to acids precluded the use of acetic acid as a solvent for the hydrogenation experiments, which were carried out on freshly prepared samples dissolved in Diethylcarbitol. The amount of material present was determined by the amount of hydrogen absorbed.

The heat of hydrogenation of heptafulvene is −92.63 ± 0.41 kcal./mole. An approximate evaluation of the heat of hydrogenation of the non-resonating system can be made on the basis of the following assumptions. The standard value of −27.1 kcal./mole is assigned to ΔH_1 of the accompanying reduction sequence (Chart III), and the cycloheptene value (−25.9 kcal./mole) is taken as a reasonable approximation of ΔH_3. An average of these figures gives −26.5 kcal./mole for ΔH_2. ΔH_4 has been determined experimentally and is found to be −26.3 kcal./mole.[34] Summation gives an over-all value of 105.8 kcal./mole and an estimated resonance energy of 13.2 kcal./mole as compared with 36.9 kcal./mole and 2.4 kcal./mole,

CHART III

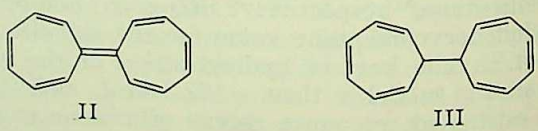


respectively, for the isomeric compounds styrene and cyclooctatetraene.

By comparing the heat of hydrogenation of heptafulvene (−92.6 kcal./mole) with that of methylenecycloheptane (−26.3 kcal./mole), a heat change of 66.3 kcal./mole is derived for the reaction, heptafulvene + $3H_2$ → methylenecycloheptane. In terms of the tropilidene model this represents an increase of 4.2 kcal./mole in the resonance energy of the cyclic triene system, which is produced by introduction of the exocyclic double bond.

Theoretical calculations of the resonance energy of heptafulvene by the molecular-orbital and valence-bond methods yield values of 1.994 β and 0.57 α, respectively.[45] In terms of kilocalories, calculated by use of the values for β and α given for benzene, the corresponding figures are 36 and 19 kcal./mole, respectively. A revised value of 16 kcal./mole may be derived from the more refined calculations of Bergmann, *et al.*[46]

Heptafulvalene and Dihydroheptafulvalene.—The resonance energy of heptafulvalene (II), which possesses two conjugated cycloheptatriene rings, has been calculated as 1.496 γ by the molecular-orbital method.[47] A corresponding calculation for the isomeric substance, stilbene, gives a value of 2.446 γ. On the basis of Wheland's value of 77 kcal./mole[42] for stilbene, the resonance energy of



II III

heptafulvalene can be expressed as 47 kcal./mole. A considerably lower figure is obtained from the hydrogenation data.

In view of the instability of heptafulvalene in the presence of acids, the hydrogenation of this substance was carried out in diethylcarbitol as in the case of heptafulvene. Unfortunately reduction proceeded with the absorption of only 95% of the theoretical amount of hydrogen for *six double bonds*. The heat of hydrogenation of this substance (−130.77 ± 0.31 kcal./mole) was thus calculated as six times the heat developed per mole of hydrogen absorbed.[48] The heat of hydrogenation of the non-resonating system was obtained by doubling

(44) E. Kováts, Hs. H. Günthard and Pl. A. Plattner, *Helv. Chim. Acta*, **38**, 1912 (1955). The values for the heats of combustion (vapor phase, 25°) of azulene and of naphthalene given in line 4 of Table 4 (−1680.7 kcal./mole and −1239.5 kcal./mole) are typographical errors and should read −1280.7 kcal./mole and −1245.8 kcal./mole, respectively. The naphthalene value cited by these authors was obtained from unpublished results of F. D. Rossini.

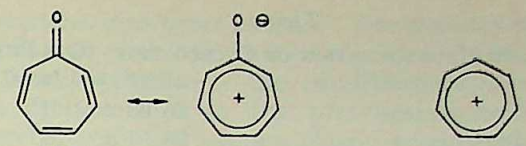
the sum of the values assumed for ΔH_1, ΔH_2 and ΔH_3 in the heptafulvene treatment (−159.0 kcal./mole). The difference between these two figures gives an approximate value of 28 kcal./mole for the resonance energy of heptafulvalene.

Hydrogenation of dihydroheptafulvalene (III) proceeded smoothly in acetic acid solution with absorption of six molar equivalents of hydrogen and a heat evolution of 138.81 ± 0.20 kcal./mole or 69.4 kcal. per cycloheptatriene ring. The latter value is in good agreement with the cycloheptatriene result (−70.5 kcal./mole)[3] if account is taken of non-bonded interactions in the reduction product involving one ring and hydrogen atoms of the other. Comparison of the results obtained for dihydroheptafulvalene and for heptafulvalene (hydrogen uptake, 6 molar equivalents) indicates that the resonance energy involved in the coupling of two cycloheptatriene rings in the latter compound amounts to about 8.0 kcal./mole. It is of interest to note that this figure is approximately twice the value of 4.2 kcal./mole obtained for conjugation of the cycloheptatriene ring and exocyclic double bond in heptafulvene.

Tropone.—Of interest as the oxygen analog of heptafulvene and as the next simpler member of the tropolone system, tropone has been treated theoretically by Brown[49] and has recently been synthesized.[9,50] The basicity of this substance and its chemical stability in acid have led to the formulation of the conjugate acid as a hydroxycycloheptatrienylium ion and to the formulation of tropone itself as cycloheptatrienylium oxide (IV). The considerable stability of the cycloheptatrienylium ion (V), which is regarded as the symmetrical parent of the seven-membered aromatic system, has been clearly demonstrated by Doering and Knox.[51]



IVa IVb V

The heat of hydrogenation of tropone to cycloheptanone over palladium-on-barium sulfate in acetic acid solution is −67.58 ± 0.30 kcal./mole. Assuming a planar structure for this molecule and using tropilidene (heat of hydrogenation, −70.49 ± 0.39 kcal./mole)[3] as the model for a tropone in which there is no interaction of the carbonyl group with the ring, the extra resonance energy in tropone resulting from this interaction is calculated as 2.9 kcal./mole. Although this stabilization can be rationalized in terms of contributing structures of type IVb, a larger value might have been expected in view of the large resonance energy (3.00 β) calculated for V. It is clear, however, that the stabilization achieved in IVb is accomplished at the expense of considerable electrostatic work of charge separation, which has the effect of reducing the measurable resonance energy.

It should be noted, finally, that the resonance energy associated with coupling of the tropilidene system with a carbonyl group (2.9 kcal./mole) is somewhat less than that derived from coupling with an olefinic linkage (4.2 kcal./mole in heptafulvene). This result finds a parallel in the benzene series where it has been shown that styrene possesses a higher resonance energy (38.2 kcal./mole)[52] than benzaldehyde (35 kcal./mole).[52] A further analogy is provided by the observation that the heat of hydrogenation of pentadiene-1,3 to pentene-1 is 1.1 kcal. lower than that of crotonaldehyde to butyraldehyde.[2c]

Heats of Hydrogenation. IV. Hydrogenation of Some *cis*- and *trans*-Cycloölefins[1]

BY RICHARD B. TURNER AND W. R. MEADOR

RECEIVED FEBRUARY 25, 1957

The heats of hydrogenation of the *cis*- and *trans*-cycloöctenes, cyclononenes and cyclodecenes have been measured in acetic acid solution at 25°. The values (kcal./mole) obtained for these olefins are as follows: *cis*-cycloöctene, −22.98 ± 0.10, *trans*-cycloöctene, −32.24 ± 0.21; *cis*-cyclononene, −23.62 ± 0.07, *trans*-cyclononene, −26.49 ± 0.14; *cis*-cyclodecene, −20.67 ± 0.08, *trans*-cyclodecene, −24.01 ± 0.09.

The heats of hydrogenation of cyclopentene, cyclohexene, cycloheptene and of *cis*-cycloöctene were measured several years ago in the gas phase by Kistiakowsky and his associates. The results of this work (Table I) were correlated by Conn, Kistiakowsky and Smith,[2] who advanced a consistent interpretation of the data based upon consideration of non-bonded repulsions appearing in the products of the various hydrogenation processes. An important outcome of the investigation was the demonstration that the heat of hydrogenation of cyclopentene is 1.7 kcal./mole *lower* than that of cyclohexene, despite the fact that strain of the cyclopentene double bond is clearly *greater* than that of the olefinic linkage in cyclohexene. Al-

[a] M. A. Dolliver, T. L. Gresham, G. B. Kistiakowsky and W. E. Vaughan, THIS JOURNAL, 59, 831 (1937). [b] G. B. Kistiakowsky, J. R. Ruhoff, H. A. Smith and W. E. Vaughan, *ibid.*, 58, 137 (1936); [c] Data from reference 2. [d] The cycloöctene was prepared by E. P. Kohler, M. Tishler, H. Potter and H. T. Thompson, *ibid.*, 61, 1057 (1939), by dehydration of cycloöctanol with β-naphthalenesulfonic acid. Material obtained by this route is substantially pure *cis*-cycloöctene.

though the hydrogenation data do not conform with predictions based on strain effects in these molecules, an entirely satisfactory explanation of the results was provided by the observation that the C–H bonds in cyclopentane are extensively eclipsed, whereas those in cyclohexane are staggered.[3] It was thus concluded that the enthalpy difference associated with repulsive interactions arising in the reduction products, cyclopentane and cyclohexane, is sufficiently large to obscure the difference in enthalpy resulting from variations of strain in the corresponding olefins. Calculations of "total strain energy" in the cyclohexane, cyclopentane, cyclohexene and cyclopentene molecules carried out by Pitzer[4] are consistent with this interpretation. The hydrogenation results have been further verified by combustion experiments, which show that the difference between the heats of formation ($\Delta H°_f$, 25°, gas phase) of cyclohexane and cyclopentane (−10.97 kcal./mole)[5] is greater than the difference between the heats of formation of cyclohexene and cyclopentene (−9.57 kcal./mole)[6] by a factor of 1.4 kcal./mole.

In their summarizing paper, Conn, Kistiakowsky and Smith[2] also directed attention to the fact that the heats of hydrogenation of cycloölefins decrease progressively in the series cyclohexene, cycloheptene, *cis*-cycloöctene in a manner suggestive of increased internal crowding in the larger cycloparaffins. The crowding hypothesis is now supported by evidence from a variety of sources which indicates that congestion in the "medium-sized" (8- to 12-membered) rings is severe. Maximum hindrance probably is attained in the cyclodecane system, although this point has not been established with certainty. An excellent summary of work in this field up to 1950 has been given by Prelog.[7] Considerable additional information bearing on the problem of internal hindrance in cyclic systems has appeared more recently. Evidence establishing the close proximity of hydrogen atoms and ring carbon atoms in medium-sized cycles is provided by the remarkable transannular hydride shifts that occur in reactions of cycloöctene,[8] cyclononene,[9] cyclodecene[10] and of cycloundecene[11] with performic acid.[12] Studies of the rates of solvolysis of various cycloalkyl *p*-toluenesulfonates have revealed a marked acceleration of rate in the 7- to 11-membered derivatives, which is attributed to relief of steric strain in the transition states in these instances.[13] Maximum acceleration of solvolysis is observed in the case of cyclodecyl *p*-toluenesulfonate.

Mention should be made finally of the precision combustion measurements of Kaarsemaker and Coops (Table II),[14] which demonstrate that in the

cycloparaffin series heats of combustion per methylene group increase in order from the C_6- to the C_9-compounds. Although the numerical differences observed in this series are small, the variations nevertheless fall outside the limits of experimental error.

In view of continued interest in the properties of cycloölefins possessing medium-sized rings, and especially in the behavior of the highly strained *trans* isomers,[15] we have measured the heats of hydrogenation of the *cis*- and *trans*-cycloöctenes, cyclononenes and cyclodecenes in acetic acid solution at 25°. The results of this investigation are listed in Table III. For purposes of comparison, the

(3) This view, which was apparently first expressed in the present connection by V. Schomaker, has since been amply confirmed. *Cf.* W. G. Dauben and K. S. [a] Deviations include uncertainty in the heat of hydrogenation of the catalyst. [b] Data from reference 16.

Although the data are largely self-explanatory, the following points may be singled out for special comment. It will be noted first that the values obtained for the *cis*-olefins show a decrease of 6.4 kcal. in passing from cyclohexene (−27.1 kcal./mole) to *cis*-cyclodecene (−20.7 kcal./mole). The general trend established for the series cyclohexene to *cis*-cycloöctene (Table I) is thus projected at least as far as the 10-membered ring derivative. While it would appear that increased steric compression in the higher cycloparaffins plays a dominant role in lowering the heats of hydrogenation of the larger cycloölefins, it is clear that differences in angular and repulsive strains in the unsaturated compounds cannot be disregarded. The fact that the heat of hydrogenation of *cis*-cyclononene is higher than that of *cis*-cycloöctene, whereas the inverse relation might have been expected in view of the combustion data of Table II, can best be explained on the basis of such considerations.

In each *cis–trans* isomer pair for which data are given, the *trans* modification possesses the higher heat of hydrogenation and hence the lower stability. The heats of isomerization (*trans* → *cis*) calculated for the 8-, 9- and 10-membered olefins from the hydrogenation results are −9.2, −2.9 and −3.3 kcal./mole, respectively, as compared with the value of −1.0 kcal./mole reported by Kistiakowsky[17] for the heat of isomerization of *cis*-butene into *trans*-butene. Conclusions regarding isomer stability that have been drawn from qualitative studies of the equilibrium behavior of the cyclic olefins in the presence of acid[15] are thereby confirmed and are placed on a quantitative basis. The difference of 9 kcal. observed in the heats of hydrogenation of *cis*- and of *trans*-cycloöctene is the largest yet obtained for any pair of *cis–trans* isomers and reflects the severe strain that accompanies incorporation of a *trans* double bond in the eight-membered ring. The question of the point in the cyclic series at which the *trans* isomer may become more stable than the *cis*, as in open-chain olefins, presents an interesting problem for future investigation.[18]

With reference to the data for *cis*-cyclodecene, mention should finally be made of the fact that the heat of hydrogenation of this substance is the lowest yet recorded for a compound possessing an isolated double bond.[19] The highest such value thus far encountered is that obtained for *cis*-di-*t*-butylethylene (−35.5 kcal./mole).[20] The spread of almost 15 kcal. in the heats of hydrogenation of these two *cis*-disubstituted olefins provides a striking demonstration of the extent to which environmental factors may be implicated in chemical transformations.

Experimental

The calorimetric procedure followed in this investigation was that described in Paper I.[16] Acetic acid was employed as the solvent in all cases, and platinum oxide was used as the catalyst throughout.

Samples of *cis*-cycloöctene, $n^{25}D$ 1.4690, b.p. 74–75° (84 mm.), and of *trans*-cycloöctene, $n^{25}D$ 1.4742, b.p. 75° (78 mm.), were kindly supplied by Prof. A. C. Cope. In view of the instability of *trans*-cycloöctene, the specimen of this substance was shipped to us in Dry Ice by air express. Upon receipt, the material was sealed in evacuated ampoules, which were stored at −15°. Measurements were carried out on the two days following arrival of the sample, and at the end of the experiment a spare ampoule was broken and the contents examined in the infrared. The absorption spectrum proved to be identical with that of pure *trans*-cycloöctene showing that no polymerization or isomerization to the *cis* isomer had occurred. Professor Cope has informed us that *trans*-cycloöctene is completely stable in acetic acid solution at room temperature for periods up to 2 hr. Careful examination of the calorimetric time–temperature curves before and after dissolution of the sample, but prior to initiation of the hydrogenation reaction, has confirmed this view.

The cyclononene and cyclodecene samples, which were generously provided by Prof. V. Prelog, possessed the following constants: *cis*-cyclononene, $n^{20}D$ 1.4791; *trans*-cyclononene, $n^{19}D$ 1.4789; *cis*-cyclodecene, $n^{21}D$ 1.4849, b.p. 90.3° (33 mm.); *trans*-cyclodecene, $n^{20}D$ 1.4799, b.p. 198–199° (760 mm.). The specimens of *cis*-cyclononene and of *cis*-cyclodecene absorbed only 95.3 and 98.0%, respectively, of the theoretical amount of hydrogen. Since both compounds were prepared by partial hydrogenation of the corresponding cycloalkynes, the most likely contaminant would appear to be cycloparaffin. Although impurities of this type would have no effect on heats of hydrogenation

(17) G. B. Kistiakowsky, J. R. Ruhoff, H. A. Smith and W. E. Vaughan, *ibid.*, **57**, 876 (1935).

(18) The conclusion of N. L. Allinger, *Experientia*, **10**, 328 (1954), derived from correlations of boiling points, densities and refractive indices, that *trans*-cyclodecene should be more stable than the corresponding *cis* isomer has been revised in the light of other considerations (N. L. Allinger, private communication).

(19) In systems possessing a high degree of resonance stabilization low heats of hydrogenation are, of course, expected. Thus benzene, with a resonance energy of 36 kcal./mole, has a heat of hydrogenation (gas phase) of 16.6 kcal. per "double bond" [G. B. Kistiakowsky, J. R. Ruhoff, H. A. Smith and W. E. Vaughan, *ibid.*, **58**, 146 (1936)].

calculated on the basis of hydrogen uptake, the presence of any appreciable amounts of unreduced acetylenes (which would, however, lead to high hydrogen uptake values) would be more serious. Careful scanning of the infrared absorption spectra of the two compounds, however, revealed no trace of acetylenic absorption.

It is a pleasure to acknowledge the considerable contribution made to this work by Professors Prelog and Cope, whose coöperation in supplying samples has been of the greatest assistance.

The Reaction of Cyanogen Halides with the Silver Salts of Carboxylic Acids

BY PIERRE H. PAYOT, WILLIAM G. DAUBEN AND LANNY REPLOGLE

RECEIVED SEPTEMBER 4, 1956

The reaction of cyanogen halides with the silver salts of carboxylic acids was studied. The major products were found to be the corresponding nitrile, acid and anhydride. The yields of these three compounds varied with the solvent employed, the yield of nitrile being highest (32%) in acetonitrile, the yield of acid being highest (82%) in nitromethane and the yield of anhydride (88%) in trichloroethylene. It is postulated that an intermediate acyl cyanate is formed and this material reacts further to give rise to nitrile and anhydride.

The silver salt–bromine degradation of Hunsdiecker has been widely used to prepare alkyl halides.[1] Recently, this reaction has been employed in the preparation of complex C^{14}-carboxyl labeled acids according to the following sequence (eq. 1).[2] Considering the relative ease by

$$RCOOH \xrightarrow[2,\ Br_2]{1,\ Ag^{\oplus}} RBr \xrightarrow{C^*N^{\ominus}} RC^*N \xrightarrow{H_2O} RC^*OOH \quad (1)$$

which C^{14}-labeled cyanogen halides can be prepared from labeled alkali metal or silver cyanides[3] and the similarity of such compounds with a halogen molecule, a modification and extension of the Hunsdiecker reaction using cyanogen halides instead of bromine was studied. Other than the usual chemical interest in the reaction of pseudohalogens, it also was of interest to see if replacement of an unlabeled carboxyl group by a labeled cyanide group could be achieved in one step (eq. 2).

$$R{-}COOAg + C^*NX \longrightarrow R{-}C^*N + AgX + CO_2 \quad (2)$$

In 1947,[4] Zappi and Bouso described a similar reaction, and in their work solid alkali metal salts of carboxylic acids were pyrolyzed in the presence of cyanogen halides at temperatures between 200–300° and nitriles were isolated in variable yields. When this reaction was performed with C^{14}-carboxyl labeled benzoic acid, Douglas, Eccles and Almond[5] observed that no displacement occurred, the evolved carbon dioxide was not labeled and the generated benzonitrile was labeled. On the other hand, when a carboxyl labeled aliphatic acid was used in the pyrolysis reaction, the carbon dioxide was labeled and the nitrile was not radioactive.[5] Evaluation of these conflicting results must await further work.

It was obvious that the drastic conditions used in this alkali metal salt and cyanogen halide reaction would limit the usefulness of the reaction to acids of simple structure if, indeed, displacement did occur. If, however, the reaction could be run with the silver salts of carboxylic acids under the conditions of the silver salt–bromine degradation of Hunsdiecker, the reaction might become a valuable method for the introduction of C^{14} into organic compounds. In line with this concept are the findings of Haszeldine and Jander[6] who report that when the silver salt of an aliphatic trifluorocarboxylic acid is allowed to react with nitrosyl chloride under the conditions of the Hunsdiecker reaction, an alkylnitroso compound and carbon dioxide are obtained.

Although the mechanism of the Hunsdiecker reaction is not clearly understood,[1] the most likely route would involve the reaction of a bromine cation, $Br^{\oplus}$, with the silver salt to form an acylhypohalite which, in turn, would decompose to alkyl halide and carbon dioxide. From what is known of the chemistry of the cyanogen halides,[7] it is clear that under certain conditions these compounds do generate $CN^{\oplus}$, and it appears that cyanogen chloride would be more likely to do this than cyanogen bromide and the bromide more likely than the iodide.[8] In the present work, cyanogen bromide was utilized since it is easier to handle than the gaseous cyanogen chloride and the easily subliming cyanogen iodide. Furthermore, since the main aim of the study was to obtain a good yield of nitrile, most experiments were not performed under identical conditions. The acid chosen for the most investigations was γ-phenylbutyric acid since this acid shows the features of both an aromatic ring and an aliphatic acid.

It was found that when the silver salt of γ-phenylbutyric acid was allowed to react with cyanogen bromide in carbon tetrachloride, the reaction was sluggish compared to the Hunsdiecker reaction. No carbon dioxide could be observed in the cold or at room temperature. Only after heating on a steam-bath was carbon dioxide evolved. The main product of the reaction was not the expected nitrile but the anhydride of the acid. The yield of nitrile was 9% and of anhydride was 75%. The silver salt mixture isolated from the reaction mixture was shown to contain silver cyanate. In several cases, approximately equimolecular amounts of anhydride and cyanate were found.

The formation of an anhydride in the reaction of silver salts is well known. For example, the anhydrides of mono- and dicarboxylic acids are obtained when their silver salts are allowed to react with iodine. Thus, silver phthalate gives phthalic anhydride and silver hypoiodite which, in turn, disproportionates into silver iodate and silver iodide.[9] Also, silver trifluoroacetate and iodine in benzene form trifluoroacetic anhydride.[10] By analogy, a reasonable explanation for the formation of anhydride and cyanate in the cyanogen halide reaction can be represented as shown below (eq. 3, 4, 5) and involves the formation of an intermediate acyl

$$RCOOAg + CNBr \longrightarrow RCOOCN + AgBr \quad (3)$$

$$RCOOCN + RCOOAg \longrightarrow RCOOCOR + AgOCN \quad (4)$$

$$RCOOCN \longrightarrow RCN + CO_2 \quad (5)$$

cyanate which can react with silver salt to form an anhydride or can decompose to give rise to a nitrile and carbon dioxide. Since such a postulate indicates a bimolecular displacement reaction for the formation of the anhydride, the influence of different solvents has been investigated. The solvents used and the results obtained are summarized in Table I.

TABLE I

REACTION OF SILVER SALTS OF CARBOXYLIC ACIDS WITH CYANOGEN BROMIDE IN VARIOUS SOLVENTS

	Solvent, %					
Nitrile	Carbon tetrachloride	Nitromethane	Acetonitrile	N,N-Dimethylformamide	Nitrobenzene	Trichloroethylene
Anhydride	9	5	32	17	21	5
Acid	75	15	28	8	64	88
	1	82	36	40	5	5

It is seen that the best yields of nitrile are obtained when a solvent of high dielectric constant is employed, the dielectric constants for acetonitrile, nitrobenzene and N,N-dimethylformamide being 37.5, 35.7 and 37.6, respectively.[11] However, when the solvent was nitromethane, a compound also possessing a dielectric constant of 37.5,[11] the yield of nitrile was very low. Simultaneously, the yield of acid was high and this reaction must be attributed to the acidic nature of the solvent. The yield of acid was also high in acetonitrile, an acidic solvent, and N,N-dimethylformamide. In this last solvent, the N,N-dimethylamide of γ-phenylbutyric acid also was formed, and this reaction may account for the liberation of free starting acid. Although no definite decision can be given as to the role of solvent in the formation of anhydride, since the various reactions were not run under the same conditions, it does seem apparent that a solvent of low dielectric constant favors the formation of this species. Such a conclusion clearly shows the oversimplification of the above postulated mechanistic pathway for the formation of the anhydride. The assumption of an intermediate acyl cyanate, nevertheless, offers a reasonable explanation for the concomitant formation of the anhydride and the silver cyanate and also accounts for the formation of the nitrile and carbon dioxide.

An alternate pathway for the formation of nitrile also must be considered. It is known that when the anhydride of a carboxylic acid is heated with potassium cyanate in benzene, imides are formed[12] and that imides on mild heating decompose to a nitrile and an acid.[13] Accordingly, silver cyanate and the anhydride, products of the silver salt–cyanogen bromide reaction, could react similarly to yield an imide which could decompose to a nitrile and an acid. It was found that under the same or similar conditions to those used in the silver salt–cyanogen bromide reaction, no imide, nitrile or acid was formed when pure silver cyanate and an anhydride were allowed to react.

Two exploratory experiments were performed with silver γ-phenylbutyrate and the other cyanogen halides. With cyanogen iodide in carbon tetrachloride, the products were 1.5% nitrile, 68% anhydride and 18% acid while with cyanogen chloride the yields were 7% nitrile, 73% anhydride and 8% acid. In addition, in this latter case, 3-phenylpropyl chloride was isolated in 2% yield. This is the only case among all the experiments where a halide was isolated and, indeed, this is surprising since cyanogen chloride should be the halide least likely to yield an $X^{\oplus}$ ion. The non-occurrence of halide in the cyanogen halide reactions explains the fact that in no instance could Simonini ester formation be demonstrated.[1]

To extend the scope of this reaction, a brief study was made with a typical aromatic acid, benzoic acid, and a typical aliphatic acid, decanoic acid. In both cases cyanogen bromide was employed and it was found that the results did not differ from those obtained with γ-phenylbutyric acid. It is of interest to note that no aromatic ring substitution was found with either acid containing an aromatic nucleus. Such substitutions have been observed in the Hunsdiecker reaction with aromatic acids containing activating groups on the ring.[14]

Finally, it can be stated that the difference between the alkali metal salt–cyanogen bromide reaction with benzoic acid run under pyrolytic conditions and the reaction performed with silver

benzoate in an organic solvent are that, in the former case, besides benzonitrile, also benzamide and cyaphenin, the trimer of benzonitrile, are isolated[4,5] but no anhydride, whereas in the latter case mainly anhydride, nitrile and acid are the products, but no amide or cyaphenin is formed. The yield of nitrile is better when the reaction is run under the pyrolytic conditions.

Experimental[15]

All solvents were purified and carefully dried. The silver salts of the carboxylic acids were prepared in the usual manner[16] and they were either dried in a vacuum oven at 60° or in a vacuum desiccator over phosphorus pentoxide at room temperature for at least 24 hr. Their purity was checked by combustion analysis.

The cyanogen halides cyanogen chloride,[17] cyanogen bromide[18] and cyanogen iodide[19] were prepared by metathesis of the halogens with alkali metal cyanides. The cyanogen bromide, before being added to the silver salts, was dried in carbon tetrachloride over phosphorus pentoxide.

All liquid reaction products were distilled through a 20″ wire-screen filled column of 12-plate efficiency if not otherwise mentioned.

Determination of Cyanate Ion. (a) Quantitative Test.[20]—A sample of the silver salt mixture obtained from the reaction of the silver salt of a carboxylic acid with the cyanogen halide was mixed in a mortar with cobaltous acetate and potassium chloride. Addition of a few drops of acetic acid followed by mixing produced a blue color when cyanate-ion was present.

(b) Quantitative Test.[20] **Cyanate Carbon.**—A sample of silver salt from the reaction mixture was treated with excess 1 *N* hydrochloric acid and the evolved carbon dioxide absorbed in standardized sodium hydroxide solution. If stronger acid concentrations were used, the cyanide was also hydrolyzed to formate and the carbon values were too high.

Cyanate Nitrogen.—The residual acidified mixture above was made alkaline with 1 *N* potassium hydroxide solution and the liberated ammonia absorbed in standardized sulfuric acid solution. Stronger potassium hydroxide solution hydrolyzed also the cyanide.

Silver cyanate was prepared from potassium cyanate and silver nitrate[21] and dried in a desiccator over phosphorus pentoxide. Following the above procedure a freshly prepared and dried sample of silver cyanate was analyzed.

Anal. Calcd. for AgOCN (149.90): C, 8.01; N, 9.34. Found: C, 7.84; N, 9.22.

In the same manner a well dried sample of silver cyanide was analyzed.

Anal. Calcd. for AgCN (133.90): C, 8.97; N, 10.46. Found: C, 0.0; N, 0.0.

An equimolecular mixture of the silver salts of decanoic, cyanic, hydrocyanic and hydrobromic acids was prepared and dried in a desiccator over phosphorus pentoxide. A sample was analyzed as above.

Anal. Calcd. for AgOCN in mixture [AgOOC-$(CH_2)_8$-CH_3 (279.26); AgOCN (149.90); AgCN (133.90); AgBr (187.80)]: C, 1.60; N, 1.87. Found: C, 1.44; N, 1.81.

Experiments with Silver γ-Phenylbutyrate and Cyanogen Bromide.—(a) In Carbon Tetrachloride as the Solvent; Addition of the Cyanogen Bromide to the Silver Salt.—A suspension of 108.4 g. (0.4 mole) of silver salt in 800 ml. of carbon tetrachloride was distilled until 100 ml. of distillate had been collected and then cooled in an ice-bath. A solution of 47 g. (0.45 mole) of cyanogen bromide in 315 ml. of carbon tetrachloride was added dropwise with stirring over a period of 1 hr. No carbon dioxide evolution could be detected. Upon heating on a steam-bath to reflux temperature, a slow evolution of carbon dioxide began. Heating and stirring were continued for 5 hr. At the end of the heating period the carbon dioxide evolution had stopped. The silver salts were filtered and washed several times with carbon tetrachloride. The carbon tetrachloride solution was extracted three times with 2 *N* sodium carbonate solution.

The alkaline aqueous extracts were combined and were acidified with 6 *N* sulfuric acid. The acidic aqueous solution was extracted with ether in an apparatus for continuous extraction. After removal of the ether the residue was distilled under reduced pressure to a cold finger and 422 mg. (0.6%) of γ-phenylbutyric acid, m.p. 47–48°, was obtained.

Subsequent extraction of the carbon tetrachloride layer with 4 *N* sodium hydroxide solution did not yield any extractable material. The carbon tetrachloride solution, washed with water until neutral, was dried with Drierite. The solvent was removed and the residue was fractionally distilled. The forerun (0.5 g., b.p. 120–126° (10 mm.)) was shown not to contain 3-phenylpropyl bromide (b.p. 120.5–121.5° (20 mm.)). The next fraction was a colorless oil, b.p. 126–127° (10 mm.), and was γ-phenylbutyronitrile, (lit.[22] b.p. 129–131° (10 mm.)), yield 5 g. (8%).

A sample of the nitrile was hydrolyzed with 25% ethanolic potassium hydroxide and gave in 80% yield γ-phenylbutyric acid.

The distillation residue crystallized at room temperature to a waxy substance which was insoluble in 2 *N* sodium hydroxide solution and which had a m.p. 25–28°. Recrystallization of a sample from ether–petroleum ether at −30° yielded γ-phenylbutyranhydride, m.p. 28–29°. The infrared spectrum was identical with that of an authentic sample.

Anal. Calcd. for $C_{20}H_{22}O_3$ (310.38): C, 77.39: H, 7.14. Found: C, 77.39; H, 7.41.

A sample of the distillation residue (13 g.) was refluxed overnight with 350 ml. of 10% aqueous sodium hydroxide solution. The alkaline solution was saturated with potassium carbonate and was continuously extracted with ether for 24 hr. No alcoholic material could be detected in this ether extract. The aqueous phase of this extraction was acidified with 6 *N* sulfuric acid (acid to congo red). This acidic mixture was continuously extracted with ether for 24 hr. The ether extract was dried with magnesium sulfate and yielded γ-phenylbutyric acid (95%), m.p. 45–47°. Hence, the non-distillable fraction consisted of 46.9 g. (75%) of the anhydride of γ-phenylbutyric acid.

The silver salts from the reaction were treated with 500 ml. of 6 *N* hydrochloric acid using a vibrating mixer. A violent evolution of hydrocyanic acid occurred and the mixture warmed up. The mixture was filtered through a mat of filter aid. The filter cake was shaken several times with portions of diisopropyl ether, and the filtrate was extracted several times with the same solvent. The combined ether extracts yielded 4 g. (6%) of γ-phenylbutyric acid, m.p. 45–47°.

γ-Phenylbutyranhydride was prepared by refluxing a mixture of 32.8 g. (0.2 mole) of acid with 200 ml. of acetic anhydride and 200 ml. of pyridine for 3 hr. After removal of the excess reagents under reduced pressure the residue was fractionally distilled, yield 21 g. (68%). This compound can only be distilled with losses due to decomposition, b.p. 200–205° (3 mm.), m.p. 28–29°. The compound shows strong absorption peaks in the infrared at 5.5, 5.83 and 9.7 μ.

Anal. Calcd. for $C_{20}H_{22}O_3$ (310.88): C, 77.39; H, 7.14. Found: C, 77.48; H, 7.35.

(b) In Carbon Tetrachloride as the Solvent; Addition of the Silver Salt to the Cyanogen Bromide.—A solution of 47 g. (0.45 mole) of cyanogen bromide in 1200 ml. of carbon tetrachloride was cooled to 0°, and a 10-g. portion of silver salt was added. After 10 minutes, the mixture was brought to reflux on a steam-bath, whereupon carbon dioxide evolution commenced. Over the period of 1 hr. 108.4 g. (0.4 mole) of silver salt was added and the heating and stirring

was continued for 10 hr. Processing in the usual way (see above) gave 500 mg. (1%) of γ-phenylbutyric acid from the sodium carbonate extract, 7.3 g. (12%) of nitrile and 44 g. (71%) of anhydride.

(c) **In Nitromethane as the Solvent.**—The silver salt (108.4 g., 0.4 mole) was suspended in 400 ml. of carbon tetrachloride, and 400 ml. of the solvent was distilled. Nitromethane (700 ml.) was then added, and over the period of 1.5 hr. 50 g. (0.47 mole) of cyanogen bromide in 350 ml. of nitromethane was added, with stirring, to the reaction mixture. During the first 0.5 hr. of the addition the reaction mixture was at room temperature and no carbon dioxide evolution occurred. The reaction mixture was then heated to slow reflux and the addition of cyanogen bromide continued. At this elevated temperature carbon dioxide evolution occurred and the heating was continued for 8.5 hr. The silver salts were filtered and washed well with carbon tetrachloride. The filtrate was processed in the usual way. The neutral fraction gave 3 g. (5%) of pure nitrile and 9.3 g. (15% assuming pure γ-phenylbutyranhydride) of crude anhydride. This crude anhydride gave a weakly positive Beilstein test for halogen. The acidified alkaline extract yielded 54 g. (82% assuming pure γ-phenylbutyric acid) of crude acidic material. This material had a m.p. of 42–45° and it gave a positive Beilstein test. When this material was distilled, approximately 4 g. of higher boiling material was obtained as a tarry distillation residue which gave a strongly positive Beilstein test.

(d) **In Acetonitrile as the Solvent.**—To a suspension of 80 g. of silver salt in 1200 ml. of purified acetonitrile containing 2 g. of cuprous cyanide, 36 g. of cyanogen bromide dissolved in 350 ml. of acetonitrile was added during the course of 2.5 hr. Upon initial heating a blue color developed which later discharged. During the entire reaction carbon dioxide was evolved. After an additional hour of heating the reaction mixture was allowed to stay at room temperature overnight.

The usual working-up procedure was modified due to the water solubility of acetonitrile. The acetonitrile layer was diluted with a large volume of carbon tetrachloride, the aqueous layer was saturated with sodium chloride, and the reaction mixture was processed in the normal manner. A yield of 32% nitrile, 28% anhydride and 36% acid was obtained.

(e) **In N,N-Dimethylformamide as the Solvent.**—A mixture of 108.4 g. (0.4 mole) of silver salt with 1500 ml. of N,N-dimethylformamide was prepared. The mixture was stirred and heated on a steam-bath and a solution of 45 g. (0.43 mole) of cyanogen bromide in 450 ml. of carbon tetrachloride was added during 1.5 hr. The carbon dioxide evolution was rather slow. The mixture was heated on the steam-bath overnight. After 8 hr. of heating there was still some carbon dioxide evolution. To the cooled mixture was added carbon tetrachloride in order to precipitate more of the silver salts. These were filtered and washed with the same solvent. Shaking the filtrate with 2 *N* sodium carbonate solution precipitated more silver salts which were filtered. The sodium carbonate extracts were continuously extracted with ether for three days in order to extract the water-soluble N,N-dimethylformamide. The acidified aqueous phase yielded 26 g. (40%) of pure γ-phenylbutyric acid. The combined carbon tetrachloride layers were dried with magnesium sulfate. After removal of the solvent a brown oil was obtained which was fractionated with a column; 6 g. (10%) of pure γ-phenylbutyronitrile was obtained, b.p. 126–127° (10 mm.). On further heating the distillation residue began to decompose. The distillation was interrupted. This residue was a liquid in which crystallization could not be induced by seeding with γ-phenylbutyranhydride. The residue was subjected to a fast distillation in a Claisen flask. This operation separated a fraction which boiled mainly between 150 and 180° at a pressure of 1 mm. from a distillation residue which solidified. This solidified material eventually yielded 5.3 g. (8%) of γ-phenylbutyranhydride. In a third distillation, using again a column, the fraction with b.p. 150–180° (1 mm.) was split into 4 g. (7%) of γ-phenylbutyronitrile and a distillation residue (20 g., dark brown) which did not solidify and which contained nitrogen. This water-insoluble oil was refluxed with 500 ml. of 10% aqueous sodium hydroxide solution until the water-insoluble layer had disappeared and until the evolution of dimethylamine ceased. The mixture from the hydrolysis yielded after acidification and after purification 16 g. (24%) of γ-phenylbutyric acid. Hence the dark oil contained N,N-dimethyl-γ-phenylbutyramide, b.p. 151–152° (1.5 mm.) (see below).

N,N-Dimethyl-γ-phenylbutyramide.—A solution of 68 g. (0.37 mole) of distilled γ-phenylbutyryl chloride[23] dissolved in 300 ml. of hexane was added with shaking to 860 ml. of an ice-cold commercial 25% aqueous solution of dimethylamine. The amide separated as an oil which did not solidify and was separated and dissolved in methylene chloride. The methylene chloride solution was washed with 2 *N* sodium carbonate solution and with water and dried with magnesium sulfate. After removal of the solvent the amide was distilled, 60 g. (84%) of a yellow oil. It distilled with decomposition at 151–152° (1.5 mm.). Upon cooling the distillate to Dry Ice temperature, large glassy crystals are formed, which melt around 20°. The amide can be recrystallized from methylene chloride–hexane, but care must be exerted since the compound is highly hygroscopic. The analytical sample was dried in a high vacuum for 24 hr. at 60° and sealed under vacuum.

Anal. Calcd. for $C_{12}H_{17}ON$ (191.26): C, 75.35; H, 8.96; N, 7.32. Found: C, 75.41; H, 8.87; N, 7.24.

(f) **In Nitrobenzene as the Solvent.**—A mixture of the silver salt (108.4 g., 0.4 mole) and 1500 ml. of purified nitrobenzene was heated on a steam-bath. During the course of 0.5 hr. 45 g. (0.43 mole) of cyanogen bromide dissolved in 450 ml. of carbon tetrachloride was added dropwise. The carbon dioxide evolution was slow and heating was continued overnight. The bulk of the solvents was distilled under reduced pressure. Carbon tetrachloride was added in order to precipitate the silver salts which were filtered. Extraction with 2 *N* sodium carbonate solution and subsequent acidification yielded 3 g. (5%) of γ-phenylbutyric acid. The carbon tetrachloride extracts, after fractional distillation, gave 12 g. (21%) of nitrile and 39.6 g. (64%) of anhydride.

(g) **In Trichloroethylene as the Solvent.**—The reaction was carried out in the usual manner using 108.4 g. (0.4 mole) of silver salt and 1500 ml. of purified trichloroethylene. The mixture was heated on a steam-bath in an atmosphere of dry nitrogen, and 45 g. (0.43 mole) of cyanogen bromide dissolved in 450 ml. of carbon tetrachloride were added during 1 hr. The carbon dioxide evolution was slow, and heating and stirring was continued for 9 more hours. The silver salts were filtered, washed with carbon tetrachloride and dried for 24 hr. in a desiccator at room temperature *in vacuo* over phosphorus pentoxide. Their weight was 68.5 g. Using the usual working-up procedure the following yields and products were obtained: 3.5 g. (5%) of γ-phenylbutyric acid from the sodium bicarbonate extract, 2.9 g. (5%) of nitrile and 55 g. (88%) of anhydride. Assay of a sample of the silver salt mixture: cyanate-C, 2.85%; cyanate-N, 3.28%. This is equimolecular to 52.3 g. of anhydride. Found: 55 g. of anhydride.

Silver Benzoate and Cyanogen Bromide.—From a mixture of 91.6 g. (0.4 mole) of silver salt and 2000 ml. of carbon tetrachloride, 500 ml. of solvent was distilled. Then 45 g. (0.43 mole) of cyanogen bromide dissolved in 450 ml. of carbon tetrachloride was added to the heated solution during the course of 1 hr. The carbon dioxide evolution was rather slow. The stirring and the refluxing were continued for 14 more hours. The weight of the dried silver salts was 70 g. Using the usual working-up procedure the following yields and products were obtained: From the sodium bicarbonate extract 5 g. (10%) of benzoic acid, which was purified by sublimation, m.p. 121–122°; 2 g. (5%) of benzonitrile, b.p. 80–81° (8 mm.) (lit.[24] 69° (10 mm.)); and 31.5 g. (70%) of benzoic anhydride, b.p. 210–220° (20 mm.), m.p. 41–43° (lit.[25] same b.p., m.p. 43°). The silver salts were treated with dilute (1:1) hydrochloric acid. This mixture was exhaustively extracted with ether, and after removal of the solvent 4 g. (8%) of benzoic acid was obtained. The assay of a sample of the silver salt mixture gave: cyanate-C, 2.16%; cyanate-N, 2.64%. This is equimolecular to 29.2 g. of benzoic anhydride. Found: 31.5 g. of anhydride.

Separation of a Mixture of Benzonitrile, Benzimide[26] and

Benzoic Acid.—If equimolecular amounts of the above listed compounds were dissolved in carbon tetrachloride, a quantitative separation could be performed by extraction of the acid with saturated sodium bicarbonate solution, the imide with 2 *N* sodium hydroxide solution, leaving the benzonitrile in the carbon tetrachloride.

Experiments with Silver Decanoate and Cyanogen Bromide.—From a mixture of 111.6 g. (0.4 mole) of silver salt and 700 ml. of carbon tetrachloride, 100 ml. of solvent was distilled. Afterwards 47 g. (0.45 mole) of cyanogen bromide dissolved in 450 ml. of carbon tetrachloride was added at room temperature over the period of 45 minutes. No carbon dioxide evolution could be observed. The mixture was refluxed on a steam-bath for 12 hr. The carbon dioxide evolution was slow. Using the usual working-up procedure the following yields and products were obtained: 49 g. (75%) of anhydride[27] and 10.7 g. (17%) of nitrile, b.p. 109–110° (10 mm.) (lit.[28] 243.7°). Only traces of acid were recovered in this experiment.

In a second experiment, where the cyanogen bromide was added to the heated mixture over a period of 1.5 hr., the carbon dioxide evolution was complete after a total heating time of 3 hr. The yield of nitrile was 4.5 g. (7%).

Experiment with Silver γ-Phenylbutyrate and Cyanogen Iodide.—Cyanogen iodide (39 g., 0.25 mole) dissolved in 400 ml. of carbon tetrachloride was added in the usual manner in portions to 62.4 g. (0.23 mole) of the silver salt in 600 ml. of carbon tetrachloride heated on a steam-bath over a period of 1 hr. The carbon dioxide evolution ceased about 0.5 hr. after the last addition of cyanogen iodide. The reaction mixture was refluxed with stirring overnight. After the usual working-up procedure 0.5 g. (1.5%) of nitrile, 24.2 g. (68%) of anhydride and 6.8 g. (18%) of acid were obtained.

Silver γ-Phenylbutyrate and Cyanogen Chloride.—Approximately 60 ml. (excess) of cyanogen chloride (b.p. 13°) was distilled over the period of 1.5 hr. directly into a slurry of 112 g. (0.41 mole) of the silver salt and 1100 ml. of carbon tetrachloride at room temperature. The reaction flask was equipped with a cold finger condenser filled with Dry Ice and *n*-butyl Carbitol. The content of the cold finger was then replaced with a Dry Ice and methanol mixture and the temperature in the cold finger kept at −20 to −10°. The reaction mixture was heated to about 60–70° and stirring was continued. There was a great initial carbon dioxide evolution, but the evolution came to an end after about 1 hr., albeit cyanogen chloride was still escaping. The mixture was stirred and refluxed for 7 more hours. Using the usual working-up procedure 4.0 g. (7%) of nitrile, 45.1 g. (73%) of anhydride, 5.4 g. (8%) of acid and 1.2 g. (2%) of 3-phenylpropyl chloride[29] were obtained.

Chemistry of the 1,4-Diamino-1,3-butadienes. I. Preparation[1]

BY MARIAN F. FEGLEY, NEWMAN M. BORTNICK AND CHARLES H. MCKEEVER

RECEIVED NOVEMBER 3, 1956

1,4-Bis-(dimethylamino)-2-butyne (I), on heating with sodium, was rearranged to 1,4-bis-(dimethylamino)-1,3-butadiene (II). The preparation and rearrangement of several homologs of I are described. On standing at room temperature, II is isomerized to a geometric isomer. Infrared evidence is adduced to assign the initial form the *cis,trans* and the new isomer, the *trans,trans* structure. In the presence of potassium bases, dimerization of I rather than intramolecular rearrangement occurred. This mixture of isomeric dimers was itself subject to rearrangement. The structures of the dimeric products were not definitely ascertained. The mechanism for these transformations of I is discussed.

We have found that 1,4-bis-(dimethylamino)-2-butyne (I) may be rearranged to 1,4-bis-(dimethylamino)-1,3-butadiene (II) by means of finely divided metallic sodium.

$$\underset{\text{I}}{(CH_3)_2NCH_2C{\equiv}CCH_2N(CH_3)_2} \xrightarrow{Na} \underset{\text{II}}{(CH_3)_2NCH{=}CHCH{=}CHN(CH_3)_2}$$

II had first been prepared in these laboratories by McKeever and Nemec[2] by passage of I over chromium oxide-containing catalysts at 300–450° in the vapor phase. Our present discovery has permitted the facile preparation of II on a large laboratory scale.

In order to control this exothermic rearrangement, dried, redistilled I was added dropwise to a stirred boiling mixture of hexane and metallic sodium dispersed in xylene.[3] From 50 g. to 300 g. of I, depending on its purity, could be converted to II per gram of sodium. The product was isolated in yields of 80 to 90% of the theoretical by distillation without prior removal or destruction of the catalyst. Alfin catalyst[4] (55% yield), metallic lithium (81% yield), metallic potassium (9% yield) and sodamide (12% yield) were catalysts of limited utility, while sodium acetylide and metallic calcium were inactive.

This rearrangement was extended to the 1,4-diamino-2-butyne derivatives shown in Table I. These were prepared by means of the cuprous chloride-catalyzed Mannich reaction[5,6] applied to acetylene and to the intermediate 3-dialkylamino-1-propynes. Properties of the corresponding 1,4-diamino-1,3-butadienes are shown in Table II. Dispersed sodium alone was not a satisfactory catalyst for the isomerization of many of the higher

[a] Refers to description in the Experimental. [b] Isomerization occurred rapidly on standing. The solid *trans,trans* derivative isolated from one run had m.p. 94–97°, ϵ_{max} 22,600 at 300 mμ. [c] C_8H_{17} = $(CH_3)_3CCH_2CH(CH_3)CH_2$–.

homologs of I. However, a previously prepared mixture of dispersed sodium and a small amount of I served well.

Although the products were not obtained in analytical purity, the large index of refraction change which was observed when 1,4-bis-(dimethylamino)-1,4-diphenyl-2-butyne was heated with the "sodium-I" catalyst indicated that rearrangement had occurred. A corresponding change was noted when 1,4-bis-(dimethylamino)-1,4-diisopropyl-2-butyne was treated in the same fashion. No pure product was isolated from the attempted rearrangement of 1,4-bis-(methylphenylamino)-2-butyne.

Our attempts to rearrange 1-dimethylamino-2-butyne and 1-dimethylamino-2-heptyne to the corresponding 1,3-butadienes failed. Inconclusive results were obtained with 1,4-dihydroxy-2-butyne, its diacetate or its dimethyl ether.

The ultraviolet absorption spectra of the butyne–butadiene pairs provided a means of estimating semi-quantitatively whether rearrangement had occurred. Since the molar extinction coefficients of most of the butadienes were 20,000–25,000 at their maxima (which fell at 280–310 mμ), while the butynes were transparent, an estimate of conversion and purity could be made on the very first experiment. The refractive indices proved more convenient for purity estimation once the best values were established for the two pure materials.

As initially formed, II is a liquid which melts below −100°. It can be stored in full containers at 5° or in carefully dried, sealed vials at room temperature for many months without change. It may be stabilized by simply not distilling the rearrangement reaction mixture. On prolonged storage at room temperature II isomerized to a form which had m.p. −1 to −3°. This isomerization occurred more rapidly when II was heated or was exposed to moisture, carbon dioxide or acids. Figures 1, 2 and 3 show the infrared absorption spectra of the two forms of II and the initial form after standing. The second form shows the relatively weak single C=C stretching absorption (Fig. 1) and strong sharply peaked hydrogen wagging absorption (Fig. 2) characteristic of *trans*-olefins and accordingly has the *trans,trans* (*t–t*) structure.

The direct rearrangement product contains a *trans*-type olefin group (Fig. 2) by its hydrogen wagging absorption; *cis* geometry is indicated by strong, doubly peaked absorption in the C=C stretching region (Fig. 1) and by broad hydrogen-wagging absorption at long wave lengths (Fig. 3). These results are consistent with the assignment of the *cis,trans* (*c–t*) structure to the isomer formed directly by rearrangement of I. This conversion of *c–t* to *t–t* II probably occurs by way of an intermediate such as $(CH_3)_2N{=}CHCH_2CH{=}\overset{+}{C}HN(CH_3)_2$.

When compound I was heated with solid potassium hydroxide, an exothermic reaction occurred at 150–180°. No II was obtained. The product was almost exclusively dimeric. The exothermic reaction was controlled by gradual addition of I to a solution of potassium *n*-octoxide in boiling xylene. At 120–140°, conversions of 70–85% to similar dimeric products were conveniently realized. These products were mixtures which rearranged on further heating in the presence of sodium dispersion with

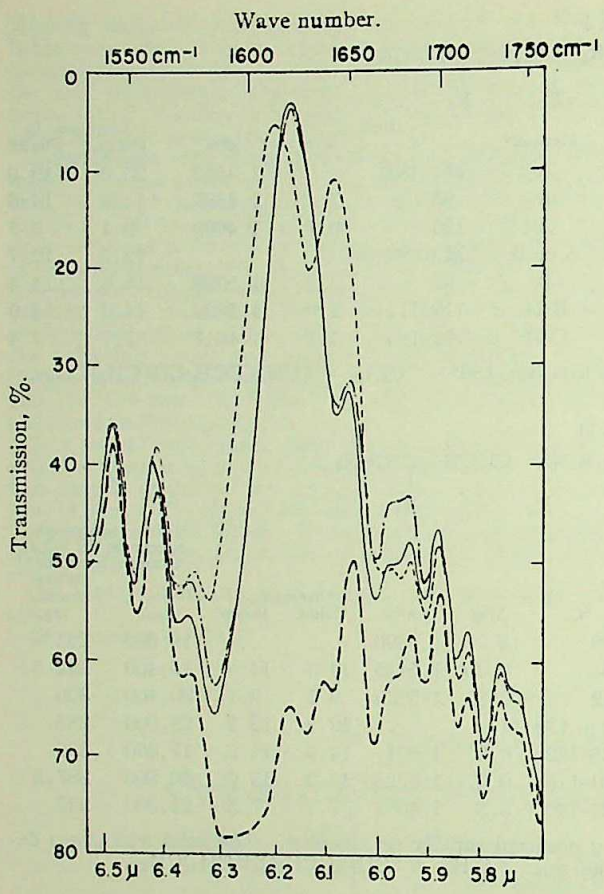

Fig. 1.—Infrared spectra of 1,4-bis-(dimethylamino)-1,3-butadienes, double bond stretching region: ———, *t,t*-II; – – – –, *c,t*-II; — · —, *c,t*-II on standing; – – – –, $CHCl_3$.

changes in refractive index and ultraviolet absorption spectra but without noticed changes in boiling range and empirical formula, $C_{16}H_{32}N_4$.

Hydrogenation in ethanol solution in the presence of Raney nickel catalyst led to the absorption of 2.8 ± 0.5 moles of hydrogen. A liquid, $C_{14}H_{31}N_3$, and a small amount of a solid, $C_{16}H_{36}N_4$,[7] were isolated, together with dimethylamine.

The dimeric product mixture decomposed slowly with evolution of dimethylamine when heated at 200°. Presence of solid potassium hydroxide stabilized the system so that heating to 240° was required to observe this decomposition. The presence of a trace of hydrogen chloride lowered the decomposition temperature to 140°, two moles of dimethylamine were eliminated per mole of dimer and a brittle black resin remained.

Attempts to extend the dimerization reaction to higher homologs were largely unsuccessful. 1,4-Bis-(diethylamino)-2-butyne gave dimeric material in very poor yield while neither the 1,4-bis-(dibutylamino) nor the 1,4-dimorpholino derivative could be converted by means of potassium *n*-octoxide in boiling xylene.

(7) The similarity between the ultraviolet absorption spectra of 1,4-bis-(dimethylamino)-2-butene and of the solid suggested the possibility that the grouping N—C—C=C—C—N may be present in the latter. If the remaining double bond is sufficiently hindered, hydrogenolysis of the allylic bond might be expected to occur in preference to double bond saturation to give $C_{16}H_{31}NC=C(CH_3)NR_2$.

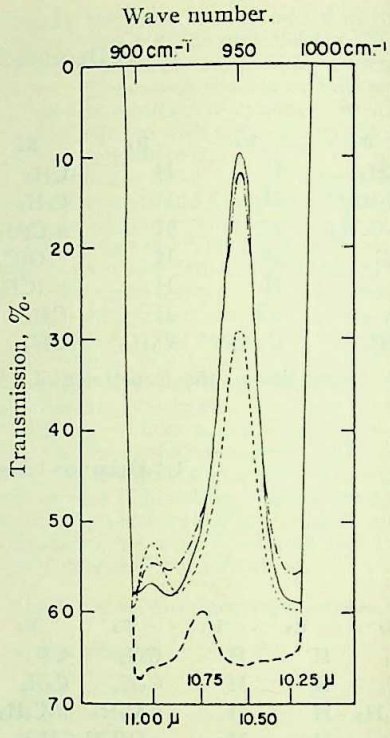

Fig. 2.—Infrared spectra of 1,4-bis-(dimethylamino)-1,3-butadienes, *trans*-olefin hydrogen wagging region: ———, *t,t*-II; – – – –, *c,t*-II; — · —, *c,t*-II on standing; – – – –, $CHCl_3$.

Dimerization was effected concurrent with rearrangement to II when metallic potassium or sodamide was employed. Although other sodium derivatives (the hydroxide, methoxide and *n*-octoxide) were ineffective in short time, small scale experiments, prolonged heating of I with sodium ethyleneglycoxide gave some dimeric material.

Complete recovery of II in experiments in which it was heated with potassium hydroxide, in the presence or absence of I, showed that II was not an intermediate in the dimerization process.

We propose a mechanism for these base-catalyzed transformations of I similar to that recently described by Jones, Whitham and Whiting[8] for the case of prototropic rearrangements of acetylenic acids.

$$\underset{\text{I}}{XCH_2C{\equiv}CCH_2X} + B^- \longrightarrow \underset{A_1}{X\bar{C}HC{\equiv}CCH_2X} + BH$$

$$\underset{A_1}{X\bar{C}HC{\equiv}CCH_2X} \longleftrightarrow \underset{A}{XCH{=}C{=}\bar{C}CH_2X} \longleftrightarrow \underset{A_2}{XCH{=}C{=}\bar{C}CH_2X}$$

$$\underset{A_2}{XCH{=}C{=}\bar{C}CH_2X} + I \rightleftharpoons \underset{B}{XCH{=}C{=}CHCH_2X} + A_1$$

$$\underset{B}{XCH{=}C{=}CCH_2X} + A \rightleftharpoons$$

$$\underset{C_1}{XCH{=}C{=}CH\bar{C}HX} + I \text{ or } B$$

$$\underset{C_1}{XCH{=}C{=}CH\bar{C}HX} \longleftrightarrow \underset{C}{XCH{=}\bar{C}{-}CH{=}CHX} \longleftrightarrow \underset{C_2}{XCH{=}\bar{C}{-}CH{=}CHX}$$

$$\underset{C_2}{XCH{=}\bar{C}{-}CH{=}CHX} + I \text{ or } B \longrightarrow$$

$$\underset{II}{XCH{=}CH{-}CH{=}CHX} + A \text{ or } C$$

The geometrical configuration is not set until the very last step in this series. Ion C must assume the conformation which makes carbon atom 2 most amenable to approach by I or B. Inspection of molecular models suggests that the $\Delta^{1,2}$-double bond must have the *cis* and the $\Delta^{3,4}$-double bond should have the *trans* orientation for this situation to obtain.

In the presence of potassium bases or if higher temperatures are used with sodium bases, ions A and C may add to I or B to give intermediates which abstract protons from I to give dimeric products. These in turn could isomerize to more highly conjugated structures.[9]

Acknowledgments.—We wish to thank Dr. James D. Stroupe and Mrs. Florence Farnum of these laboratories for their determination and interpretation of the ultraviolet and infrared absorption spectra reported herein.

Experimental[10]

1,4-Bis-(dimethylamino)-2-butyne (I). Method A.—Bis-(dimethylamino)-methane (5.0 moles, 543 g. of 94% purity) was treated with aqueous formaldehyde solution (5.75 moles, 539 g. of 36.2% concentration) with stirring and cooling to keep the temperature below 50°. Cuprous chloride (20 g., 0.2 mole) was added. The flask was then fitted with a gas inlet tube which extended below the surface of the liquid and a gas outlet tube which was connected to a manometer. All stoppers and connections were wired in place. A stream of acetylene, which had been washed with water and with concentrated sulfuric acid, then dried over soda lime, was admitted at about 1.33 atm. The absorption of acetylene was very rapid; in 50 minutes, 136 g. (5.23 moles) was absorbed. The temperature was maintained at about 50° by intermittent cooling. The mixture was maintained at 50° for an additional 3 hr., then cooled and filtered with the aid of Celite. The mixture was dried over flaked sodium hydroxide then distilled at atmospheric pressure. 3-Dimethylamino-1-propyne (78 g., 9%), b.p. 82°, and I (491 g., 73%), b.p. 181–183°, were obtained.

Method B.—Method A was modified by preparing the intermediate, R_2NCH_2OH, by adding R_2NH (1.0 mole) to 36% aqueous formaldehyde solution (1.02–1.05 moles) with cooling. The lower concentration of R_2NCH_2OH thus employed led to higher ratios of mono- to disubstituted acetylene derivatives than did method A.

Method C.—Method A was modified by preparing the intermediate, $R_2NHCH(R^1)OH$, by adding R_2NH (1.0 mole) to the aldehyde (1.0 mole) in the absence of solvent, while maintaining the temperature below 35°. When R^1 was not H, the monosubstituted acetylene derivative was the major product of the reaction.

2,2,4,11,13,13-Hexamethyl-6,9-bis-(dimethylamino)-7-tetradecyne. Method D.—3,5,5-Trimethylhexanal (1066 g., 7.5 moles) was treated with dimethylamine (339 g., 7.5 moles) through a gas inlet while the mixture was stirred and maintained below 50° by external cooling. An aqueous phase separated and was discarded. The organic layer, after drying over anhydrous sodium sulfate (1141 g., 6.1 moles of crude alkylolamine), 3-dimethylamino-5,7,7-trimethyl-1-octyne (1171 g., 6.0 moles) and cuprous chloride (2 g.) were combined and heated at 170–190° for 6 hr. The reaction mixture was cooled and filtered. The filtrate was distilled under reduced pressure to give the product (1541 g., 4.24 moles, 71%), b.p. 128–133° (1 mm.), $n^{20}D$ 1.4617.

1,4-Bis-(methylphenylamino)-2-butyne.—This compound was prepared from 1,4-dichloro-2-butyne and N-methylaniline according to the procedure of W. Reppe (reference 5c, p. 79).

Anal. Calcd. for $C_{18}H_{20}N_2$: N, 9.1. Found: N, 9.1.

3-Morpholino-1-butyne.[11,5c] **Method E.**—A solution of cuprous chloride (13.5 g.) in concentrated hydrochloric acid (84 g.) was added to morpholine (200 g., 2.3 moles) with stirring and cooling. Acetylene (89 g., 3.4 moles) was introduced through a gas inlet tube and was absorbed at about 1.33 atm. during 20 hours while the temperature was maintained at 105–115°. The mixture was diluted with ethanol (1 volume) and filtered. The ethanol was removed by distillation under reduced pressure, and the residue was washed with 13% sodium hydroxide solution (230 ml.). The organic layer was separated, the aqueous layer was washed with diethyl ether (two 100-ml. portions), and the combined organic layers were dried over anhydrous potassium carbonate. Distillation gave 3-morpholino-1-butyne (108 g., 0.77 mole), b.p. 55–62° (0.1 mm.), $n^{20}D$ 1.4715, in 34% yield based on morpholine and 45% yield based on the acetylene absorbed.

***cis,trans*-1,4-Bis-(dimethylamino)-1,3-butadiene (II). Method F.**—Sodium (16 g., of 50% dispersion[3] in xylene, 0.35 mole) was treated with xylene (90 ml.) and hexane (500 ml.), and the mixture was heated to reflux (72°). The heat source was removed and freshly distilled 1,4-bis-(dimethylamino)-2-butyne (I, 1500 g., 10.7 moles) was added in a fine stream during 3.5 hr. A log was kept of the refractive index *vs.* I added to ensure that unreacted I did not accumulate. The product was distilled under reduced pressure to remove first the hexane then the xylene. The product (1275 g., 85% yield) had b.p. 75–80° (7 mm.), $n^{20}D$ 1.549.

***trans,trans*-1,4-Bis-(dimethylamino)-1,3-butadiene.**—On standing in a stoppered bottle at room temperature for two

months *cis,trans*-II had darkened somewhat and had rearranged to a form which had m.p. −4°. Redistillation gave the pure *trans,trans*-II, b.p. 80° (2 mm.), $n^{20}D$ 1.555, m.p. −3 to −1°.

Anal. Calcd. for $C_8H_{16}N_2$: N, 19.97. Found: N, 19.91, 19.95.

This rearrangement could be carried out much more rapidly by adding traces of acids or water. In 24 hr. at room temperature or 3 hr. at 65–70° in the presence of 1 drop of water or acetic acid, the melting point of II (10 g.) rose from <−70° to −4°. Prolonged room temperature storage of *trans,trans*-II led to resinification.

2,2,4,11,13,13-Hexamethyl-6,9-bis-(dimethylamino)-6,8-tetradecadiene. Method G.—Hexane (50 g.) and 50% sodium dispersion[3] in xylene (4 g.) were heated to reflux, the source of heat was removed and compound I (14 g., 0.10 mole) was added dropwise. Thereafter, 2,2,4,11,13,13-hexamethyl-6,9-bis-(dimethylamino)-7-tetradecyne (136 g., 0.37 mole) was added during 39 minutes. The reaction mixture was stirred and heated for an additional 2.5 hr. Distillation under reduced pressure gave (a), 10 g., b.p. 68–187° (4 mm.), $n^{20}D$ 1.5420; and (b), 131 g., b.p. 187–192° (4 mm.), $n^{20}D$ 1.4986. Cut a was chiefly II while cut b represented a 94.5% yield of the desired product in high purity as judged by its ultraviolet spectrum (ϵ_{max} 21,900 at 295 mμ).

Dimerization of 1,4-Bis-(dimethylamino)-1,3-butadiene.—A mixture at I (150 g., 1.07 mole), xylene (150 ml.) and potassium metal (0.75 g., 0.02 mole) dissolved in 1-octanol (4.25 g.) was stirred and heated under reflux for 5 hr. Distillation under reduced pressure gave the product (126 g., 84%), b.p. 72–132° (0.2 mm.). Redistillation (powdered potassium hydroxide in the pot) of a combination of products from several such runs gave a series of fractions at 1.0 mm. whose physical properties indicated that a mixture of dimeric materials was present.

Hydrogenation of 1,4-Bis-(dimethylamino)-2-butyne Dimer.—The once-distilled dimer, b.p. 115–118° (0.15 mm.), $n^{19}D$ 1.5220–1.5250, prepared as above (133 g., 0.475 mole), ethanol (30 ml.) and Raney nickel (10 g. of catalyst rinsed with ethanol) were hydrogenated at 170 atm. and 110–116° during 8.5 hr. Dimethylamine (0.227 mole) was recovered in the processing. Distillation and redistillation of selected cuts gave 8.5 g. of liquid, b.p. 81–90° at 0.20 mm., $n^{20}D$ 1.4693. (*Anal.* Calcd. for $C_{14}H_{31}N_3$: N, 17.41; mol. wt., 241. Found: N, 17.46; mol. wt., 253) along with some solid material m.p. after recrystallization from heptane 104–105.5°.

Anal. Calcd. for $C_{16}H_{36}N_4$: C, 67.60; H, 12.68; N, 19.72; mol. wt., 284. Found: C, 67.76; H, 12.57; N, 19.04; mol. wt., 277.[12]

The same solid was obtained in low yields by hydrogenation in ethanol solution at 3 atmospheres in the presence of platinum oxide catalyst.

Chemistry of 1,4-Diamino-1,3-butadienes. II. A New Synthesis of N-Substituted Pyrroles[1]

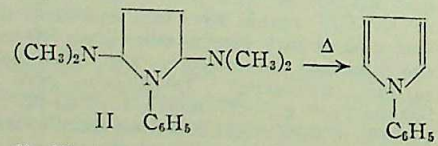
BY MARIAN F. FEGLEY, NEWMAN M. BORTNICK AND CHARLES H. MCKEEVER

RECEIVED NOVEMBER 3, 1956

N-Substituted pyrroles have been prepared by interaction of 1,4-bis-(dimethylamino)-1,3-butadiene and primary amines in the presence of an acidic catalyst.

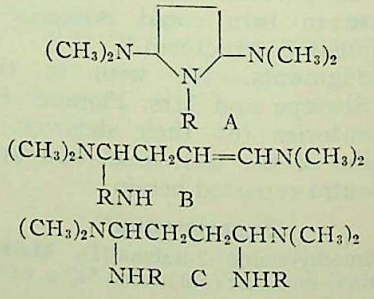
Primary amines have been found to react with 1,4-bis-(dimethylamino)-1,3-butadiene (I)[2] in the presence of catalytic amounts of acids. The unstable cyclic addition product II was formed with evolution of heat when I and aniline were mixed in the presence of a trace of acetic acid.

$$C_6H_5NH_2 + \underset{\text{I}}{(CH_3)_2NCH{=}CHCH{=}CHN(CH_3)_2} \longrightarrow$$



When II was distilled at atmospheric pressure, a low yield of N-phenylpyrrole was isolated together with dimethylamine, aniline, I and polymeric products.

The reaction of benzylamine with I required the addition of more acetic acid for its initiation than was the case with aniline and I. Ultraviolet spectroscopic assay[2] of an equimolar mixture showed that 85% of I had disappeared. Thus, a 1:1 addition product must have constituted a major portion of the mixture. It seems likely that products having the structures A–C were all in equilibrium with the starting materials.



Distillation of the reaction mixture gave a 40% yield of N-benzylpyrrole.

n-Butylamine failed to react with I in the presence of acetic acid. Addition of a few drops of concentrated hydrochloric acid led to evolution of dimethylamine and formation of N-*n*-butylpyrrole. This observation has formed the basis for a general procedure for the preparation of N-substituted pyrroles (Table I).

The mixtures of primary amine and I were treated with acid while a stream of inert gas was used to sweep out the dimethylamine as it was liberated. The reaction mixtures were treated with solid potassium carbonate and then distilled to isolate the pyrroles. In some experiments, removal

A.*, **37**, 4071 (1943), gave $n^{20}D$ 1.5839, b.p. 132–133° (13 mm.). [i] Both products were isolated from a single run. [j] The reaction was started at the lower temperature and completed at the higher temperature. [k] At 23.5°. [l] At 23°. [m] At 24°. [n] $[O(CH_2CH_2)_2NCH{=}CH]_2$.

of excesses of the amine reactant was accomplished by washing an ether solution of the reaction mixture with cold dilute hydrochloric acid solution, with water and then with dilute sodium hydroxide solution. Drying and distillation gave pure samples.

The method worked well for primary amines of proper basicity ($K_b \geq 10^{-7}$). Neither the presence of –OH, $-NH_2$, CH_2=$CHCH_2$–, CH_2=CHO–, cyclic urea groups nor branching at the carbon atom bearing the amino group interfered with pyrrole formation.

The reaction failed when aminoacetonitrile, α-aminoisobutyronitrile or 2-aminopyridine was employed. The low yield obtained when aniline was employed was not improved with subsequent study. Only polymeric material resulted when the reaction of ammonia with I was investigated.

Experimental[3]

Reaction of Aniline with 1,4-Bis-(dimethylamino)-1,3-butadiene (I).—A mixture of aniline (9.3 g., 0.10 mole) and I (14.0 g., 0.10 mole) was treated with glacial acetic acid (6 drops) whereupon an exothermic reaction ensued. The temperature was kept below 60° with cooling until the entire reaction mixture solidified. The temperature rose to 65–70°. The crude addition product was crystallized from diethyl ether or petroleum ether (30–60°) by cooling to −70°, m.p. 71–73°. The infrared absorption spectrum showed no absorption bands corresponding to the stretching of C=C, C=N or N–H bonds. The normal monosubstituted aromatic bands at 3100, 3060, 3030, 1603 and 1508 cm.$^{-1}$ were in evidence. The product decomposed on standing at room temperature; this fact accounts for the poor analysis shown below.

Anal. Calcd. for $C_{14}H_{23}N_3$: N, 18.0. Found: N, 16.8.

A batch of material prepared as above and then treated with potassium carbonate (1 g.) was distilled at atmospheric pressure. Dimethylamine was evolved, considerable tar remained in the pot and from the distillate was obtained aniline (5 g.) and a fraction, b.p. 225–250° (1 + g.). Redistillation of the latter gave 0.5 g., b.p. 80–90° (1 mm.), which froze in the receiver. Two recrystallizations from 30–60° petroleum ether gave N-phenylpyrrole, m.p. 60–61°.

Reaction of Benzylamine with I.—Benzylamine (5.35 g., 0.05 mole) and I (7.00 g., 0.05 mole) were treated with glacial acetic acid (3 drops). A mildly exothermic reaction ensued; the temperature rose to 53° before falling slowly to room temperature. From the ultraviolet absorption spectrum of the mixture, 85% of I had disappeared. All efforts to isolate a pure sample of the addition product failed. The reaction mixture was distilled at atmospheric pressure. The cut (3 g., 40% yield), b.p. 225–260°, m.p. 128°, was redistilled to give the analytical sample, 1.5 g.,

(3) All temperatures are uncorrected. Elemental analyses were carried out by the analytical laboratories of the Public Domain. CC-0. Gurukul Kangri Collection, Haridwar

b.p. 80-100° (1 mm.), 246° (760 mm.), m.p. 15°, $n^{20}D$ 1.569.

Anal. Calcd. for $C_{11}H_{11}N$: N, 8.9. Found: N, 8.9.

N-Methylpyrrole.—A mixture of 40% aqueous methylamine (219 g., 3.2 moles), I (80 g., 0.57 mole), glacial acetic acid (15 drops) and concentrated hydrochloric acid (9 drops) was heated slowly with stirring to 44°, then the heat source was removed. After 30 minutes at that temperature, the mixture became homogeneous. The mixture was maintained at 44° for another hour then allowed to stand at room temperature overnight. The reaction mixture was cooled in an ice-bath and acidified by the careful addition of 18% hydrochloric acid. The mixture was thrice extracted with ether and the combined organic layers were dried over anhydrous potassium carbonate, filtered and distilled to give the product, 21 g. (46% yield), b.p. 114°, $n^{23.5}D$ 1.4855.

N-Cyclohexylpyrrole.—Cyclohexylamine (75 g., 0.75 mole) and I (75 g., 0.53 mole) were treated with acetic acid (9 drops) and concentrated hydrochloric acid (5 drops) while nitrogen was swept slowly through the stirred mixture. The vent gas from the condenser was passed through a scrubber which contained 350 ml. of 2.8 *N* hydrochloric acid solution. After the mixture was heated at 70 ± 5° for 4 hr., 1.0 mole of dimethylamine had been liberated. Potassium carbonate (1 g.) was added and distillation of the reaction mixture gave (a) b.p. 53–60° (17 mm.), 17 g., $n^{20}D$ 1.4589 (recovered amine); (b) b.p. 60° (17 mm.) to 62° (1 mm.), 8.5 g., $n^{20}D$ 1.5060 (intermediate cut, contained product contaminated with 10% recovered amine); (c) b.p. 62–63° (1 mm.), 48 g., $n^{20}D$ 1.5111; (d) residue, 18 g., polymeric.

Anal. (Cut c) Calcd. for $C_{10}H_{15}N$: N, 9.4. Found: N, 9.4.

Correlation of Solvolysis Rates. VIII. Benzhydryl Chloride and Bromide. Comparison of *m*Y and Swain's Correlations[1]

BY S. WINSTEIN, ARNOLD H. FAINBERG AND E. GRUNWALD

RECEIVED JANUARY 17, 1957

In this paper are reported rates of solvolysis of benzhydryl chloride and bromide and the correlation of these and other data in the literature by means of the *m*Y relation. The dispersion of log *k vs.* Y plots into separate lines for each solvent pair, observed previously with *t*-butyl, α-phenylethyl and neophyl halides, is even more marked with the benzhydryl halides. The contributing causes of such dispersion include structural limitations of the *m*Y relation with respect to variation of both the R and X parts of RX. The leaving group specificity is especially marked with F, fluorides tending to be very fast in carboxylic acid solvents. Ion pair return, which depresses the observed solvolysis rate below the ionization rate by variable amounts depending on the nature of the solvent, contributes to the observed dispersion in some cases. Swain and Mosely's conclusion that the solvolysis of *t*-butyl chloride is not limiting and that gradation of mechanism continues far past *t*-butyl as structure is varied so as to make solvolysis more nearly limiting is based to a large extent on the solvolytic behavior in the series *n*-BuBr, *t*-BuCl, $(C_6H_5)_3CF$. In the view of Swain and Mosely, the unusually high rate of solvolysis of trityl fluoride in acetic acid is caused by the change in structure of the R part of RX from *t*-Bu to $(C_6H_5)_3C$. In our view, it is caused instead by the change of X in RX from Cl to F. Examination of $(k_{ROH}/k_{AcOH})_Y$ values for a whole group of substances supports the designation of *t*-butyl chloride solvolysis in the common solvents as limiting. The relations between Grunwald and Winstein's two-parameter, Swain, Dittmer and Kaiser's three-parameter and Swain, Mosely and Bown's four-parameter correlations of solvolysis rates are discussed and the numerical fits obtained are compared.

The three preceding papers of this series[2-4] were concerned with the correlation of the rates of solvolysis of *t*-butyl, α-phenylethyl and neophyl halides by the linear free energy relationship[5] 1.

$$\log k = \log k_0 + mY \qquad (1)$$

A marked dispersion of the data into separate lines, one for each solvent pair, was noted. In this paper we examine new data for benzhydryl chloride and bromide and related data from the literature which show this dispersion to an even greater degree.

The point of view adopted in this paper is somewhat different from that of 1948.[5a] In the original *m*Y treatment,[5a] the intent was to separate the total effect of solvent change into a variable Y, characteristic of the solvent, and a variable *m*, characteristic solely of RX. With the limited data then available, this approach succeeded for aliphatic compounds. However, the data for α-phenylethyl and benzhydryl chloride could not be fitted to the Y values for the aliphatic compounds in all of the solvent pairs with a single value of *m*. This was, of course, a manifestation of dispersion[2-4,5d] of lines and was recognized as a limitation of the *m*Y relationship. It was handled by introducing a second set of Y values with which it was possible to correlate the data for both compounds and which was recommended for general use with α-aryl derivatives. The parameter *m* was still considered constant for any one RX.

As more data became available,[2-4,5d,6] the limitations of the original *m*Y treatment became more and more apparent, and the pattern of dispersed lines evolved. To fit the data in the next higher approximation, *m* is a function of both RX *and* of the solvent pair.[2-4,5d] Since the burden of accounting for the structural limitations of the original *m*Y treatment[5a] has thus been shifted on to *m*, there is no advantage in retaining more than one set of Y values. The set based on *t*-butyl chloride[5c] has therefore been used in this paper.

On the basis of the new findings, the use of sol-

volysis rates to detect limiting solvolysis[5a,b,7] has been re-examined, and the mY correlation of solvolysis rates has been compared with other correlations recently proposed by Swain and coworkers.[8,9]

Results

Table I lists all of the first-order rate constants now available for the solvolysis of benzhydryl chloride and bromide in mixtures of water with ethanol, methanol, acetic acid, dioxane and acetone, and in mixtures of acetic and formic acids. About two-thirds of the data are new; the others duplicate previous values or are taken directly from literature sources.

TABLE I

SPECIFIC RATES OF SOLVOLYSIS[a] OF BENZHYDRYL CHLORIDE AND BROMIDE

Solvent, vol. %[b]	$10^5 k$, sec.$^{-1}$[c] 25.0°	50.0°	$\Delta H^{\ddagger}$, kcal./mole (25°)	$\Delta S^{\ddagger}$ e.u. (25°)

[a] Unless otherwise noted, halide analysis was employed. [b] x vol. % A − B means x volumes of A plus 100 − x volumes of B, each at 25° before mixing. [c] The over-all average deviation of the rates which were constant was ±1.0% of k. [d] Unless otherwise noted, initial concentration 0.02–0.03 M. [e] Recalculation of data previously reported gives at 25.0°, $10^5 k$ = 5.63,[15] 5.30,[17] 5.72,[16] 5.75,[10] 4.85[18]; $\Delta H^{\ddagger}$ 21.99,[15] 19.16,[10] 20.69[18]; $\Delta S^{\ddagger}$ −4.2,[15] −13.6,[10] −8.9.[18] [f] Previously reported[10] 49.3. [g] At 15.0°, reported by Benfey, Hughes and Ingold.[14] [h] Contained 0.032 M lithium acetate and/or formate, plus 0.01 M Ac_2O. [i] Calculated for 0.032 M lithium acetate from data[19] at other salt concentrations. [j] Contained 0.065 M lithium acetate and/or formate plus 0.01 M Ac_2O. [k] Initial rate constants; these rates drifted down during the runs; see Experimental section. [m] Contained 0.068 M lithium acetate plus 0.01 M Ac_2O. [n] Böhme and Schürhoff[20] report data at several temperatures in eight solvent compositions covering the range 60–95 wt. % dioxane–H_2O. [p] Initial rate constant; the rate drifted up in the course of the run; see Experimental section. [q] Average deviation ±3%, followed over the range 50–90% reaction. [r] This value is the average of data previously reported.[11,21,22] [s] Calculated from data previously reported[11,21,22] at 0.0°. [t] At 0.0°. [u] $10^5 k$ at 40.0° = 10.60. [v] Contained 0.068 M lithium acetate. [w] Acidimetric analysis employed; initial concentration of benzhydryl bromide 0.010–0.012 M.

Table I also lists the values of the thermodynamic quantities of activation, $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$. The solvent range covered by these data is narrower than in the case of the t-butyl,[3,23] α-phenylethyl[2,3] and neophyl halides,[4] because of the difficulty of determining solvolysis rates in the highly aqueous solvents. The region in which the varia-

tion of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ with solvent composition had previously been found to be the most complex for other compounds[2,3,23] had, unfortunately, to be omitted.

The general level of $\Delta S^{\ddagger}$ for benzhydryl chloride in ethanol, methanol and the acetic and aqueous acetic acid solvents is -8 ± 1 e.u.; this value compares with -4 and -9 for *t*-butyl and α-phenylethyl chlorides, respectively, in the same solvents.

For benzhydryl chloride, in acetic acid–water mixtures, the increase in rate in going from anhydrous acetic acid to acetic acid 2 *M* in water involves principally a decrease in $\Delta H^{\ddagger}$, this being opposed by a much smaller decrease in the entropy term. Employing the **ABC** classification scheme set up in an earlier paper[23] to describe the relative contributions of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ to change in rate due to solvent variation, this behavior can be described as **C**. In the aqueous dioxanes and acetones, the increase in rate arising from increase in water content is principally the result of a large increase in $\Delta S^{\ddagger}$, opposed by a much smaller increase in the $\Delta H^{\ddagger}$ term; this behavior is **A**. The trends observed with benzhydryl chloride are quite analogous to those previously found for *t*-butyl,[23] α-phenylethyl[2] and neophyl[4] chlorides over the same ranges of solvent composition.

For the four solvents for which comparison can be made, the increase in rate arising from change of leaving group from chloride to bromide is made up of an average decrease in $\Delta H^{\ddagger}$ of 0.5 ± 0.3 kcal./mole plus an average increase in $\Delta S^{\ddagger}$ of 3 ± 2 e.u. Again, these results are similar to those previously noted for the *t*-butyl,[3] α-phenylethyl[3] and neophyl[4] systems.

For benzhydryl bromide in 0–60% dioxane–ethanol, *ca.* two-thirds of the increase in rate with increasing ethanol content is contributed by increase in $\Delta S^{\ddagger}$, the remainder being furnished by decrease in $\Delta H^{\ddagger}$. For these data, which fall into the **B** class, $\Delta S^{\ddagger}$ is quite accurately linear in $\Delta H^{\ddagger}$. Salomaa[24] has previously reported linear relations between $\Delta S^{\ddagger}$ and $\Delta H^{\ddagger}$ for solvolysis of several α-haloethers in dioxane–ethanol mixtures; however, in contrast with our results, his data describe an **A** behavior.

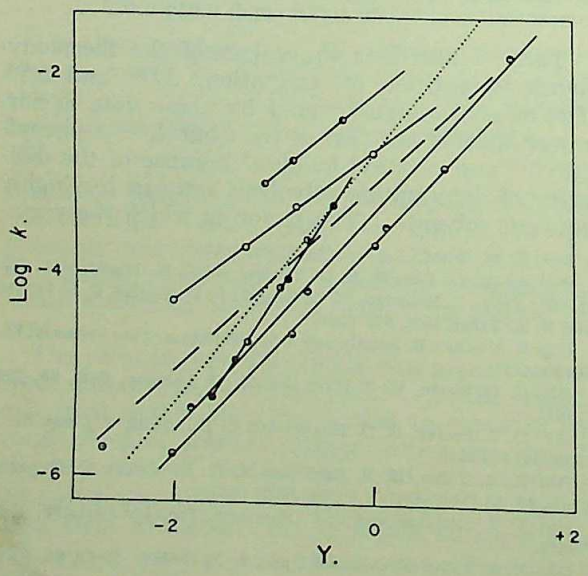

Fig. 1.—Plot of log *k vs.* Y for solvolysis of benzhydryl chloride at 25.0° in: EtOH–H_2O, ○; MeOH–H_2O, ◐; *i*-PrOH, ⊙; dioxane–H_2O, ◒; Me_2CO–H_2O, ◓; AcOH–H_2O, ●; AcOH–HCOOH, ◑. The dashed line is the least squares line for all of the data; the dotted line is given by equation 5, based on Swain, Mosely and Bown's compound parameters.

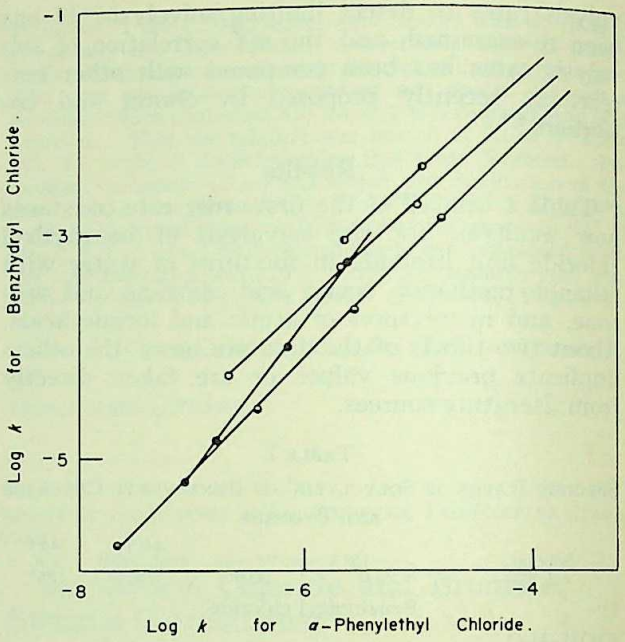

Fig. 2.—Plot of log *k* for solvolysis of benzhydryl chloride at 25.0° *vs.* log *k* for solvolysis of α-phenylethyl chloride at 25.0° in: EtOH–H_2O, ○; MeOH–H_2O, ◐; dioxane–H_2O, ◒; AcOH–H_2O, ●.

*m***Y Plots.**—When the data for benzhydryl chloride at 25.0°, in 24 solvent compositions, are fitted to equation 1 by the method of least squares, values of $m = 0.927$ and $\log k_0 = -3.062$ are obtained. However, the probable error of the fit,[25] *r*, equal to 0.408, is very large for this whole group of solvents. The plot in Fig. 1 of log *k* for benzhydryl chloride *vs.* **Y** shows clearly that each solvent pair should be considered separately. Thus, the four points for dioxane–water in the 60–90 vol.% range form an excellent straight line lying below those for ethanol–water and methanol–water mixtures, while the lines for the carboxylic acid-containing mixtures start low and cut across the others with very much higher slopes. The parameters *m* and log k_0 of equation 1, together with the probable error of the fit,[25] *r*, for the separate lines for each solvent pair are listed in Table II for benzhydryl chloride. With this modification of the original[5a] *m***Y** relation, the average *r* is now 0.02, quite satisfactory for correlative and interpolative purposes. However, for extrapolation these relations should be applied with caution if high accuracy is desired. While curvature of the lines is almost imperceptible in the ranges covered, it is obvious that at least some

[a] k in sec.$^{-1}$. [b] Containing 0.038 M lithium acetate and/or formate. [c] Containing 0.068 M lithium acetate. [d] This equation reproduces the data of Böhme and Schürhoff,[20] reported for a mole ratio of [RCl]/[H_2O] of 1/500 in 60–90 wt. % dioxane–H_2O, with a probable error r = 0.037. [e] Data in 80 and 85% Me_2CO–H_2O lie considerably above this line. [f] The point for 70% Me_2CO–H_2O is far out of line and was omitted in this calculation.

of the lines for the aqueous solvents must curve very considerably in the higher water region, since they must all intersect at pure water.

Although the data listed in Table I for benzhydryl bromide cover a more limited solvent range than for the chloride, they suffice to show that the plot of log k for the bromide *vs.* Y involves even greater dispersion than was found for the chloride. This is in line with the previous observation[3] comparing the α-phenylethyl halides. Again, treating the data for each solvent pair separately, the fits are satisfactory, as is shown in Table II.

Also listed in Table II are the values of m and log k_0 for a number of related compounds, including benzhydryl and triphenylsilyl fluorides and five trityl derivatives, for which suitable data are available from the literature. The data are not sufficient in most cases to test adequately the validity of equation 1 for each of the solvent pairs.[28] Nevertheless, on fitting the data to equation 1, the phenomenon of dispersion is again observed. The dispersion of the lines from each other, and of individual points for other solvent pairs from these lines is large, for trityl acetate rivaling and for trityl fluoride exceeding that shown by benzhydryl chloride in Fig. 1.

(26) C. G. Swain and C. B. Scott, THIS JOURNAL, **75**, 246 (1953).

(27) C. G. Swain, R. M. Esteve, Jr., and R. H. Jones, *ibid.*, **71**, 965 (1949).

(28) The lines for trityl thiocyanate in 50–80% Me_2CO–H_2O and for trityl fluoride in 40–100% EtOH–H_2O are quite good; that for trityl fluoride in aqueous acetone shows considerable positive curvature, particularly in the low water region (Table II, footnote *e*).

Dispersion of mY Plots.—It is clear from this and preceding papers in this series that dispersion of the plots of log k *vs.* Y into separate lines for each binary solvent pair is a general phenomenon. There are definite structural limitations to the linear free energy relationship 1. For one thing, the structure of the R part of RX cannot be varied indiscriminately without introducing marked dispersion. Thus, it already has been noted[4] that the plot of log k for α-phenylethyl chloride *vs.* log k for *t*-butyl chloride (*i.e.*, *vs.* Y) shows much more dispersion and curvature of lines than a plot of log k for α-phenylethyl chloride *vs.* log k for neophyl chloride. In the former comparison, only one of the compounds possesses a phenyl group to delocalize charge in the transition state, while in the latter case, both compounds have a phenyl group. Thus it can be anticipated that a plot of log k for benzhydryl chloride *vs.* log k for α-phenylethyl chloride will show much less dispersion than the plot *vs.* Y; this is shown in Fig. 2. The parameters for the equations for the lines in this plot are presented in Table III.

The lines for the ethanol–, methanol– and dioxane–water mixtures can be extrapolated to yield an average value of log k = 0.7 ± 0.2 for benzhydryl chloride in pure water at 25°. The probable reason for the high initial slope for the acetic acid–water line is discussed below; from Fig. 2 it would appear that this line must curve strongly downward to meet the other lines at the point for pure water.

TABLE III

CORRELATION OF SOLVOLYSIS RATES AT 25.0° *via* THE EQUATION LOG k_{RX} = a LOG $k_{R'Y}$ + b

RX	RY	Solvent range	No. of points	a	b	r
$(C_6H_5)_2CHCl$	$C_6H_5CHClCH_3$	80–100% EtOH–H_2O	3	0.910	1.814	0.031
$(C_6H_5)_2CHCl$	$C_6H_5CHClCH_3$	90–100% MeOH–H_2O	2	.955	2.313	...
$(C_6H_5)_2CHCl$	$C_6H_5CHClCH_3$	60–90% dioxane–H_2O	4	.973	1.737	.045
$(C_6H_5)_2CHCl$	$C_6H_5CHClCH_3$	0–4 M H_2O in AcOH	4	1.335	4.203	.014
$(C_6H_5)_2CHBr$	$(C_6H_5)_2CHCl$	EtOH, 80% Me_2CO–H_2O,[a] 70–90% dioxane–H_2O	5	0.938	1.058	.019
		0–2 M H_2O in AcOH	3	1.085	0.880	.000

[a] The points for 70 and 90% Me_2CO–H_2O appear to be out of line and were omitted from this calculation.

Another structural limitation to the mY relation is a leaving group specificity, the blend of solvent influences for correlation of, *e.g.*, a chloride being not quite appropriate for, *e.g.*, a bromide. This was illustrated most clearly with the neophyl halides in the preceding paper.[4] As before,[3,4] the effect of variation of leaving group can be isolated by plotting log k for benzhydryl bromide *vs.* log k for the chloride as in Fig. 3. From this plot, it is seen that the dispersion of lines for the mixtures of water with ethanol, dioxane and acetone is minor; it is the acetic acid-containing solvents that show large dispersion, bromide appearing to be too slow in rate with respect to chloride by as much as one power of ten. The parameters for the equations of these lines are listed in Table III.

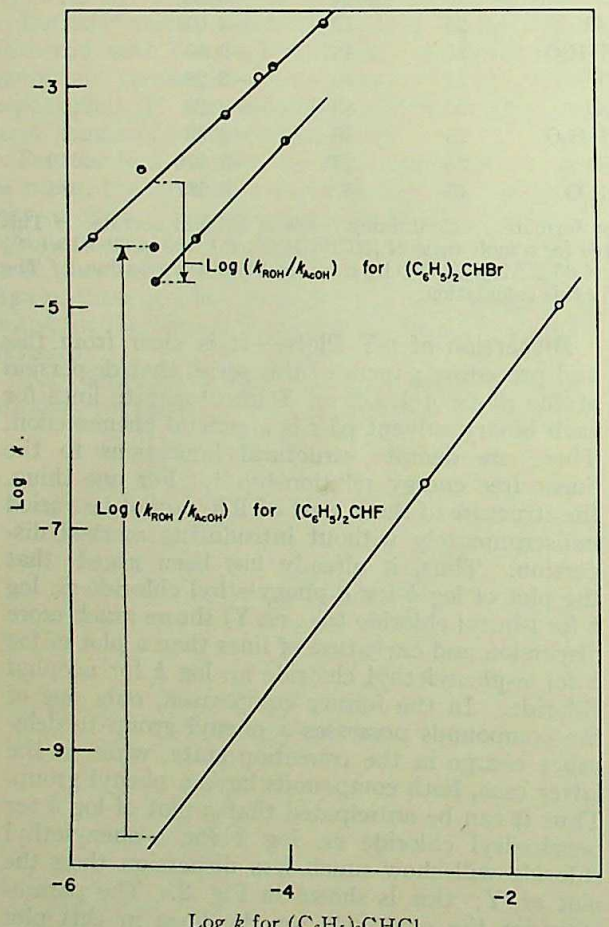

Fig. 3.—Plot of log k for benzhydryl bromide and fluoride *vs.* log k for benzhydryl chloride at 25.0° in: EtOH–H_2O, O; dioxane–H_2O, ◒; Me_2CO–H_2O, ◓; AcOH, ●; AcOH–H_2O, ◑.

As in the case of the neophyl halides,[4] a useful measure of the effect of the leaving group specificity is the quantity log k_{ROH} − log k_{AcOH}, the vertical gap between the aqueous alcohol line and the acetic acid point in a plot of log k for bromide *vs.* log k for chloride. This is given in Table IV along with the analogous information for the t-butyl, α-phenylethyl and neophyl halides. For the neophyl system, data on the toluenesulfonate are available[19] and, as shown in Table IV, the sign for log k_{ROH} − log k_{AcOH} is negative instead of positive as in the case of the bromide. In other words, using chloride as standard, neophyl p-toluenesulfonate tends to be relatively fast in acetic acid while the bromide tends to be slow.

TABLE IV

VERTICAL GAPS, LOG k_{ROH} − LOG k_{AcOH}, IN PLOTS OF LOG k_{RX} *vs.* LOG k_{RCl}

RX	Temp., °C.	log k_{ROH} − log k_{AcOH}
Neophyl OTs[19]	50	−0.30
Neophyl Br	50	+ .45
t-Butyl Br	25	.52
α-Phenylethyl Br	25	.80
Benzhydryl F	25	−5
Benzhydryl Br	25	+0.93

The importance of the leaving group specificity is most strikingly demonstrated by the plot of log k for benzhydryl fluoride *vs.* benzhydryl chloride in Fig. 3. Benzhydryl fluoride is relatively very fast in acetic acid, log k_{ROH} − log k_{AcOH} being estimated as −5.

Previously[4] it seemed reasonable to discuss the leaving group specificity in terms of the importance of hydrogen bonding to the leaving group in the solvolysis transition state. On this basis, the data in Table IV suggest that the importance of hydrogen bonding falls off in the order F >> OTs > Cl > Br. This order is a reasonable one, the position of F in this series being in line with the well-known tendency for fluorine to hydrogen bond. Another indication of the tendency for strong interaction between fluorine and a proton donor in solvolysis is the acid catalysis observed with fluorides.[29,30]

In this connection, it is instructive to note that a large fluoride specificity is *not* evident with the p-

nitrobenzoyl system, the ratio $(k_{ROH}/k_{AcOH})_Y$ for the fluoride being closely similar to that for the chloride. This is shown in Table V, which also contains other data required in subsequent sections. The data appear to indicate that carbon–halogen bond breaking is not involved in the rate-determining step, the solvolysis presumably involving an addition mechanism.[43]

such return exists, the "titrimetric" solvolysis rate constant, k_t, is only a fraction, F, of the true ionization rate constant, k_1. In the solvolysis of *exo*-norbornyl bromide, for instance, the ionization rate, measured polarimetrically,[46] exceeds the titrimetric rate by a factor of 24 in acetic acid but only 5 in 80% ethanol. With *threo*-3-phenyl-2-butyl *p*-toluenesulfonate, the ionization rate exceeds the titrimetric one by a factor of 4.6 in acetolysis but only 1.2 in formolysis.[47]

TABLE V

SUMMARY OF COMPOUND PARAMETERS IN CORRELATION OF SOLVOLYSIS OF VARIOUS SUBSTANCES

[a] Using the data for 40 and 100% EtOH–H_2O only; the point for 80% EtOH–H_2O appears to be far out of line. [b] $(k_{ROH}/k_{HCOOH})_Y$. [c] At 100°. [d] Swain, Mosely and Bown[9a] omitted the data for *t*-butyl bromide from their calculations, stating "they appeared to interfere with convergence of the successive approximation procedure employed." [e] Rate in formic acid at 70.0° estimated from rate reported[31] at 25.13° by assuming $\Delta S^{\ddagger} = +1.5$ e.u.; the value found[40] for acetic acid. [f] Given by Streitwieser,[42] who calculated it from unpublished data of W. E. Doering and M. Finkelstein.

Superimposed on the dispersion arising from variations in structure discussed above is the disturbance arising from ion pair return.[44] This phenomenon, first demonstrated in the acetolysis and rearrangement of α,α-dimethylallyl chloride,[45] involves return to the covalent condition of a varying fraction of the ion pair intermediates. Where

Since Y is a measure of solvent ionizing power, equation 1 is designed to correlate rates of ionization to the first intermediate in solvolysis rather than composite titrimetric rate constants, k_t. When ion pair return is involved, k_t falls below the true ionization rate to a degree which bears no necessary relation to the ionizing power of the solvent. For example, ion pair return is serious in solvolysis of α,α-dimethylallyl chloride[45] in acetic acid, but it is absent in ethanol, a solvent with a closely similar Y value.

With the benzhydryl halides, there is evidence that ion pair return strongly influences the titrimetric rate. Unpublished exploratory work employing thiocyanate ion as a carbonium ion-trap in the acetolysis of benzhydryl chloride and bromide suggests that the true ionization rate of these compounds in acetic acid is at least 10 times the titrimetric solvolysis rate for the chloride and 15–20 times that for the bromide. For α-phenylethyl chloride and bromide, the corresponding factors are

3 and 7. Thus, ion pair return would appear to account for part of the apparent slowness of these bromides in acetic acid when compared with the corresponding chloride. It also accounts for a part of the over-all slowness of these compounds in acetic acid relative to other solvents in which ion pair return plays a lesser role. It is significant in this connection that similar experiments with *t*-butyl chloride indicate that its titrimetric acetolysis rate is very close to, if not identical with, its rate of ionization.

The pattern of the plots of log k for benzhydryl chloride *vs.* Y and *vs.* log k for α-phenylethyl chloride in Figs. 1 and 2 is consistent with some disturbance from ion pair return. For example, the very high slopes observed for the acetic acid–water lines, as compared with those for the non-acid containing solvent mixtures, would arise from decreasing[46] ion pair return as the water content of the mixtures is increased. Furthermore, the relatively complete elimination of return at an intermediate solvent composition would be expected to give rise to the downward curvature in the acetic acid–water line that appears to be required in Fig. 2, in order for this line to intersect those for the other aqueous solvents at the point for pure water.

Limiting Solvolysis.—In the view of Swain and Mosely,[7] solvolysis of *t*-butyl chloride is not limiting, the gradation of mechanism continuing far past *t*-butyl as structure is varied to favor such solvolysis. Their conclusion is based to a large extent on the gradation in solvolytic behavior in the structural series *n*-BuBr, *t*-BuCl, $(C_6H_5)_3CF$. Trityl fluoride[7b] fails to yield a single line in an mY plot and the rate in acetic acid is anomalously fast, being *ca.* 10^3 times as fast in this solvent as in aqueous alcohol with a corresponding Y value (Table V). This relatively high rate in acetic acid was in line with Swain's expectations based on the trend in the $(k_{ROH}/k_{AcOH})_Y$ ratio from *n*-BuBr to *t*-BuCl (Table V) and appeared to confirm his views.

In our view, the very low value of $(k_{ROH}/k_{AcOH})_Y$ for trityl fluoride compared to *t*-butyl chloride is caused primarily by the change in departing group from Cl to F rather than by the change in R from *t*-butyl to trityl. The theory that solvolysis rates of fluorides in acetic acid are relatively very fast due to specific hydrogen bonding[4] has already been explored and is consistent with the data for the benzhydryl system (Table IV). It is significant that trityl fluoride is relatively fast in acetic acid by a factor similar to that for benzhydryl fluoride (Table V). In fact, in a plot of log k for trityl fluoride *vs.* log k for benzhydryl fluoride, the point for acetic acid lies within 0.2 log unit of the ethanol–water line. On the other hand, in contrast with the fluoride, benzhydryl chloride is not relatively fast, but in fact relatively slow, in acetic acid (Table V).

In previous work, which was restricted to OTs, Cl and Br leaving groups,[5b] the approach to limiting character of solvolysis was judged from the $(k_{ROH}/k_{AcOH})_Y$ ratios, which were used as measures of $(\partial \log k/\partial N)_Y$. While the dispersion in mY plots makes this ratio not as quantitative a criterion as it was formerly believed, it is still useful in a semi-quantitative fashion if one omits the fluorides. As is brought out in Table V, $(k_{ROH}/k_{AcOH})_Y$ drops from *ca.* 10^4 to 1 as structure is varied in the direction of more limiting solvolysis from *p*-nitrobenzoyl chloride through methyl bromide, ethyl bromide, benzyl *p*-toluenesulfonate and isopropyl bromide to *t*-butyl chloride. The ratio is also *ca.* unity (within a very small factor) for pinacolyl, *trans*-2-bromocyclohexyl and neophyl arylsulfonates, neophyl chloride and bromide, and 1-bromobicyclo-[2.2.2]octane. Since *t*-butyl chloride is no more sensitive to nucleophilic character of solvent than these compounds, with their unique structural features favoring limiting solvolysis, the indications are strong that *t*-butyl chloride solvolysis is also limiting in the usual solvents.

As brought out earlier in this paper, $(k_{ROH}/k_{AcOH})_Y$ ratios increase again as structure is varied through the α-phenylethyl and benzhydryl chlorides and especially the bromides. This apparent increased sensitivity to nucleophilic character is logically ascribed, not to the ionization step in the solvolysis of these materials, but rather to ion pair return.

Swain, Mosely and Bown's Four-parameter Equation.—In principle, one could hope to correlate all solvolysis rates with one equation, including those in which there is nucleophilic participation by solvent. Such an equation[48] is 3, which is an integrated form of equation 2 employed by Winstein, Grunwald and Jones[5b] in their discussion of the contributions of nucleophilic character, N, and ionizing power, Y, to solvolysis rate. Thus, if the partial derivatives in equation 2 are constant at l and m, respectively, equation 2 leads to the integrated form 3.

$$d \log k = \left(\frac{\partial \log k}{\partial N}\right)_Y dN + \left(\frac{\partial \log k}{\partial Y}\right)_N dY \quad (2)$$

$$\log (k/k_0) = lN + mY \quad (3)$$

$$\log (k/k_0) = c_1d_1 + c_2d_2 \quad (4)$$

While Winstein, Grunwald and Jones[5b] were interested in relative values of $(\partial \log k/\partial N)_Y$, or l, for different substances, they employed the integrated form of equation 2 only where lN was regarded as either negligible (Lim.) or as relatively constant. An example of the latter is the solvolysis of *n*-butyl bromide in a series of aqueous alcohols. As a measure of $(\partial \log k/\partial N)_Y$, there was employed the ratio $(k_{ROH}/k_{RCOOH})_Y$.

Swain and co-workers[9a] have attempted recently a general correlation of solvolysis rates with the aid of the four-parameter equation 4. Formally, this is simply equation 3 with different notation for the compound and solvent parameters. However, there do exist some differences of viewpoint.

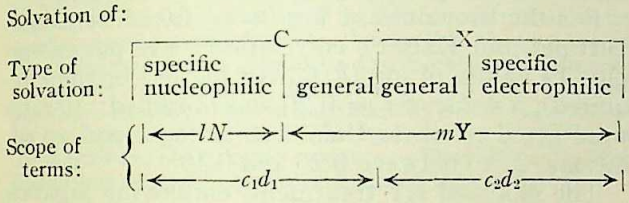
Swain stresses specific solvation of the leaving group and the reacting carbon atom, each by an individual solvent molecule in an electrophilic or nucleophilic role, respectively. The parameters d_1 and d_2 are measures of solvent nucleophilic and electrophilic character, respectively, and c_1 and c_2

(48) In view of the structural limitations discussed above and in the previous paper,[4] it would seem that really successful fits would require more than two terms on the right-hand side of equation 3. For example, dissection[4] of the mY term into two contributing terms already makes three terms necessary.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

are measures of substrate sensitivity to these solvent characteristics. There apparently exists a difference in the kind of solvation meant to be accommodated by the lN and mY terms, on the one hand, and the c_1d_1 and c_2d_2 terms, on the other. It is helpful to first divide solvation[49] into solvation of carbon and solvation of X and also to classify solvent functions[50] into (i) general and (ii) specific short range nucleophilic or electrophilic ones. Then the difference in intended meaning of the lN and mY or the c_1d_1 and c_2d_2 terms may be depicted by the scheme.



Swain's use of the term nucleophilic character, measured by d_1, is broader than ours. We restrict the term nucleophilic to covalent solvation, according to the original more conventional usage, while Swain uses it for electrostatic as well as covalent solvation.[51]

A substantial body of solvolysis data has been processed on the basis of equation 4 by Swain, Mosely and Bown.[9a] The data covered a wide range of nucleophilic participation, either by solvent or by a neighboring group, and covered various departing groups, including F, OTs, Cl and Br. The conditions imposed were $d_1 = d_2 = 0.00$ for 80% ethanol, $c_1 = c_2 = 1.00$ for t-butyl chloride, $c_1/c_2 = 3.00$ for methyl bromide and $c_1/c_2 = 0.333$ for trityl fluoride. There are a number of fundamental difficulties associated with this treatment. (1) The *a priori* choice of c_1/c_2 values for methyl bromide and trityl fluoride is, in effect, an arbitrary assumption regarding the reaction mechanism for these compounds. (2) The treatment makes no allowance for ion pair return; the rate constants used in the treatment are titrimetric rate constants, k_t, whereas the rate constants which one might hope to be able to correlate are $k_1 = k_t/F$. Although F may vary from unity to small values, no provision is made for such a variation. (3) No allowance is made for leaving group specificity.[4]

Although Swain, Mosely and Bown's measures of fit of the four-parameter equation were generally satisfactory,[9a] this indication of the success of their treatment is to some extent illusory. For most of the solvents they treated, d_1 values are within the narrow range of -0.2 ± 0.2. For these solvents, the contribution of the c_1d_1 term in equation 4 tends to be negligible for many substances. In Table VI are listed some compounds for which this is true. Omitting the acetic acid or formic acid solvent, the rate constants may be fitted with the c_2d_2 term alone with a mean deviation of ± 0.25 in the log k for the 9 compounds, in contrast with ± 0.20 using both the c_2d_2 and c_1d_1 terms. The c_2d_2 term alone does essentially as well as both terms for the nucleophilic solvents for this group of compounds, which includes benzoyl chloride, t-butyl chloride, benzhydryl chloride and trityl fluoride. Thus, c_2d_2 is essentially equal to mY in the treatment employing equation 1. In fact, the c_2 values tend to be equal to the m values of the mY correlation in aqueous alcohol mixtures. Table V shows this near identity of c_2 and m values for MeBr, EtOTs, EtBr, n-BuBr, $C_6H_5CH_2OTs$ and i-PrBr. The only commonly employed solvents with significantly lower nucleophilic character are acetic and formic acids, with d_1 values of -4.6 ± 0.2. More often than not, the rate constant in only one of these solvents was available. Therefore, this one solvent often constituted the only one where the c_1d_1 term was really significant. In such cases, the d_1 value used for this solvent was essentially responsible for setting the c_1 value. Without additional solvents to cover a more substantial range of d_1 values, a good test of the four-parameter equation is not obtained.

TABLE VI

COMPARISON OF THE FITS OF SWAIN'S FOUR-PARAMETER EQUATION WITH THOSE OBTAINED EMPLOYING ONLY THE c_2d_2 TERM

Compound	No. of solvents[a]	No. of solvents omitted	Average deviation: 4-parameter equation 4	Average deviation: $\log(k/k_0) = c_2d_2$
C_6H_5COCl	11	1	±0.23	±0.23
p-$CH_3C_6H_4COCl$	3	1	±0.28	±0.27
2-$CH_3OC_6H_{10}OBs$	3	1	± .09	± .18
2-$BrC_6H_{10}OBs$	3	1	± .11	± .22
$(C_6H_5)_2CHCl$	7	2	± .16	± .29
$(C_6H_5)_3CSCN$	6	0	± .09	± .10
$(C_6H_5)_3COC_6H_4NO_2$	3	1	± .09	± .09
$(C_6H_5)_3CF$	6	1	± .28	± .34
t-BuCl	11	4	± .25	± .34
	Weighted average		± .20	± .25

[a] Includes all solvents except those containing carboxylic acid, for which the d_1 term is large and cannot be neglected.

Because of the fundamental difficulties associated with the treatment, the derived c_1 parameters must be regarded as completely empirical and as having no mechanistic significance as measures of substrate sensitivity to nucleophilic character of the solvent.[5d] This fact also has been pointed out by Swain, Mosely and Bown,[9a] but we wish to emphasize it by means of further examples. Thus, according to the c_1 substrate parameter, sensitivity to nucleophilic character increases in the order: MeBr = EtBr < i-PrBr < t-BuCl. Also, it increases as structure is changed from isopropyl to pinacolyl p-bromobenzenesulfonate. Furthermore, according to c_1 values, solvolysis of *trans*-2-bromocyclohexyl p-bromobenzenesulfonate, with neighboring bromine playing the close-range nucleophilic role, is just as sensitive to nucleophilic character of solvent as is the solvolysis of methyl bromide. Just as striking a discrepancy is supplied by the case of the bridgehead bromide, 1-bromobicyclo[2.2.2]octane, studied by Doering and Finkelstein.[52] Thus, according to the c_1 values, solvolysis of this substance is more sensitive to nu-

cleophilic character of solvent than is the solvolysis of methyl bromide.

The four-parameter equation offers little assistance with the problem of dispersion of lines which has been treated in this and preceding papers.[2-4] For the sake of illustration, the case of benzhydryl chloride will be examined more closely. For this substance, c_1 and c_2 are essentially equal,[9a] being 1.24 and 1.25, respectively (Table V). For *t*-butyl chloride, $c_1 = c_2 = 1.00$, by definition. The plot of log *k* for benzhydryl chloride *vs.* Y is therefore predicted by equation 4 to have the form 5, using an average value $c_1 = c_2 = 1.245$. Thus, one single straight line should encompass all solvent mixtures. This line is shown in Fig. 1 by a dotted line. Obviously, the observed dispersion is not anticipated.

$$\log k = \log k_0 + 1.245\mathrm{Y} \qquad (5)$$

Comparison of Numerical Fits.—In this section we compare the fit of the modified *m*Y treatment with that of the four-parameter equation and also with the "special two-parameter equation" 6 of Swain, Dittmer and Kaiser.[9b] Equation 6 was

$$\log (k/k_0)_{\mathrm{RX}} = \log (k/k_0)_{\mathrm{MeBr}} + ab \qquad (6)$$

proposed as an alternative to equation 4; *a* is a compound parameter and *b* is a solvent parameter.[53]

Swain and co-workers[9] have tested the "goodness of fit" of their equations by means of a variable, Φ, which evaluates the deviations from the equations in relation to the variation of the data. By this criterion their correlations were satisfactory for both of their equations. When the same criterion is used to evaluate the modified *m*Y treatment, the correlation is nearly perfect, Φ being close to 100%.

An alternative measure of fit is the probable error, *r*, which evaluates the deviations regardless of the variation of the data and discounts the adjustable parameters.[54] While Φ is more useful when one wishes to find out whether or not a given equation will correlate a set of data, the probable error is more useful, after the correlation has been demonstrated, in testing whether or not the data are being fitted within their experimental error. For the rate constants reported in this and preceding papers in this series, the probable error in log *k* is about 0.01. However, since data from other sources are also used, we estimate that a perfect correlation might yield a somewhat larger *r*, probably not exceeding 0.02.

In the initial correlation[5a,b] of solvolysis rates with the two-parameter equation 1, in which all rate constants for a given compound were fitted to a single line, 74 values of log (k/k_0) were fitted with 38 constants with a probable error of 0.06; the two worst fits were off by 0.27 and 0.13 unit in log *k*.

(53) It should be noted that equation 6 contains one more parameter than equation 1. This becomes evident when equation 1 is written in the form

$$\log (k/k_0)_{\mathrm{RX}} = m \log (k/k_0)_{\mathrm{BuCl}}$$

Inasmuch as we regard equation 1 as a two-parameter equation, we regard equation 6 as a three-parameter equation.

(54) $r = 0.6745\sqrt{\Sigma d^2/(n-f)}$, where d_i is the absolute value of the difference between the *i*th calculated and experimental value, *n* is the number of pieces of data being fitted, and *f* is the number of adjustable parameters employed.

Using the same basis for comparison, Swain, Mosely and Bown[9a] correlated a much wider range of compounds and solvents with the 4-parameter equation. They fitted 146 values of log (k/k_0) with 86 constants with a probable error of 0.20; of these, 11 values were fitted to worse than 0.40 and an additional 23 to between 0.20 and 0.40 in log *k*. The 15 rate constants for *t*-butyl chloride were fitted with a probable error of 0.30. Ten rate constants for benzhydryl chloride were fitted with a probable error of 0.30, not much improved over the 0.40 obtained by the single *m*Y line treatment of the 24 pieces of data listed in Table I.

For the 91 values of log (k/k_0) fitted by Swain, Dittmer and Kaiser's correlation[9b] (34 parameters plus 19 values of log (k/k_0) for methyl bromide required), a value of $r = 0.20$ was obtained; 10 rates were fitted to worse than 0.40 in log *k* and an additional 21 to between 0.20 and 0.40.

The modified *m*Y treatment, employing separate lines for each solvent pair, applied to all of the data reported and summarized in this and preceding[2-4,5c,23] papers fits 760 values of log *k* with 372 constants[55] with a probable error of *ca.* 0.025 in log *k*. This modification of the original *m*Y relation permits inclusion of many cases of non-limiting solvolysis, even in solvent mixtures of varying nucleophilic character such as acetic acid–water. For comparison, application of Swain, Mosely and Bown's four-parameter correlation[9a] to this same set of data would have required 434 constants.

In our opinion, equations 4 and 6 may be useful for obtaining fairly rough estimates of rate constants over a rather wide range of compounds and solvents. The modified *m*Y treatment comes close to fitting data within their experimental error and is most suitable for accurate fitting over a more narrow range of compounds and solvents.

Experimental Part

Benzhydryl Chloride.—The method of Farinacci and Hammett[16] was used to prepare the benzhydryl chloride, b.p. 137° (5.0 mm.), f.p. 17.8°, f.p. depression to half frozen 0.4°, $n^{20}\mathrm{D}$ 1.5959, $n^{25}\mathrm{D}$ 1.5937; reported b.p. 146.5–147.6° (6 mm.),[16] f.p. 17.6°,[56] $n^{19.5}\mathrm{D}$ 1.5959.[57] An average of 49 solvolysis infinities gave a purity of 98.7 ± 0.4%. The material was quite stable when stored *in vacuo* in the solid state at 5°.

Benzhydryl Bromide.—Treatment of a pentane solution of benzhydrol, m.p. 65.5–66.5°, with anhydrous hydrogen bromide, as described by Courtot[58] gave benzhydryl bromide, b.p. 151–153° (5 mm.), m.p. 38.2°. Alternatively, diphenylmethane, b.p. 114° (5 mm.), f.p. 24.6–24.8°, was brominated[59] to give benzhydryl bromide, b.p. 153–156° (5 mm.), m.p. 36.2–37.4°. Recrystallization from pentane followed by distillation at 107° (0.7 mm.) raised the f.p. to 38.7°, f.p. depression to half frozen 0.4°. Other authors[58-63] have reported f.p.'s ranging from 42 to 46°.

(55) These include 130 values of Y, all of which can be calculated from the 40 parameters required for the power series for Y in terms of mole fraction of fast component (Table II of ref. 5c).

An average of 39 solvolysis infinities gave a purity of 99.3 ± 0.3% for the sample employed.

Solvents.—Preparation of solvents was described in detail in an earlier paper in this series[5c]; in general, the solvents employed for the rate runs herein reported were from the same batches as those employed[5c] to determine Y.

Kinetic Measurements.—The techniques employed for the kinetic runs and halide analysis have been described previously.[5c] Some hydrolysis was found to occur in the case of the benzhydryl halides during the extraction procedure (*e.g.*, 2% hydrolysis in forty shakes of a 5-ml. aliquot of 0.032 *M* benzhydryl chloride in AcOH in 25 ml. of pentane with 10 ml. of H_2O; *ca.* 3% hydrolysis for the bromide under the same conditions). However, it was shown, for benzhydryl chloride, that if rigorous standardization[64] of the extraction procedure[5c] is adhered to, the amount of hydrolysis during extraction is proportional to the concentration of unreacted organic halide present. Under this circumstance, it can be shown that, as long as, in the calculation of the integrated rate constant, all points, and particularly the zero point, are based on the concentration of halide ion obtained *via* the extraction procedure, this hydrolysis has no effect on the magnitude of the rate constants. Thus, if f is the fraction of unreacted RX hydrolyzed during the extraction

$$(a - fa)/[(a - x) - f(a - x)] = a(1 - f)/[(a - x)(1 - f)] = a/(a - x)$$

and, therefore, the integrated rate constant $k = (2.303/t) \log [a/(a - x)]$ is unaffected by such hydrolysis.

Experimental Results.—The new data reported in Table I were based on an average of 7 points per run followed past 50 to 80% of completion. The average deviation for all of the rates which were first order within experimental error was ±0.9% for benzhydryl chloride and ±1.0% for the bromide. For the rate runs which drifted, the entries in Table I, suitably footnoted, are the estimated initial rates. These estimates were made empirically by linear extrapolation to zero reaction of a plot of integrated rate constant *versus* percentage reaction. The magnitudes of these drifts, expressed empirically as percentage change in k per 0.01 *M* reaction calculated from the true zero of reaction time, are listed in Table VII. The drifts are manifestations of opposing salt effects, and they will be considered more fully in a later paper.

(64) The extent of hydrolysis was shown to depend on the number of shakes employed in the first aqueous extraction.

TABLE VII

DRIFTS IN RATE CONSTANTS DURING SOLVOLYSIS OF BENZHYDRYL CHLORIDE AT 25°

Solvent	Change in k per 0.01 *M* reacn., %
90% Dioxane–H_2O	+3
100% AcOH[a]	0
95% AcOH–HCOOH[b]	−5
90% AcOH–HCOOH[b]	−8
85% AcOH–HCOOH[b]	−11
75% AcOH–HCOOH[a]	−16
4 *M* H_2O in AcOH[a]	−5

[a] Contained 0.068 *M* lithium acetate and/or formate. [b] Contained 0.038 *M* lithium acetate and/or formate.

The Solvolyses of Some Tertiary Halides in Dimethylformamide and N-Methylpropionamide

BY SIDNEY D. ROSS AND MORTIMER M. LABES

RECEIVED FEBRUARY 27, 1957

The solvolyses of *t*-butyl bromide and dimethylneopentylcarbinyl chloride have been studied in both N-methylpropionamide and dimethylformamide, and *t*-butyl chloride has been studied in the latter solvent. The results obtained are discussed in terms of current mechanisms for solvolytic reactions.

There has been considerable interest recently in dimethylformamide as a medium for organic reactions.[1] The attractive properties of dimethylformamide are its exceptional solvent power for both organic and inorganic compounds and its high polarity, as indicated by its dielectric constant of 36.71 at 25°.[2] In this latter respect, N-methylpropionamide, which has received very little attention, perhaps because it is not available commercially, is of even greater interest, since its dielectric constant at 30° is 164.3,[2] a value more than twice that of the dielectric constant of water.

Because of these highly polar characteristics, dimethylformamide and N-methylpropionamide might be expected to be particularly effective solvents for S_N1 solvolyses.[3] To explore this possibility, we have studied the rates of solvolysis of three tertiary, aliphatic halides, *t*-butyl chloride, *t*-butyl bromide and dimethylneopentylcarbinyl chloride, in these two solvents. Since the inception of this work, some results on the reaction of *t*-butyl bromide in dimethylformamide have appeared in the literature.[1d]

Experimental

Materials.—Eastman Kodak Co. White Label *t*-butyl bromide and *t*-butyl chloride were distilled from phosphorus pentoxide prior to use, b.p.'s 72–73° and 50–51°, respectively. Dimethylneopentylcarbinyl chloride was prepared by the procedure described in the literature[4]; b.p. 51.5–53° at 28 mm., $n^{20}D$ 1.4308. Eimer and Amend, C.P. sodium bromide was dried in a vacuum oven over phosphorus pentoxide for two days prior to use. Eastman Kodak Co. White Label tetraethylammonium bromide was crystallized from isopropyl alcohol and dried *in vacuo*. Tetraethylammonium nitrate was prepared by adding equivalent nitric acid to a 10% aqueous solution of tetraethylammonium hydroxide (Eastman Kodak Co.). The solution was concentrated by distillation at a water-pump vacuum, and the salt which crystallized was recrystallized two times from isopropyl alcohol and dried *in vacuo;* m.p. 280° dec.[5]

N,N-Dimethylformamide (du Pont technical grade) was

distilled from calcium oxide; b.p. 45–46° at 12–13 mm., $n^{25}D$ 1.4299, specific resistance 1.7×10^6 ohm-cm. N-Methylpropionamide was prepared according to D'Alelio and Reid[6] and distilled from calcium oxide before use; b.p. 103° at 12–13 mm., $n^{25}D$ 1.4340, specific resistance 8.3×10^5 ohm-cm. The latter solvent contained 0.002–0.008% water by volume, the former 0.09–0.13% water, as determined by Karl Fischer titration in both cases.

Rate Measurements.—All of the reacting solutions were kept in thermostats which maintained the temperatures given in Tables I and II to ±0.1°. The reactions were run either in glass-stoppered flasks from which aliquots were taken at appropriate time intervals or individual aliquots were sealed in glass ampoules, which were then placed in the thermostats. Aliquots were quenched by adding them to benzene, and the benzene solution was extracted first with dilute nitric acid and then two times with distilled water. Except as otherwise indicated in Tables I and II, the aqueous extracts were analyzed for halide ion by the Volhard method for runs in which the initial concentrations of organic halide were greater than 0.02 *M*, and by potentiometric titration using a silver–silver halide electrode and a Leeds–Northrup type K-2 potentiometer where the initial concentrations of organic halide were below 0.02 *M*.

Results

The results of all the rate studies in dimethylformamide are compiled in Table I, and the rates in N-methylpropionamide are given in Table II. In the case of *t*-butyl bromide, the product results almost entirely from an elimination reaction, as indicated by the final olefin titers and the fact that, in the one case where the rate was followed by titrating for the olefin formed, the rate constant does not differ appreciably from the rate constant obtained by halide titration.[7] It is also probable that small amounts of *t*-butyl alcohol are formed in these reactions as a result of the traces of moisture present in the two solvents.

Some typical data for the reaction of *t*-butyl bromide in dimethylformamide are given in Tables III and IV and in Table V for the same halide in N-methylpropionamide. At low halide concentrations in dimethylformamide (Table III) and at all halide concentrations in N-methylpropionamide, the instantaneous rate constants show no trend with time. At higher initial halide concentrations in dimethylformamide (Table IV), the instantaneous rate constants increase with time. This is due to the operation of a positive salt effect as shown in Fig. 1. The ionic strengths shown in this plot are the concentrations of the added salts plus one-half the initial *t*-butyl bromide concentrations, *i.e.*, the ionic strength at 50% reaction.

It is particularly noteworthy that the two bromides accelerate the rate more strongly than does tetraethylammonium nitrate. Spieth and Olson[8] have reported similar results for *t*-butyl bromide in aqueous acetone with added lithium perchlorate, lithium bromide and lithium chloride. All three salts accelerated the rate, with the perchlorate having the largest effect and the chloride the least effect. In connection with our data, we consider it

t-BuBr	.0955[a]	39.2		.12 ± 0.01
t-BuBr	.197	39.2		.13 ± 0.01
t-BuBr	.0785	50.7		5.0 ± 0.2
t-BuBr	.0810	50.7	0.1002 Et_4N^+, NO_3^-	5.4 ± 0.1
t-BuBr	.0788	50.7	0.0922 Et_4N^+, Br^-	4.9 ± 0.2

[a] Final olefin titer = 97%. [b] Run conducted in glass-stoppered flask. All other runs were in sealed tubes. [c] Abbreviation for dimethylneopentylcarbinyl chloride.

In the one run where the olefin formed was determined as a function of time, the ampoules, containing a 5-ml. aliquot, were broken under 100 ml. of carbon tetrachloride containing 10 ml. of a freshly standardized solution of bromine in carbon tetrachloride. This solution was allowed to stand 30 minutes, 10 ml. of 10% aqueous potassium iodide was added and the liberated iodine was titrated with standard thiosulfate solution. This same procedure was used in determining infinity olefin titers.

pertinent that conductivity measurements on potassium nitrate and potassium bromide in dimethylformamide at 25°[9] indicate that the bromide is much less associated than is the nitrate in this solvent, since the bromide shows only a small deviation from the calculated, limiting Onsager slope, whereas the nitrate shows a very sizable deviation. This suggests that the differences that we observe between bromides and nitrates may be due, in part at least, to differences in the extent of ion-pairing. At any rate, there is no evidence for any retardation of the rate by bromide ion. In dimethylformamide there is a clear acceleration of the rate with added bromide ion. In N-methylpropionamide, the instantaneous rate constants are constant with time, and a run with added tetraethylammonium bromide shows no significant slowing of the rate.

Discussion

The usual description of the mechanism of solvolysis reactions is in terms of the SN1–SN2 (and/or E_1–E_2) classification of the Hughes–Ingold school.[3,10] The SN1 and E_1 reactions involve a rate-determining ionization to a cationic intermediate. The solvent functions, largely in an electrophilic manner, to heterolyze the C–X bond and solvate the anion, and no covalent interaction between the cation and the solvent is required. The SN2 and E_2 mechanisms, on the other hand, involve a concerted process, in which the solvent functions both

by virtue of its ionizing power and its nucleophilic character.

It is now generally recognized that these reaction categories are limiting mechanistic extremes of a gradation of mechanisms, reflecting a continuous spectrum of transition states. The existence of borderline or intermediate cases has been recognized by the Hughes–Ingold school.[10,11] Winstein, Grunwald, *et al.*, classify all cases in which there is evidence both for an intermediate and covalent interaction of the cation with the solvent as borderline cases and have discussed these in terms of the canonical structures, I, II and III, contributing to the transition state.[12] Swain and his coworkers[13] have emphasized the importance of ion–dipole solvation bonds to the cation as well as co-

Z: R–X	Z–R: X	Z: R^+: X
I	II	III

valent solvation bonds to the cation and have argued that, in almost all solvolytic reactions, the solvent is involved in both a nucleophilic and an electrophilic capacity.

A striking feature of the solvolysis reactions in dimethylformamide and N-methylpropionamide is that they are unexpectedly slow, even if one allows that these solvents do not rival hydroxylic solvents in their capacity for electrostatic solvation.[14] More striking, the rates in the two solvents are very similar in spite of the fivefold difference in dielectric constant. Nevertheless, the activation energies in these solvents are the ones usually obtained for these halides.[12] We have rate data at three temperatures in both solvents for *t*-butyl bromide and at two temperatures in dimethylformamide for *t*-

butyl chloride. For *t*-butyl bromide, these result in activation energies of 23 ± 1 kcal. in N-methylpropionamide and 22.1 ± 0.5 kcal. in dimethylformamide. For *t*-butyl chloride in dimethylformamide the activation energy is 25 ±1 kcal.

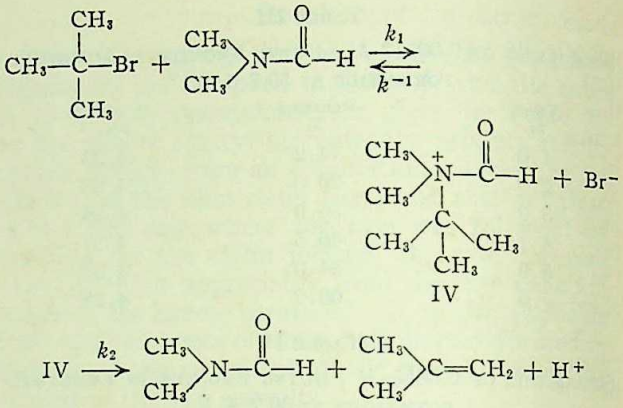
As another criterion of mechanism, we have applied the Winstein–Grunwald equation[12] to our data. According to this equation

$$\log k = \log k_0 + mY$$

the difference in the logarithms of the rate constants for the first order solvolysis of a given substance in a solvent and in the standard solvent, 80% aqueous ethanol, is the product of two parameters, m, the compound parameter, and Y, a measure of the ionizing power of the solvent. Since the m's and log k_0's are known[4b,12] for all three halides, we can calculate Y-values for both solvents. For dimethylformamide, we can obtain three Y-values, one for each halide on which we have rate data. The resulting values for Y are −3.47 from *t*-butyl chloride, −2.46 from *t*-butyl bromide and −3.72 from dimethylneopentylcarbinyl chloride. Similarly, for N-methylpropionamide, we can obtain two Y-values, −2.60 from our rate data with *t*-butyl bromide and −3.14 from our rate data with dimethylneopentylcarbinyl chloride. Clearly, our rate results are not correlated satisfactorily by the Winstein–Grunwald equation. However, in spite of the impressive success achieved by the Winstein–Grunwald equation in correlating the rates of solvolysis of organic halides with solvent change and the usefulness of this equation in diagnosing solvolytic mechanisms, it does not follow that an absence of correlation, in a particular instance, necessitates a basic difference in mechanism.

This point has been emphasized in a searching and cogent analysis of the Winstein–Grunwald relation by Wilputte-Steinert and Fierens.[15] As these authors have indicated, for a given halide m cannot be expected to be constant in all solvents, since the delocalization of charge must produce variable perturbations which depend on the nature, and composition of the solvent.[16] Also, the ionizing power, Y, is not an intrinsic property of the solvent. The solvation process is not limited to the carbon–chlorine bond. It must involve the entire circumference of the halide structure and, as the halide structures are varied, there must result differences in the degree of solvation of the initial states and transition states.

The reactions of halides in dimethylformamide have been discussed in terms of an intermediate or product involving covalent bonding of the cation to the solvent.[1c,d] For the solvolysis of *t*-butyl bromide in dimethylformamide, one might write[17]

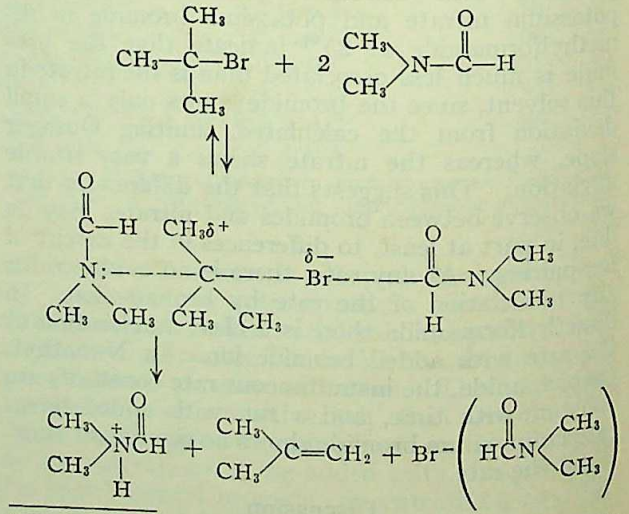


As written, this mechanism suggests a backside attack by the solvent on the C–Br bond. However, it is possible that IV results from a frontside attack as the C–Br bond is being broken. If we assume a steady state with respect to IV, the rate expression is

$$\text{rate} = \frac{k_1 k_2(\text{bromide})}{k_{-1}(\text{Br}^-)} + k_2$$

Since, in this case, there is no slowing of the rate by added bromide ion and since the rate of bromide ion liberation is equal to the rate of olefin formation, $k_2 >> k^{-1}(\text{Br}^-)$, and the rate $\cong k_1$(bromide).[18]

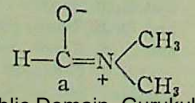
In addition, there is the possibility of a concerted elimination reaction involving two or more solvent molecules. This type of mechanism was first suggested by Holysz,[19] who studied the dehydrohalogenation of 4-halo-3-ketosteroids in dimethylformamide. This mechanism might be represented as



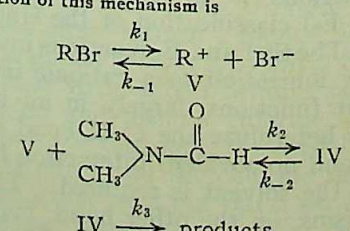
(15) L. Wilputte-Steinert and P. J. C. Fierens, *Bull. soc. chim. Belg.*, **64**, 308 (1955).

(16) In this connection, it is pertinent to point out that the substituent constants in the Hammett equation vary markedly with solvent changes; H. H. Jaffé, *Chem. Revs.*, **53**, 191 (1953).

(17) In structure IV we have followed the previous practice[1c,d] of making the nitrogen atom the nucleophilic center of the dimethylformamide molecule. As was pointed out by a referee, it is also probable that, in dimethylformamide, the nitrogen acts electrophilically and the oxygen nucleophilically. Dimethylformamide shows restricted rotation about its carbon–nitrogen bond (W. D. Phillips, *J. Chem. Phys.*, **23**, 1363 (1955); H. S. Gutowsky and C. H. Holm, *ibid.*, **25**, 1228 (1956)) suggesting a large contribution from structure a.



(18) A variation of this mechanism is



If we assume a steady state with respect to both IV and V and, further, that terms involving (k_{-1}(Br$^-$)) are negligible with respect to the other terms present, we again find that rate $\cong k_1$(bromide).

Although this mechanism has been depicted as involving only two solvent molecules, it is possible that more than two are involved or, alternatively, that a single solvent molecule is involved in a cyclic transition state as suggested by Kornblum and Blackwood.[1d] In this case, too, the roles of the oxygen and nitrogen atoms of dimethylformamide may be reversed.[17] Also, the ion–dipole solvation bond to carbon may be from the front rather than the rear. In any case, the kinetics would be those observed.

Our results do not permit us to make a choice between these possibilities. It is clear that there may be solvolytic reactions in which the solvent functions in a purely electrophilic manner. It is equally probable that there are solvolytic mechanisms in which the action of the solvent is entirely nucleophilic. Between these two extremes there must be a broad range of mechanisms in which two or more solvent molecules are involved and in which the solvent acts both electrophilically and nucleophilically. These mechanisms, thus, reflect an equally broad and continuous spectrum of transition states differing in the configurations of the solvating solvent molecules and are best considered as differing in degree but not in kind.

Perfluoroalkylzinc Compounds. I. The Preparation and Properties of Perfluoroalkylzinc Halides[1,2]

By William T. Miller, Jr., Elliot Bergman[3] and Arnold H. Fainberg

Received January 30, 1957

Convenient methods for the preparation of perfluoroalkylzinc compounds of the type R_FCF_2ZnI (solvated) are described together with the results of related work on the reactions of fluoroperhaloalkyl bromides and iodides with metallic zinc. The perfluoroalkylzinc iodides as exemplified by perfluoro-*n*-propylzinc iodide are shown to be thermally stable in solution and inert to carbon dioxide and to oxygen. They are strong Lewis acids, in contrast to the alkylzinc iodides. They are readily hydrolyzed, cleaved by halogen and converted into olefins by pyrolysis. They are unreactive with organic electrophiles, but under vigorous conditions in the presence of such compounds containing active hydrogen they tend to yield R_FCF_2H rather than addition products.

Introduction

Evidence for the existence of perhaloalkylzinc compounds was first obtained in attempting to dehalogenate fluoroperhalo compounds which do not contain halogens other than fluorine in the 1,2-relation to produce olefins. Reduced products were isolated by hydrolysis of reaction mixtures under conditions which suggested the intermediate formation of perhalo zinc compounds.[4] Efforts were then made to prepare perfluoroalkylzinc compounds, and it was found that perfluoro-*n*-propylzinc iodide could be obtained readily in dioxane solution.[5] The present paper presents work on the preparation and properties of solvated perfluoroalkylzinc compounds of the type R_FCF_2ZnX and on related reactions of fluoroperhaloalkyl iodides and bromides with metallic zinc.

The preparation of solutions of zinc and cadmium perfluoroalkyls from trifluoromethyl iodide and heptafluoro-*n*-propyl iodide has been reported independently by Haszeldine[6] with experimental work on heptafluoro-*n*-propylzinc iodide appearing more recently.[7] Earlier attempts by Emeléus and Haszeldine to prepare organozinc compounds from trifluoroiodomethane and pentafluoroiodoethane yielded only fluoroform and pentafluoroethane as organic products.[8]

Discussion and Results

In the present work all of the fluoroperhaloalkyl iodides and bromides tested were found to react with zinc dust in donor-type solvents such as aliphatic ethers and pyridine at or below reflux temperatures. Depending upon the structure of the perhaloalkyl halide and the choice of solvent and reaction conditions, one or more products of the type shown below were isolated. Organozinc compounds have been obtained only when Y is fluorine. When Y is chlorine intramolecular dehalogenation ordinarily occurs readily and always with great ease when Y is bromine or iodine.

$$R_FCFYCF_2X + Zn \xrightarrow{\text{solvent}} R_FCF{=}CF_2 \quad (I)$$

X = Br or I: R_FCFYCF_2ZnX (II)

Y = F or other halogen: $R_FCFYCHF_2$ (III)

$[R_FCFYCF_2-]_2$ (IV)

Perfluoro-*n*-propyl iodide was found to react readily with zinc in dioxane to yield more than 75% perfluoro-*n*-propylzinc iodide (II) plus small amounts of heptafluoropropane (III). Perfluoro-*n*-propyl bromide reacted in 1,2-dimethoxyethane after a long induction period to yield 60% of the corresponding zinc compound (II). Perfluoro-*n*-pentyl iodide reacted sluggishly with zinc in dioxane to yield a mixture of perfluoro-*n*-pentylzinc iodide (II), undecafluoro-*n*-pentane (III) and perfluoro-*n*-decane (IV). The perhalomethanes failed to

give detectable quantities of organozinc compounds under any of the conditions utilized. Trifluoroiodomethane was converted into fluoroform (III), dichlorofluoroiodomethane yielded dichlorofluoromethane (III) plus the dimer product (IV) and bromodichlorofluoromethane yielded condensed material in addition to undergoing general decomposition to form inorganic products. 1,2-Dichloro-1,2,2-trifluoroiodoethane yielded only its dehalogenation product, chlorotrifluoroethylene (I), under the experimental conditions utilized.[9]

The reactions between zinc and fluoroperhaloalkyl iodides and bromides were greatly facilitated by the presence of a donor-type solvent. In the absence of solvent or in the presence of non-donor type solvents such as benzene, methylene chloride and ethyl heptafluoro-*n*-butyrate, no reaction was observed with *n*-propyl iodide at temperatures up to 100°. Haszeldine and Walaschewski obtained somewhat similar results at moderate temperatures and have reported that perfluoro-*n*-propyl iodide and zinc react at 310° to yield perfluoro-*n*-hexane.[7] The behavior of perfluoroalkyl iodides with zinc differs from that of alkyl iodides, which yield dialkylzinc compounds at elevated temperatures in the absence of solvent.[10]

Perfluoro-*n*-propylzinc Iodide.—It was found that perfluoro-*n*-propylzinc iodide could be conveniently prepared in high yield by reaction of zinc with perfluoro-*n*-propyl iodide in dioxane or 1,2-dimethoxyethane solution at temperatures up to about 100°. Other donor-type solvents such as pyridine also could be utilized. Small amounts of heptafluoropropane always were formed during reaction of the perfluoroiodide with zinc, but once formed the zinc compound was stable in solution at reflux temperatures for prolonged periods and on storage at room temperature for more than a year. This thermal stability in solution, which is in striking contrast to the instability at relatively low temperatures exhibited by the corresponding magnesium[11,12] and lithium[13] compounds, suggests that the formation of monohydroperfluoroalkanes during the preparation of perfluoroalkylzinc compounds proceeds by free radical abstraction of a hydrogen atom from solvent rather than by removal of a proton by a perfluorocarbanion as previously suggested.[7] The low order of reactivity found with carbonyl compounds described below also argues against the availability of a reactive carbanion.[14]

Attempts to prepare perfluoro-*n*-propylzinc iodide in ethyl ether solution led to the rapid evolution of heptafluoropropane with the production of little, if any, zinc compound. This anomalous result in diethyl ether is attributed to small amounts of peroxide which were found to be present. Since typical free radical type inhibitors such as hydroquinone (quinone) were found to quench the reaction, these observations can be accounted for by an organic peroxide–zinc induced free radical chain reaction between the iodide and ether. Similarly, Emeléus and Haszeldine isolated only pentafluoroethane from the reaction of pentafluoroiodoethane with zinc–copper couple in ethyl ether.[8] However, Haszeldine and Walaschewski[7] subsequently reported no difficulty with this solvent. Pierce, McBee and Judd,[13] following up our preliminary report,[4] obtained only heptafluoropropane by reaction of perfluoro-*n*-propyl iodide with zinc in commercial dioxane, a solvent which readily forms peroxide on exposure to air. The choice and purity of solvent utilized for the preparation of perfluoroalkylzinc compounds is thus shown to be of primary importance. Peroxide-free dioxane and 1,2-dimethoxyethane were found to be effective and convenient solvents; 1,2-dimethoxyethane was especially advantageous in some instances because of greater solubility of its addition compounds.[15] The purity of the zinc metal utilized for reaction was not indicated as critical. All dry unoxidized samples of commercial zinc dust tested worked well. Similarly the reaction temperature did not exert a major effect upon the yield of perfluoro-*n*-propylzinc iodide over the range investigated (*ca.* 25–100°).

The concentration of heptafluoropropyl iodide in solution was found to be the most important variable in determining the relative yields of organozinc compound II and of dimer product IV. With dropwise addition of the iodide to zinc dust suspended in dioxane no perfluoro-*n*-hexane could be isolated. On the other hand, when a concentrated solution of iodide was employed in a sealed tube, a vigorous exothermic reaction occurred to form perfluorohexane as the major product. These observations suggest that the dimerization reaction proceeds by a bimolecular homolytic type reaction of the iodide on the zinc surface rather than by secondary reaction with perfluoropropylzinc iodide. This conclusion was supported by the observed failure of a filtered solution of perfluoropropylzinc iodide in dioxane to react with additional added iodide. Haszeldine and Walaschewski[7] obtained perfluoro-*n*-hexane in up to 45% yield by a sealed-tube reaction of perfluoro-*n*-propyl iodide with zinc in dioxane. Henne obtained 77% perfluoro-*n*-hexane by the same type reaction in refluxing acetic anhydride–methylene chloride.[16,17]

The chemical reactivity of the perfluoroalkylzinc compounds was found to lie between that of the stable relatively unreactive perfluoroalkylmercury compounds[8] and the unstable highly reactive perfluoroalkylmagnesium compounds.[5,11,12] The fol-

(9) Some coupled product probably was formed also; see R. N. Haszeldine, *J. Chem. Soc.*, 4423 (1952); A. L. Henne, THIS JOURNAL, **77**, 2334 (1955).

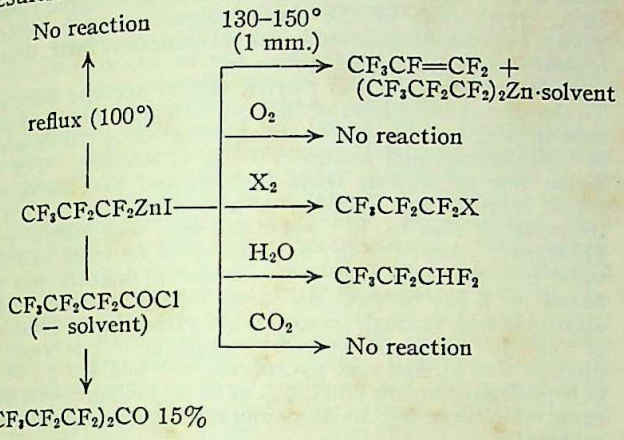
lowing chart summarizes illustrative experimental results.



No reaction was observed with oxygen over long periods. Hydrolysis proceeded slowly with the addition of water at room temperature. The addition of aqueous acid or base increased the rate of hydrolysis markedly. Chlorinolysis and brominolysis occurred exothermally, but heating to 80–100° was required for rapid reaction with iodine. This behavior is in strong contrast to that of the lower alkyl zinc compounds which react vigorously with water at room temperature and ignite with the halogens and with oxygen.[18] The hydrolysis and halogenolysis reactions demonstrate the presence of the carbon–zinc bond.

An outstanding property of the perhaloalkylzinc halides is their strength as Lewis acids. Perfluoropropylzinc iodide exhibits a low order of reactivity with organic electrophilic systems. Attempts to carry out typical organo-metallic synthetic reactions in dioxane solution were unsuccessful. At low temperatures little reaction occurred. Perfluoropropylzinc iodide could be prepared in acetone solution. Carbon dioxide was without effect at 100°. Aldehydes, ketones, anhydrides and acid halides containing enolizable hydrogen were unreactive but yielded heptafluoropropane and condensation and solvent cleavage products on long refluxing. Less complete consumption of the zinc compound took place with reactants containing no α-hydrogen, but none of the desired addition products could be isolated.[19] By largely removing the dioxane solvent from perfluoro-*n*-propylzinc iodide at low pressure and treating the solid residue with perfluoro acid chlorides the corresponding perfluoro ketones were obtained in low yields. However, even under these conditions acetyl chloride and acetic anhydride, which contain enolizable hydrogen, yielded only heptafluoropropane.

The increase in acid strength of the perhaloalkylzinc halides over that of the alkylzinc compounds may be accounted for by the strong electron-attracting property of the perfluoropropyl group, which results in a more polar carbon–zinc bond and higher solvation energies. The high energies of solvation contribute to the ease of formation of the zinc compounds in donor-type solvents and to their stability once formed. Efforts to remove solvent completely without decomposition were unsuccessful.[21] As indicated above, removal of solvent *in vacuo* left a crystalline residue of solid perfluoropropylzinc iodide solvent complex. Sublimation of the solid dioxane complex yielded perfluoropropene and a very small amount of perfluoropropylzinc dioxanate. Pyrolysis of the corresponding 1,2-dimethoxyethane addition compound gave a higher yield (50%) of perfluorodi-*n*-propyl zinc as the etherate in addition to perfluoropropene.[22]

Experimental[23–25]

Starting Materials.—Perfluoroacids were purchased from the Minnesota Mining and Manufacturing Co. Silver salts of perfluoroacids were prepared by previously described procedures.[26] Pure, peroxide-free dioxane was prepared by the method of Fieser.[27] Other ethers were purified by refluxing with and distilling from sodium wire under dry nitrogen. They were stored in the dark over sodium under nitrogen. Baker and Adamson 90% zinc dust was used in all experiments.

Perfluoroalkyl Iodides.—Heptafluoro-*n*-propyl iodide was prepared in 92% yield by a procedure similar to that described by Hauptschein and Grosse.[26] Found: b.p. 39.3° (736 mm.), f.p. −95.3, f.p. dep. 0.1°, $n^{20}D$ 1.3281, d^{20}_4 2.0566, mol. wt. 295 and 299 (vapor density), $MR^{20}D$ 29.22; reported[26]: b.p. 41.2°, $n^{20}D$ 1.3272, d^{20}_4 2.0626; calculated for C_3F_7I: mol. wt. 296, $MR^{20}D$ 29.64.[28]

Perfluoro-*n*-amyl iodide was prepared in 65% yield by heating an intimate mixture of 108 g., 0.257 mole of dry silver perfluoro-*n*-hexanoate and 85 g., 0.334 mole, of iodine in a distilling flask with a free flame. Found: b.p. 94° (755 mm.), $n^{17}D$ 1.3310; reported[29]: b.p. 94°, $n^{31.5}D$ 1.3243.

Trifluoroiodomethane was prepared in 80% yield by the method of Henne.[30] It was washed with aqueous alkali, dried by passage through concentrated sulfuric acid or phosphorus pentoxide and used without further purification.

Bromodichlorofluoromethane was prepared by the vapor phase bromination of dichlorofluoromethane at 475° by the procedure of Miller and Howald.[31] Found: b.p. 50.4° at 727 mm., $n^{20}D$ 1.4308; reported[31]: b.p. 50.2° (734 mm.), $n^{20}D$ 1.4304.

Dichlorofluoroiodomethane was prepared in 44% yield by treating bromodichlorofluoromethane with sodium iodide in acetone for 3 hr. at 120°.[31] Found: b.p. 87–90° (735 mm.), reported[31] b.p. 90°.

Perfluoroacid Chlorides.—Perfluoroacid chlorides were prepared by the reaction of the corresponding acids with phosphorus pentachloride (10–20 mole per cent. excess) followed by distillation of the crude product from a small

(21) The isolation of small amounts of $CF_3CF_2CF_2ZnI$ by fractional vacuum sublimation has been reported by Haszeldine and Walaschewski.[7]

amount of dimethylaniline. In this way trifluoroacetyl chloride, b.p. −20 to −19° (740 mm.), and perfluoro-*n*-butyryl chloride, b.p. 38–39° (740 mm.), were obtained in 76 and 89% yields, respectively.

Perfluoro-*n*-propylzinc Iodide.—The following preparative procedure gave consistently reproducible results. A 1-l. three-necked flask was fitted with a sealed stirrer, a dropping funnel and a reflux condenser in series with a Dry Ice trap and charged with 39.2 g., 0.60 gram-atom, of zinc dust. The apparatus was flushed with warm dry nitrogen and 120 ml. of dioxane added; 20 ml. of a solution of 88.8 g., 0.300 mole, of perfluoro-*n*-propyl iodide in 60 ml. of dioxane was added and the stirred solution warmed to 100°. The reaction started at about 60°.[32] The remainder of the solution was added without external heating at such a rate that gentle reflux was maintained. Shortly after this period of about 2 hr. reaction was complete, as evidenced by a drop in temperature. The Dry Ice trap contained 5.2 g., 10%, of 1,1,2,2,3,3,3-heptafluoropropane; 25 g. of water was added to the reaction flask, and the mixture refluxed for 4 hr. during which time 39 g., 77%, of heptafluoropropane was collected. Found: b.p. −17° (735 mm.), f.p. −148.5° without depression, mol. wt. 168 and 168, narrow carbon–hydrogen infrared absorption band at 3.36 μ; reported[33]: b.p. −18 to −17°; calculated for C_3HF_7, mol. wt., 170.

In order to demonstrate positively that the heptafluoropropane produced during the reaction could not be accounted for by hydrolysis of the zinc compound,[34] the reaction was run under rigorously anhydrous conditions in an all-glass apparatus. The zinc dust was introduced into the apparatus and dried with a stream of nitrogen while warming the flask. Dry dioxane, 158 g., was introduced under a blanket of nitrogen. The zinc was maintained in suspension by a magnetic stirrer and the dioxane refluxed. After 15 minutes a 15-ml. sample of dioxane was removed and a Karl Fischer titration[35] for water was found to be indistinguishable from a blank determination. Perfluoro-*n*-propyl iodide, 93.0 g., 0.314 mole, was added dropwise to the stirred zinc suspension at such a rate that the mixture remained at approximately 75°. A total of 6.8 g. (13%) of heptafluoropropane, free of perfluoropropene, and 6.2 g. (7%) of starting iodide were collected in the trap.[36] The reaction mixture was filtered free of zinc through a sintered glass filter and the residual zinc washed with 43 g. of dioxane. The combined filtrates were refluxed with 50 ml. of water to yield 36.3 g., 68%, of heptafluoropropane. One to two grams of an oil, b.p. >100°, remained in the hydrolyzate.

The above procedure was repeated using 1,2-dimethoxyethane as solvent. The reaction could be started at room temperature. A 0.240-mole run afforded 2.5 g., 6%, of perfluoropropane and 2 g., 3%, of starting iodide. Hydrolysis of the filtered solution yielded 33.5 g. which on redistillation gave 30.5 g., b.p. −19° (739 mm.), of heptafluoropropane corresponding to a 75% yield of zinc compound based on starting iodide.

Using 84 g. of pyridine and 42 g. of benzene as solvent and maintaining the reaction temperature at 60° by the rate of iodide addition, 71 g. of heptafluoro-*n*-propyl iodide yielded 5% heptafluoropropane, 10% recovered iodide and 42% zinc compound. The reaction mixture unlike those obtained with the above ether solvents was dark colored, tarry and difficult to filter.

The all-glass apparatus also was used as described above with ethyl ether as solvent. Upon addition of each portion of a total of 62 g. of iodide to 39 g. of zinc in 92 g. of ether, a deep red color appeared which gradually faded. A total of 37 g. of material was condensed in the cold trap. Distillation gave 15 g. of heptafluoropropane, b.p. −17° (734 mm.), and 22 g. of ether-soluble residue which contained iodine (sodium fusion). The residue reacted with zinc in ether to give a gas and was assumed to be unchanged iodide, 36%. Hydrolysis of the dark ethereal reaction mixture gave <1 g. of heptafluoropropane showing that little, if any, organozinc compound was present.

A similar reaction was carried out in acetone solution. To the stirred suspension of 10.4 g., 0.16 gram-atom, of zinc dust in 44 g. of dry acetone was added 39 g., 0.13 mole, of heptafluoropropyl iodide in 11 g. of acetone. The reaction was so mild at room temperature that all of the iodide solution was added over a 2-minute period. The temperature rose to 50° when the zinc was stirred very vigorously. After 0.5 hr. only 0.5 g. of material had distilled into the cold trap. The reaction mixture was refluxed for 8 hr. to yield 8.4 g. of volatile product which after bubbling through concentrated sulfuric acid consisted of 5.3 g., 24%, of heptafluoropropane. The reaction mixture was filtered and hydrolyzed to yield 7.0 g., 31%, of heptafluoropropane and 3.3 g. of an oil boiling over a wide range which appeared to be mainly condensation products of acetone.

Perfluoro-*n*-propylzinc Bromide.—A glass ampoule was charged with 5.0 g., 0.020 mole, of perfluoro-*n*-propyl bromide, 1.6 g., 0.025 gram-atom, of zinc dust and 10 ml. of 1,2-dimethoxyethane and rocked mechanically while heated up stepwise to 90° over a 73-hr. period. The zinc did not appear to react. The ampoule was set aside, and it was observed after 1.5 months that the zinc was etched and crystalline material had formed. No heptafluoropropane or starting material was found. Hydrolysis yielded 2.0 g. of heptafluoropropane corresponding to a 60% yield of heptafluoro-*n*-propyl zinc bromide.

Perfluoro-*n*-amylzinc Iodide.—A solution of 49.0 g., 0.124 mole, of perfluoro-*n*-amyl iodide in 50 ml. of dioxane was added dropwise to a stirred suspension of 9.2 g., 0.14 gram-atom, of zinc in 100 ml. of dioxane maintained at 65° by an oil-bath. The reaction was not exothermic. The second half of the iodide solution was added over a 0.5-hr. period with the temperature held at 85°. After stirring for an additional 5 hr. at 80–82° and standing overnight, 7.0 g. of undecafluoropentane was isolated which was identified by its infrared spectrum and its b.p. of 45° (755 mm.). Traces of unsaturated material were present as indicated by decolorization of acetone permanganate solution. A lower liquid layer separated out of the dioxane. This material, 8.0 g., b.p. 146–148° at 755 mm., $n^{20}D$ <1.3 and m.p. 32°, contained fluorine but no iodine; reported[37] for perfluoro-*n*-decane: b.p. 144°, m.p. 36°.

Hydrolysis of the reaction mixture yielded 9.5 g., 28% of undecafluoropentane, b.p. 45° and $n^{20}D$ <1.3. Calcd. for C_5HF_{11}: C, 22.23; mol. wt., 270. Found: C, 22.4; mol. wt., 271, 271.

Attempted Reaction of Perfluoro-*n*-propylzinc Iodide with Heptafluoro-*n*-propyl Iodide.—A filtered solution of 0.22 mole of heptafluoro-*n*-propylzinc iodide in 105 ml. of 1,2-dimethoxyethane was refluxed with 64.5 g., 0.218 mole of heptafluoro-*n*-propyl iodide for 24 hr. No insoluble material separated. Distillation yielded 51.5 g., b.p. 39–42°, $n^{20}D$ 1.3283, an 80% recovery of the propyl iodide. Similar reactions with dioxane solutions of perfluoropropylzinc iodide and *t*-butyl chloride, perfluoroallyl iodide and 1,2-dichlorotrifluoroiodoethane also failed to give coupled products.

Dimerization of Heptafluoro-*n*-propyl Iodide. Perfluoro-*n*-hexane.—The exact procedure of Henne[16] was repeated and found to yield 62% perfluoro-*n*-hexane and 13% heptafluoropropane. In a second run the acetic anhydride was replaced by 1,2-dimethoxyethane. Forty-eight grams, 0.162 mole, of heptafluoro-*n*-propyl iodide, 19.6 g. (0.298 gram-atom) of zinc dust, 16 ml. of 1,2-dimethoxyethane and 42 ml. of methylene chloride were sealed in a Pyrex ampoule at Dry Ice temperature. On warming to room temperature an exothermic reaction took place. After rocking one day at room temperature, it was observed that a new liquid layer had appeared. After eight days the ampoule was vented to yield 3 g., 11%, of heptafluoropropane. The residue was distilled *in vacuo* to yield a two-phase system. The lower layer, 19.8 g., after separation, yielded 17 g., b.p. 57.0°, 62%, of perfluoro-*n*-hexane; found: $n^{20}D$ <1.3, d. 1.71 (gravitometer), mol. wt. 336,

(32) Induction periods of a few minutes were observed in only two out of more than fifty preparations.

(33) A. F. Benning and J. D. Park (1950), U. S. Patent 2,490,764.

(34) Since heptafluoropropane was evolved throughout the reaction period, it was considered unlikely that simple hydrolysis could explain its formation.

(35) J. Mitchell and D. M. Smith, "Aquametry," Interscience Publishers, Inc., New York, N. Y., 1948, p. 120.

(36) Unless otherwise indicated trap materials were worked up as follows. The trap was immersed in an ice-bath and the material b.p. <0° was distilled into another trap. The crude fractions were identified by spectroscopic examination and chemical tests, *e.g.*, the unsaturation test with potassium permanganate.

and 344, immiscible with benzene or ether; reported[16]: n_D^{20} <1.3, d^{20}_4 1.6995, b.p. 57°., calcd. for C_6F_{14}: mol. wt. 338. The residual salts in the ampoule were hydrolyzed to yield 5.5 g., 20%, of heptafluoropropane.

The above procedure was repeated using only 1,2-dimethoxyethane as solvent. Heptafluoropropane, perfluoro-*n*-hexane and heptafluoro-*n*-propylzinc iodide were obtained in 15, 47 and 29% yields, respectively.

Attempted Preparation of Other Zinc Compounds.—Reactions between powdered zinc metal and the following compounds were carried out under conditions found favorable for the preparation of heptafluoro-*n*-propylzinc iodide.

Trifluoroiodomethane.—A 500-ml. three-necked flask which was fitted with a mechanical stirrer, a thermometer and a Dry Ice reflux condenser and connected in series with Dry Ice and liquid nitrogen traps was charged with 19.6 g., 0.30 gram-atom, of zinc and dried as described above; 14 g. of 1,2-dimethoxyethane and 21 g. of trifluoroiodomethane were added to the flask. Reaction started on warming with the palm of the hand but was quenched by adding 124 g. of additional solvent; 20 g. of additional iodide was added slowly to the flask through the Dry Ice condenser but reaction failed to start. On warming a sudden reaction caused the loss of some material, but now the remaining 35 g. of the total of 76 g., 0.39 mole, of iodide was added at such a rate that the reaction mixture remained at 60–65°. During the reaction 10 g., 39%, of fluoroform (infrared spectrum) was collected in the liquid nitrogen trap. Found: mol. wt., 70.8, 70.9. Calcd. for CHF_3: mol. wt., 70.0. Hydrolysis of the reaction mixture gave no fluoroform indicating that a stable zinc compound was not formed. Considerable fluoride ion was present in the reaction mixture.

Bromodichlorofluoromethane.—This reaction was carried out as described above for the preparation of heptafluoro-*n*-propylzinc iodide in dioxane in the all-glass apparatus; 36.4 g., 0.20 mole, of bromide was added to the stirred suspension of 16 g., 0.23 gram-atom, of zinc in 80 ml. of dioxane maintained at 50°. The mixture became dark in color and after stirring overnight at 55–60° was black. No material was collected in the cold trap on hydrolysis. The filtered solution yielded no low boiling material. Steam distillation yielded 2.1 g., n_D^{20} 1.4198, and a liquid residue of 11 g. The hydrolysis mixture gave strong tests for fluoride, chloride and bromide ions.

Dichlorofluoroiodomethane.—As described above, 92 g., 0.402 mole, of iodide and 41 g. of 1,2-dimethoxyethane were added to 57.6 g., 0.88 gram-atom, of zinc suspended in 199 g. of solvent at such a rate that the temperature was maintained at 30°. The reaction mixture was distilled to yield 21 g., b.p. up to 25°, and 18 g., 44%, of dichlorofluoromethane, b.p. 10–13°, identified by its infrared spectrum; reported[38] b.p. 8.9°. This material contained formaldehyde and methyl iodide in small amounts. A dinitrophenylhydrazone, m.p. 162–165°, was prepared; its infrared spectra was superimposable with that of authentic formaldehyde dinitrophenylhydrazone. Steam distillation of the reaction mixture gave no dichlorofluoromethane, showing that no zinc compound was present, but gave 10 g. of a liquid product. Redistillation yielded 5.7 g., b.p. 86–101°, n_D^{26} 1.4041 to 1.4118. This material contained fluorine and chlorine, and its infrared spectrum corresponded to that of *sym*-difluorotetrachloroethane n_D^{26} 1.4122, b.p. 91°. It corresponded to 14% of the starting material.

1,2-Dichlorotrifluoroiodoethane.—A solution of 21.1 g., 0.076 mole, of iodide in 34 ml. of dioxane was added to 6.5 g., 0.10 gram-atom of zinc, suspended in 24 ml. of dioxane during a 2-hr. period while maintaining the temperature at 15–20°. A total of 5.5 g., b.p. <0°, identified as chlorotrifluoroethylene (63%) by its infrared spectrum, was isolated. Hydrolysis of the reaction mixture yielded no hydrogen compounds.

Pyrolysis of Perfluoro-*n*-propylzinc Iodide.—An apparatus consisting of a 500-ml. round flask, with a 1-in. diameter neck 13 in. long was connected in series with two traps and charged with 78 ml. of dioxane solution containing 0.244 mole[39] of perfluoro-*n*-propylzinc iodide. The dioxane was removed *in vacuo* to the second trap by gradually warming the flask to 60° and lowering the pressure to 1 mm. With the pressure at 1 mm. the flask and first trap were isolated from the rest of the system by a stopcock, and the first trap was cooled in liquid nitrogen. The flask was immersed in a deep oil-bath, 3.5 in. of the neck of the flask was covered with oil and the temperature raised to 150–160°. Distillate was collected in the trap and small amounts of a white crystalline sublimate condensed on the cooler portion of the neck of the flask. After 15 hr. the reaction was stopped and the volatile material in the trap bubbled through concentrated sulfuric acid to remove dioxane. In this way 29 g., 79%, of perfluoropropene (infrared spectrum), b.p. less than 0°, was collected. Photochemical bromination of 8.1 g. (0.054 mole) of the propene distillate from a similar pyrolysis with 6.5 g. (0.041 mole) of bromine in a Pyrex ampoule yielded on simple distillation 11.7 g. of 1,2-dibromohexafluoropropane. Found: b.p. 70.0–72.0° (734 mm.), $n^{20}D$ 1.3588, d^{20}_4 2.163, MR_D 31.53, reported[40]: b.p. 72–73° at 740 mm., $n^{20}D$ 1.3588, d^{20}_4 2.1693; calcd. for $C_3Br_2F_6$: $MR^{20}D$ 31.50.[28]

The white hygroscopic sublimate (*ca.* 0.5 g.) contained traces of iodide which could be removed by resublimation. It reacted with water to give a gas, decomposed on heating to give perfluoropropene (infrared spectrum), reacted vigorously with bromine, gave a Tollens test and burned only when held in a flame. The reactions of this sublimate suggested that it was perfluorodi-*n*-propylzinc dioxanate.

Reactions of Perfluoro-*n*-propylzinc Iodide.—The following reactions were carried out with perfluoropropylzinc iodide prepared as described above. Solid dioxane solvate containing from one to two moles of dioxane per mole of perfluoro-*n*-propylzinc iodide was prepared by removing excess solvent under reduced pressure.

Iodine.—When 0.17 mole of zinc compound was treated with 50.8 g., 0.200 mole, of iodine in 90 ml. of diozane, no apparent reaction occurred until the mixture was warmed. The mixture was refluxed and perfluoro-*n*-propyl iodide distilled out. A total of 38.7 g., 77%, of product was thus obtained. Found: b.p. 39 to 41°, $n^{20}D$ 1.3281, mol. wt. 292 and 293.

Bromine.—Similarly to the reaction with iodine, 64 g., 0.40 mole, of bromine was added dropwise to 0.18 mole of zinc compound in 100 ml. of dioxane. The mixture turned iodine colored and the temperature rose to 80°. After approximately one-half of the bromine was added, refluxing occurred at the distillation head which was cooled by ice-water. The low boiling material, 33 g., was collected in a Dry Ice trap. Distillation yielded: (1) 26.8 g., b.p. 11.0–13.8° (740 mm.), mol. wt. 231 and 232; (2) 8 g., b.p. 25–45°, 2 g. of which b.p. 35–45°, $n^{20}D$ 1.3281. Fraction 1 was estimated by infrared spectrum and molecular weight, to be a mixture of heptafluoropropane and heptafluoropropyl bromide corresponding to yields of 23 and 44%. Redistillation of (1) yielded an end fraction, mol. wt. 246 and 247, f.p. −145.5 to −146.5°; found for perfluoro-*n*-propyl bromide prepared from silver perfluoro-*n*-butyrate and bromine: b.p. 12°, f.p. −144.0°; calcd. for C_3BrF_7: mol. wt. 249. Fraction 2 was principally perfluoro-*n*-propyl iodide, presumably formed by reaction of iodine with the zinc compound.

Chlorine.—Twenty-eight ml. of dioxane solution containing 0.029 mole of perfluoro-*n*-propylzinc iodide was placed in a two-necked flask fitted with a thermocouple extending into the solution and a Dry Ice reflux condenser in series with a trap. Chlorine, 19 g., 0.27 mole, was condensed into the flask; the temperature rose to 75° and the mixture turned iodine colored. The mixture was allowed to reflux for several hours and the volatile product then passed through a strongly basic sulfite solution to yield 5.5 g. of material identified as a mixture of heptafluoropropane, 46 mole per cent., and perfluoro-*n*-propyl chloride, 54 mole per cent., by infrared and molecular weight analysis; found: mol. wt. 189; calcd. for C_3ClF_7: mol. wt. 205. Ampoule-to-ampoule distillation yielded an end fraction, 0.5 g., with an infrared spectrum essentially identical with that of perfluoro-*n*-propyl chloride; found: mol. wt. 205, 207.

Hydrolysis of the reaction mixture gave no heptafluoropropane nor did any perfluoro-*n*-propyl iodide separate from

(38) A. F. Benning and R. C. McHarness, *Ind. Eng. Chem.*, **31**, 912 (1939).

(39) For convenience the titers of the zinc compound solutions given are calculated from the moles of perfluoro-*n*-propyl iodide used to prepare the zinc compound minus the moles of heptafluoropropane and of unchanged iodide isolated during the preparation.

(40) W. T. Miller, Jr., Chap. 32, *Nat. Nuclear Energy Ser.*, Div. VII, I, "Prepn., Properties and Technol. of Fluorine and Org. Fluorine Compds.," McGraw-Hill Book Co., Inc., New York, N. Y., 1951.

the aqueous solution. The production of heptafluoropropane during the bromination and chlorination of perfluoro-*n*-propylzinc iodide presumably was due to reaction with hydrogen halide produced by the halogenation of dioxane at the reaction temperatures employed.[41]

Oxygen.—A solution of 0.114 mole of zinc compound in 90 ml. of dioxane failed to gain weight or show any positive signs of reaction when dry oxygen was bubbled into it at a rate of 0.5 mole per hour at room temperature. Likewise, at 90° after two days no evidence of reaction was observed. One gram, 5%, of heptafluoropropane was evolved during this period. Hydrolysis yielded 15 g. or a total of 16 g., 82%, of heptafluoropropane and the hydrolyzate was free of fluoride ion.[42]

In a parallel experiment with oxygen, 0.144 mole of zinc compound in dioxane was illuminated with eight G.E. 15 watt B.L. fluorescent bulbs placed concentrically around and one inch from the Pyrex reaction flask. No positive evidence of reaction was observed during 48 hr. with the solution at 35° and an oxygen flow of 0.5 mole per hour. The temperature was raised to 90–100° and the oxygen flow continued for five days during which time 18 g. of condensate collected in the Dry Ice trap. The system lost 9 g. in weight, presumably by oxygen entrainment. Separation of the trap material yielded 1.5 g., 6%, of heptafluoropropane, and 11 g., b.p. 40°, $n^{20}D$ 1.3290, identified as perfluoro-*n*-propyl iodide, 26%. Hydrolysis of the reaction mixture, which gave a faint test for fluoride, yielded 3 g., 12%, of heptafluoropropane. Distillation of the hydrolysate from excess silver sulfate yielded only 1.4 meq. of acid.

Carbon Dioxide.—A solution of 0.261 mole of zinc compound was placed in a dry lecture cylinder and 70 g., 1.6 moles, of carbon dioxide was added with the cylinder cooled in Dry Ice. The cylinder was closed with a steel valve and heated in a reciprocating shaker at 106° for 110 hr. Carbon dioxide was vented through a sintered glass disk into 500 ml. of 14*N* caustic to yield 4 g. of heptafluoropropane, 9%, which was free of perfluoropropene as tested by infrared spectrum and acetone permanganate. Water, 50 ml., was added to the bomb which was then heated at 100° for 2 hr. to yield 30 g. of material, b.p. <0°, which on redistillation gave 25 g., 56%, of heptafluoropropane, b.p. −13.0 to −12.5° (740 mm.). No perfluorobutyric acid was obtained by distillation of the hydrolyzate from excess silver sulfate.

Carbonyl Compounds.—The essential technique in the reactions summarized below was to heat the reactants together under the conditions specified. The volatile products were isolated by distillation and the residual salts hydrolyzed in order to estimate the quantity of unchanged zinc compound. The percentage yields listed are regarded as approximate values. Water-insoluble products remaining in the hydrolyzate were partially investigated. Only in the case of perfluoro acid chlorides were detectable quantities of the desired products, ketones, produced. The reaction mixtures in which most of the zinc compound was consumed during the heating period were characteristically dark and tarry. The reaction mixtures in which most of the zinc compound was unchanged, despite the relatively high temperatures employed, remained fairly clean. Varying amounts of ester by-products were shown to be formed by cleavage of dioxane in the reactions with acid halides and anhydrides.

Illustrative results are summarized below. In each case following the name of the organic reagent is given: the number of moles organic reagent per mole of zinc compound, the reaction time and temperature, the percentage heptafluoropropane (I) evolved during the reaction period and the percentage unchanged zinc compound II and/or other products isolated. Percentages are based on the initial concentration of zinc compound.[39]

Perfluoro-*n*-propylzinc Iodide in Dioxane Solution.—*Paraformaldehyde:* 3.3, 5.5 days at 130°, 46% I (containing some formaldehyde), 42% II. *Benzophenone:* 0.82, 18 hr. at 80° plus 7 days at 115°, 8% I, 62% II. *Ethyl perfluoro-n-butyrate:* 1.1, 24 hr. at 80° plus 4 hr. at 105°, I and II were not determined quantitatively, but 75% ethyl perfluoro-*n*-butyrate was recovered. *Benzoyl chloride:* 0.84, 18 hr. at 90°, 14% I, 49% II (β-chloroethyl benzoate, ethylene glycol dibenzoate and possibly β-iodoethyl benzoate were shown to be present). *Perfluoro-n-butyryl chloride:* 1.5, 2 hr. at 60°, 8% I, 76% II. 1.4, 16 hr. at 110°, 63% I (containing some acid chloride), 31% II.

Perfluoro-*n*-propylzinc Iodide Solid Dioxane Solvate.—One to two moles of dioxane plus approximately 0.25 mole of zinc iodide were present per mole of organozinc compound. Complete conversion of the zinc compound took place in each case. *Acetic anhydride:* 5.6, 12 hr. at 110°, 56% I. *Acetyl chloride:* 4.4, 12 hr. at 90°, 78% I. *Benzoyl chloride:* 1.8, 12 hr. at 130–140°, 59% I, 17% heptafluoro-*n*-propyl iodide. *Trifluoroacetyl chloride:* 2.4 (plus chlorobenzene diluent), 15 hr. at 120°, compound I was mixed with trifluoroacetyl chloride and was not determined quantitatively, 6% perfluoro-2-pentanone. *Perfluoro-n-butyryl chloride:* 1.9, 65 hr. at 120°, compound I was mixed with perfluoro-*n*-butyryl chloride; 15% perfluoro-4-heptanone, b.p. 72–74° (738 mm.), yielded a solid ammonia adduct, m.p. 57.5–58.5°, phenylhydrazone, m.p. 35–37°, and formed a liquid hydrate; reported[43] for perfluoro-*n*-heptanone b.p. 75° (740 mm.).

Preferential Replacement Reactions of Highly Fluorinated Alkyl Halides. I. Preparation of Certain Fluorinated Allyl Iodides[1,2]

BY WILLIAM T. MILLER, JR., AND ARNOLD H. FAINBERG

RECEIVED MARCH 12, 1957

Certain fluorinated allyl chlorides, including 3-chloropentafluoropropene and 2,3-dichlorotetrafluoropropene, have been found to react readily with sodium iodide in anhydrous acetone to yield 3-iodopentafluoropropene and 2-chloro-3-iodotetrafluoropropene, respectively. Other compounds such as 1,1,2,3-tetrachlorodifluoropropene and 1,3-dichlorotetrafluoropropene were completely inert under more rigorous conditions. The resistance of the latter two compounds to substitution suggests that the ready reaction of the first two does not involve direct reaction at the α-carbon atom, but rather anionic attack by iodide ion on the γ-carbon atom, with allylic shift and elimination of chloride ion, an S_N2' mechanism.

As part of a general investigation of the reactivity of X in highly halogenated compounds of the type RCF_2X, $RCFXR'$ and $RR'R''CX$, where X = Cl, Br or I, a number of compounds containing the group $CClF_2$ in the allylic and benzylic positions have been prepared. Physical properties for these compounds, and for their precursors and derivatives, are listed in Table I. For the

(1) Presented at the 119th Meeting of the American Chemical Society, Boston, Mass., April, 1951, Abstracts of Papers, p. 24-M. Based in part on the thesis submitted by Arnold H. Fainberg to the Graduate School of Cornell University in partial fulfillment of the requirements for the Ph.D. degree, June, 1950.

The bulk of the trichloride was prepared by the photochemical addition of chlorine to the chloropentafluoropropene fraction obtained from the high-temperature thermal reaction of chlorotrifluoroethylene.[3,8] The physical properties of this trichloride (compound Ic in Table I) were found to differ markedly from those previously reported in the literature for 1,2,3-trichloropentafluoropropane by Henne and Newby.[4] For this reason, pure samples of the trichloride were synthesized from several compounds of known identity. The purity of these samples (Ia, Table I) was established by cooling curves; in both cases freezing point depressions were less than 0.1°. Repetition of the synthesis of Henne and Newby gave a trichloride Ib with virtually the same properties as Ia. These properties differ markedly from those of the other isomeric trichlorides which can be formed by the addition of chlorine to the isomeric chloropentafluoropropenes, namely, 1,1,2-trichloropentafluoropropane (V) and 1,2,2-trichloropentafluoropropane.[5a-c] On the basis of the physical properties of the pure compounds, it was concluded that Ic was at least 75%, and probably > 90% 1,2,3-trichloride, the impurity being the 1,1,2- and/or the 1,2,2-trichlorides.

The chloropentafluoropropene IIb obtained by dechlorination of Ic was therefore at least 75% 3-chloropentafluoropropene, the impurity being the 1- and/or 2-chloroölefins.

In view of the similarity of the physical properties, particularly f.p. and density, of the 1,1,2-trichloride (Va) to those reported by Henne and Newby[4] for their 1,2,3-trichloride, it was considered advisable to check their report that 3-chloropentafluoropropene undergoes rearrangement on treatment with antimony trifluorodichloride to form 1-chloropentafluoropropene. Their result was fully confirmed by the present work.

Reactions with Iodide Ion.—α-Chloro-α,α-difluorotoluene, 1,3-dichlorotetrafluoropropene, and 1,1,2,3-tetrachlorodifluoropropene were found to be completely inert to the action of sodium iodide in anhydrous acetone, even at elevated temperatures for prolonged periods of time. In sharp contrast, 3-chloropentafluoropropene and 2,3-dichlorotetrafluoropropene reacted readily at room temperature with the iodide reagent to yield, respectively, 3-iodopentafluoropropene and 2-chloro-3-iodotetrafluoropropene. These reactions have been shown to involve reversible equilibria, in which the allyl chlorides are highly favored over the iodides.[17] That the iodides can be isolated at all is attributed only to the enormously greater solubility of sodium iodide than that of sodium chloride in anhydrous acetone,[18] with consequent displacement of the equilibria toward the iodides.

The resistance of the allylic chlorine in $CClF{=}CFCClF_2$ and $CCl_2{=}CClCClF_2$ to attack by iodide ion suggested that the ready reaction of $CF_2{=}CFCClF_2$ and $CF_2{=}CClCClF_2$ does not involve direct reaction at the α-carbon atom. This is in line with the observation that the chlorine in compounds of the type RCF_2Cl, where R is phenyl or saturated perhaloalkyl, is not capable of substitution by iodine under the same reaction conditions.

On the other hand, an S_N2' mechanism[20,21,22] involving initial attack by the iodide ion on the far γ-carbon atom with allylic shift and elimination of chloride ion, as shown below, is consistent with the observed differences of reactivity of the allyl chlorides

$$I^- + CF_2{=}\underset{|}{C}{-}CF_2Cl \rightleftharpoons$$

$$[I\cdots CF_2\cdots\underset{|}{C}\cdots CF_2\cdots Cl]^- \rightleftharpoons ICF_2{-}\underset{|}{C}{=}CF_2 + Cl^-$$

Implicit in this formulation is the structural requirement: attack by iodide ion productive of allyl iodide occurs on $CF_2{=}$, but not on $CFCl{=}$ or $CCl_2{=}$. It is considered of direct significance that the identical structural requirement has been found for base-catalyzed additions to fluoroölefins leading to saturated products. Thus, in every case reported to date in which olefins of the type $CF_2{=}CX^1X^2$ (X = H, Br, Cl and/or F) have been treated under basic conditions with BH (B = OAlk,[23 to 31] OAr,[32] NR_2,[25,33] SR[34]), saturated addition products have been reported.[35] Furthermore, these products invariably have the structure

(34) K. E. Rapp, *et al.*, *ibid.*, **72**, 3642 (1950).

(35) There are two apparent exceptions; Tarrant and Brown[30] reported the isolation of only unsaturated ethers from the reaction of $CF_2{=}CCl_2$ and $CF_2{=}CClF$ with sodium *t*-butoxide in *t*-butyl alcohol, and Pruett, *et al.*,[33] obtained $CHClFCF{=}NC_4H_9$ from the action of $C_4H_9NH_2$ with $CF_2{=}CClF$. However, in both cases the authors believe that the saturated addition product was actually formed first, and that it subsequently split out HF. This view is partly substantiated by the report of Barr, *et al.*,[27] of the isolation of a saturated ether from the reaction of $CF_2{=}CClF$ with *t*-butyl alcohol in the presence of base; this ether was found to be highly unstable both thermally and in

$CF_2BCX^1X^2H$,[36] in which the anionic fragment B is attached to the carbon atom bearing the two fluorine atoms.

In sharp contrast to the behavior of the fluoroolefins containing the $CF_2=$ group described above, those containing $CClF=$ or $CCl_2=$ such as $CClF=CClF$,[25] $CCl_2=CClF$[25] and $CCl_2=CClCF_3$[37] are relatively unreactive and do not appear to undergo base-catalyzed addition leading to saturated products. Under conditions resulting in reaction, they tend to give vinyl ethers instead.

A two-stage mechanism which accounts for the phenomenon of base-catalyzed addition and elimination of vinyl and allyl halogen, as well as for the highly preferred orientation of addition, has been proposed by Miller, *et al.*[24,25] In it, the first, rate-controlling step involves nucleophilic attack on $CF_2=$. Similarly, the S_N2' mechanism here proposed for the iodide–chloride interchange requires rate-controlling attack at the $CF_2=$ group by such relatively mild nucleophiles as iodide and chloride ion.

It is obvious that the allyl chlorides which have been found reactive to the iodide reagent are of such a structure as to yield the same organic iodide by allylic rearrangement as by direct substitution at the allylic carbon atom. For these compounds, it would appear that a definitive proof of mechanism can only be obtained by the use of labeled carbon. However, product analyses and kinetic results are consistent with the proposed S_N2' mechanism for the reactions with halide ions of structures of the type $CF_2=CXCCl_2F$, X = F or H.[38]

Properties of the Fluorinated Allyl Iodides.—The fluorinated allyl iodides were obtained as clear, colorless liquids by distillation in the dark under an inert atmosphere (for $CF_2=CClCF_2I$ vacuum distillation was necessary, since some thermal decomposition was encountered at the boiling point at atmospheric pressure). In the air and on exposure to light they rapidly turned purple due to liberated iodine, $CF_2=CClCF_2I$ being less stable than $CF_2=CFCF_2I$. The allyl iodides were found to be strongly lachrymatory, as were also $CF_2=CClCClF_2$ and the olefin dibromides.

Some reactions of these iodides have been investigated, and will be reported in a subsequent paper in this series.

Experimental Methods

Dehalogenation.—Dechlorinations were carried out by adding, through an addition funnel, the compound being dechlorinated to a well-stirred refluxing mixture of zinc dust in absolute methyl or ethyl alcohol. Induction periods could be substantially eliminated by the initial addition of a small amount of zinc chloride to the reaction mixture.[39] To take care of the very considerable heat of reaction, water-cooling of the reaction flask was employed. The product was continuously distilled out of the reaction mixture as formed. With these techniques, the rate of reaction for virtually all the dechlorinations run in this Laboratory to date employing zinc dust and methyl or ethyl alcohol as the solvent was found to be very rapid. This is in contrast to several reports in the literature of very sluggish reaction.[40,41]

Products and recovered starting materials were always obtained as minimum boiling azeotropes with the alcohol used as the solvent. Physical properties and compositions of some of the azeotropes encountered are given in Table II.

TABLE II

AZEOTROPES

Component A	Component B	B.p., °C. Pure A[a]	B.p., °C. Azeotrope[b]	Bar. press., mm.	$n^{20}D$ Pure A	$n^{20}D$ Azeotrope	Wt. % B in azeotrope

[a] B.p. t_c adjusted to barometric pressure p_0 at which azeotrope b.p. was taken by use of equation $t_c = t_0 + 0.043(p_0 - p_0)$ where t_0 is observed b.p. of pure compound at pressure p_0.[6] [b] Observed value.

It would appear that azeotrope formation between halogenated compounds and alcohols is a general phenomenon. It has proved to be very useful in the recovery of high-boiling products, since it eliminates having to work up the residue.

For compounds boiling below room temperature, the alcohol was removed by treatment with P_2O_3 and fractional distillation therefrom. Compounds boiling above room temperature were extracted with ice-water, treated with P_2O_5, filtered and fractionally distilled. Distillation from P_2O_5 is not recommended for compounds boiling higher than about 70°, because of decomposition of the products of the P_2O_5–alcohol reaction.

Allylic Fluorination.—Swarts[42] prepared $C_6H_5CCl_2F$ and $C_6H_5CClF_2$ by treating benzotrichloride with SbF_3 for

(36) Hanford and Rigby[23] in a patent claimed that ethers with the reverse orientation were also formed. However, they cited no experimental evidence for this. They did report that $CF_2=CClF$ and $CF_2=CHCl$ gave $CHClFCF_2OEt$ and CH_2ClCF_2OEt, respectively, and gave chemical evidence for the structure of the latter. Tarrant and Brown[30] cite the formation of both difluoro- and chlorofluoro- acetamides from $CF_2=CClF$ and amines "under certain conditions." These results appear to be in contrast to those of other workers (see above).

periods of two weeks or more at room temperature. The method proved unsatisfactory for large-scale preparation, particularly of the monofluoride. In line with previous observation,[43] heating the mixture at atmospheric pressure gave only benzotrifluoride and the reaction was accompanied by much decomposition. However, it was found that rapid reaction between the SbF_3 and benzotrichloride sets in at 100–110°. This is too low a temperature to permit distillation at atmospheric pressure out of the reaction mixture of the intermediate fluorination products ($C_6H_5CClF_2$ boils at 140°, $C_6H_5CCl_2F$ at 180°). By lowering the pressure to 25–50 mm. so as to bring the boiling points of the intermediate fluorination products below the temperature at which reaction sets in, it was found possible to isolate either of the intermediates as the predominant product.

This technique was found to be equally effective in the isolation of the intermediate fluorination products of hexachloropropylene, and will very likely prove applicable to allylic fluorinations in general.

The fluorination products invariably carried over volatile antimony salts with them. These salts were difficult to remove quantitatively by the usual technique of washing with aqueous HCl, nor could they be separated by fractional distillation. It was found that they could be removed quantitatively by treatment of the material with a high-boiling organic base, such as quinoline. An insoluble complex was formed, which could be filtered off; the excess quinoline was then separated by fractional distillation.

Quantitative removal of the volatile antimony salts prior to distillation was found essential in the isolation of the intermediate fluorination products of benzotrichloride, for they were found to cause disproportionation[44,45] of these products to the trifluoride and trichloride. This reaction was also encountered with the intermediate fluorination products of hexachloropropylene.[47]

The formation of a cloudy solution or precipitate on the addition of one drop of quinoline to several ml. of a compound was found to constitute a sensitive test for the presence of antimony halides. Application of this test to other compounds prepared by fluorination with antimony salts revealed that all compounds so prepared boiling higher than 75–100° contained trace amounts of antimony salts. Such compounds were therefore given the quinoline treatment prior to distillation. It is suggested that the rather wide discrepancies between the densities of a number of compounds reported in this paper and those previously reported may be due to the presence of small amounts of antimony salts in the earlier preparations (densities previously reported are consistently higher).

Physical Properties and Analytical Data.—Physical properties were determined as described previously.[7,44] Densities of liquids boiling below room temperature were taken in sealed 10- or 25-ml. pycnometers.

Samples were decomposed for halide analysis by peroxide fusion in a Parr bomb.[48]

Experimental Results

Fluorination of $CCl_3CClFCCl_2F$ and $CCl_2FCClFCClF_2$.—These fluorinations were carried out by the method of Henne and Flanagan.[49] A steel lecture cylinder (Matheson Co.) was charged with 122 g. of HF, 173 g. of HgO (1.60 eq.) and 96 g. of $CCl_3CClFCClF_2$[50] (0.33 mole). The cylinder was sealed with a steel valve and heated to 175° for 40 hours with shaking. The reaction product was steam distilled from the cylinder into an aqueous solution of KOH, separated as the lower layer, dried over P_2O_5, and fractionally distilled to give 54 g. of $CClF_2CClFCClF_2$, b.p. 72–74° (0.23 mole, 70% yield), center cut Ia, b.p. 72.9° (738 mm.).

In a similar manner, 35 g. of $CCl_2FCClFCClF_2$[51] (0.14 mole), 93 g. of HF and 32 g. of HgO (0.30 eq.), held at 175° for 24 hours with shaking, gave 22 g. of $CClF_2CClFCClF_2$, b.p. 72.8–73.3° (0.093 mole, 65% yield); the center cut had physical properties virtually identical with those found for Ia.

In neither of the above runs was anything obtained boiling lower than 72°, thus further demonstrating the resistance of terminal $-CClF_2$ and internal $-CClF-$ groups in saturated perhalo compounds to further fluorination under the reaction conditions employed.[52]

Fluorination of $CCl_3CClFCCl_3$.—The fluorination of $CCl_3CClFCCl_3$ was carried out with SbF_3Cl_2, following the directions of Henne and Newby[4] as closely as possible. The fluorinating agent was prepared by condensing 44 g. of Cl_2 (0.62 mole) in a lecture cylinder containing 216 g. of SbF_3 (1.20 moles), sealing it, and warming to room temperature for 3 hours. By reaction of 160 g. of $CCl_3CClFCCl_3$[54] (0.53 mole) with this fluorinating agent there was obtained 109 g. of material, $n^{20}D$ 1.3489, the bulk of which distilled (from quinoline) at 70–73°. Physical properties of the purest cut, Ib, b.p. 72.7° (737 mm.), are listed in Table I.

Dechlorination of $CClF_2CClFCClF_2$.—In a typical run, 1188 g. of $CClF_2CClFCClF_2$ (5.0 moles, Ic)[55] was dechlorinated with 500 g. of 90% zinc dust in 1400 ml. of absolute ethanol to which 20 g. of $ZnCl_2$ had been added, to give 770 g. of an ethyl alcohol azeotrope (<1% EtOH) of $CF_2{=}CFCClF_2$, b.p. 5.6–6.3°, plateau at 6.3° (743 mm.) (91% conversion, 95% yield), plus 60 g. of material, b.p. 61.6° (756 mm.), shown to be the ethyl alcohol azeotrope of $CClF_2$-$CClFCClF_2$ (*ca.* 20% EtOH). Thus, drowning the latter in water, and treating with P_2O_5, followed by fractional distillation gave $CClF_2CClFCClF_2$, b.p. 73.1° (743 mm.), d^{20}_4 1.653, $n^{20}D$ 1.3505. Fractional distillation of the ethyl alcohol–$CF_2{=}CFCClF_2$ azeotrope from P_2O_5 gave IIb, b.p. 6.2° (732 mm.); mol. wt. calcd. 166.5, found 165.

The purest sample of $CF_2{=}CFCClF_2$ obtained, IIa, b.p. 6.5° (741 mm.), was prepared by dechlorination of Ia. It added bromine readily to give $CBrF_2CBrFCClF_2$ (III), b.p. 112.4° (744 mm.).

Reaction of $CF_2{=}CFCClF_2$ with SbF_3Cl_2.—The procedure of Henne and Newby[4] was followed as closely as possible. To a fluorinating agent prepared as described above from 82 g. of SbF_3 (0.61 mole) and 13 g. of Cl_2 (0.18 mole) in a lecture cylinder was added 102 g. of $CF_2{=}CFCClF_2$ (IIb, 0.61 mole). The cylinder was warmed, with shaking, to 95–105° for 21 hours, then 125–130° for 12 hours more. From the cylinder was distilled 98 g. of material, which gave, on fractional distillation, 6 g. of $CF_2{=}CFCF_3$ (VI), b.p. −30.7 to −29.6° (741 mm.) (0.04 mole, 7% yield), plus 64 g. of a C_3ClF_5, b.p. 5.5–7.7° (0.38 mole, 63% yield), center cut b.p. 7.4° (745 mm.), shown to be almost pure $CClF{=}CFCF_3$ (IV) by photochemical chlorination to CCl_2-$FCClFCF_3$ (Va), b.p. 71.1° (737 mm.). Physical properties of a somewhat less pure sample (judging by the respective cooling curves) of $CCl_2FCClFCF_3$ (Vb), b.p. 72.5–.9° (744 mm.), prepared[56] by the addition of F_2 to $CCl_2{=}CClCF_3$, are also listed in Table I for comparison.

Fluorination of $C_6H_5CCl_3$.—In a typical run in which the monofluoride was the desired product, 293 g. of $C_6H_5CCl_3$ (1.5 moles), held at 115–120°, was treated in several portions with 90 g. of SbF_3 (1.5 equiv.) at a pressure of 50 mm., the product being distilled out as formed. It was treated with 10 ml. of quinoline, filtered through charcoal, and fractionally distilled to give 1 g. of $C_6H_5CF_3$, b.p. 46.5–47.5° (100 mm.) (1% yield); 37 g. of $C_6H_5CClF_2$, b.p. 79–81° (100 mm.) (0.23 mole, 19% yield); 101 g. of $C_6H_5CCl_2F$, b.p. 108–113° (100 mm.) (0.56 mole, 46% yield); and 54 g. of $C_6H_5CCl_3$ (0.28 mole, 18% recovered).

The yield of difluoride was improved by using twice the above proportion of SbF_3 and operating at 25 mm.

Refractionation of the above compounds gave center cuts $C_6H_5CF_3$ (VII), b.p. 100.9° (731 mm.); $C_6H_5CClF_2$ (VIII), b.p. 139.7° (739 mm.); $C_6H_5CCl_2F$ (IX), b.p. 94.5° (50 mm.); and $C_6H_5CCl_3$ (X), b.p. 146.9° (100 mm.).

Fluorination of CCl_2=$CClCCl_3$.—Fluorination of CCl_2=$CClCCl_3$ at atmospheric pressure has been reported.[5b] To increase the yields of the intermediate fluorination products, the reduced pressure technique was employed. In a 1-liter 3-neck flask fitted with stirrer, addition funnel, and wide bore take-off tube leading to an ice-cooled receiver was placed 720 g. of SbF_3 (4.0 moles). The reaction flask was immersed in an oil-bath at 200–230°, the pressure lowered to 150 mm., and 1245 g. (5.0 moles) of CCl_2=$CClCCl_3$, (XI), b.p. 141.4° (100 mm.) added over a half-hour period. The stirrer was started up as soon as possible, and a mixture of products distilled out at 100–130 mm. The crude mixture was extracted several times with 1:2 aq. HCl, treated with 20 ml. of quinoline, filtered through charcoal, and given a rapid preliminary fractional distillation at 30 mm. Under these conditions, the following yields were obtained. The variations in yield were determined by the rate of take-off, slower take-off favoring the more highly fluorinated products.

Run	Recovered CCl_2=$CClCCl_3$, %	Yield, % CCl_2=$CClCCl_2F$	Yield, % CCl_2=$CClCClF_2$	Yield, % CCl_2=$CClCF_3$
1	6	15	62	7
2	6	39	51	5
3	18	62	29	3
4	34	79	15	1

Refractionation gave the following center cuts: CCl_2=$CClCCl_2F$ (XII), b.p. 169.2° (735 mm.); CCl_2=CCl-$CClF_2$ (XIII), b.p. 127.1° (738 mm.); and CCl_2=$CClCF_3$ (XIV), b.p. 87.4° (730 mm.).

Preparation of CF_2=$CClCClF_2$.—Dechlorination[5b] of $ClF_2CCl_2CClF_2$ (XVa)[7] with zinc dust in ethanol gave CF_2=$CClCClF_2$ (XVI), b.p. 43.8° (747 mm.), in 90% yield. The cooling curve for the olefin had a freezing point depression of <0.1°, in contrast to the much larger depression of 1.7° found for its precursor XVa, which had been prepared by fluorination of $CCl_3CCl_2CClF_2$.[7] However, photochemical addition of Cl_2 to XVI gave a ClF_2CCl_2-$CClF_2$ (XVb), b.p. 111.7° (747 mm.), which had a f.p. depression of 1.5°. Apparently XVa contained a small amount of a dechlorinatable impurity capable of depressing its freezing point, but which, on dechlorination, gave an olefinic impurity in the CF_2=$CClCClF_2$ which formed a solid solution with the latter.

Photochemical addition of Br_2 to XVI gave $CBrF_2$-$CBrClCClF_2$ (XVII) for which a satisfactory cooling curve could not be obtained.

Action of Sodium Iodide in Acetone on CF_2=$CFCClF_2$.—In a typical reaction, 1250 g. of CF_2=$CFCClF_2$ (IIb, 7.5 moles) was treated with 1366 g. of NaI (9.1 moles) in 3500 ml. of anhydrous acetone (prepared by refluxing reagent grade acetone over Drierite, and fractionally distilling therefrom). Reaction occurred at room temperature as evidenced by the precipitation of NaCl (of greater than 98% purity in the early stage of reaction). After ten days at room temperature, the remaining low-boiling material was rapidly distilled off, and the product was worked up by drowning the reaction mixture, in five times its volume of water, washing with several portions of iced dilute aqueous $NaHSO_3$ to remove iodine and acetone, drying over P_2O_5, filtering and fractionally distilling. In this way was obtained 324 g. of recovered C_3ClF_5, b.p. 5.3–6.3° (737 mm.); 1150 g. of CF_2=$CFCF_2I$, b.p. 53.0–53.6° (738 mm.) (4.5 moles, 60% conversion); and 30 g. of higher boiling material, discussed further below. Refractionation of the CF_2=$CFCF_2I$ gave a center cut XVIII, b.p. 53.6° (734 mm.).

Anal. Calcd. for C_3F_5I: I, 49.2; mol. wt., 258. Found: I, 49.2; mol. wt., 264.

Boiling point, molecular weight, iodine analysis, unsaturation to $KMnO_4$ in acetone, and molar refraction support the molecular formula C_3F_5I. The structural formula proposed is consistent with substitution of chlorine in CF_2=$CFCClF_2$ by iodine with or without allylic rearrangement; any other structure would involve rearrangement of carbon–fluorine bonds, which is considered highly unlikely under the conditions of the reaction. In further support of the allylic structure is the fact that a number of reactions[17] of the iodide regenerate, directly or indirectly, the known CF_2=$CFCClF_2$ and $ClF_2CClFCClF_2$.

In another run, using the same quantity of reagents, the reaction was carried out by holding the mixture at reflux. The temperature of the reaction mixture rose asymptotically from 20 to 47° in five days, and remained at 47° for the next five days. In this way, 1250 g. of CF_2=$CFCClF_2$ (7.5 moles, b.p. 6.8° (755 mm.), b. range 0.1°, f.p. −144.2°, f.p. dep. 2°, obtained from dechlorination of Ic) gave 120 g. of C_3ClF_5, b.p. 6.6–7.1° (center cut b.p. 6.6° (743 mm.), b. range <0.1°, f.p. −151°, f.p. dep. very large), plus 980 g. (3.8 moles, 51% conversion) of CF_2=$CFCF_2I$, b.p. 52–54° (center cut b.p. 53.8° (739 mm.), f.p. −130.6°, f.p. dep. 0.2°), plus smaller amounts of several higher boiling by-products which appear to have been formed by substitution of fluorine by iodine. Among these were 55 g. of a compound, b.p. 93–98°, center cut, b.p. 97.5° (744 mm.), b. range 0.1°, d^{20}_4 2.1270, $n^{20}D$ 1.4010; and 200 g. of another compound, b.p. 70.6° (50 mm.), b. range 0.1°, f.p. −43.6°, f.p. dep. 0.1°, d^{20}_4 2.1691, $n^{20}D$ 1.4811. In addition, a small amount of a compound b.p. −30° was obtained. Further work on these by-products is in progress.

A portion of the recovered C_3ClF_5 fraction was treated with NaI in acetone, and found to react further, thus demonstrating the presence of CF_2=$CFCClF_2$. However, evidence that at least one other C_3ClF_5 isomer also was present was furnished not only by the physical properties of the material itself, but also by addition of chlorine to another portion of the material to give a $C_3Cl_3F_5$, b.p. 71.5–72.0° (739 mm.), d^{20}_4 1.6606–1.6609, $n^{20}D$ 1.3512–1.3517. It is believed that the impurity resulted from a concentration of impurity originally present in the starting material, rather than rearrangement of the allyl chloride.

Action of Sodium Iodide in Acetone on CF_2=$CClCClF_2$.—To a solution of 825 g. of NaI (5.50 moles) in 2000 ml. of anhydrous acetone at 22° was added 905 g. of CF_2=CCl-$CClF_2$ (XVI, 4.94 moles). Reaction occurred at a considerably faster rate than for CF_2=$CFCClF_2$; in half an hour the temperature rose to 32°, then started falling. After 45 hours at room temperature, the reaction product was drowned in water and worked up as described above for CF_2=$CFCF_2I$ to give 160 g. (0.87 mole, 18%) of recovered CF_2=$CClCClF_2$, b.p. 35–45°, center cut b.p. 43.6° (740 mm.), b. range <0.1°, f.p. −120.8°, f.p. dep. 0.1°, d^{20}_4 1.5398, $n^{20}D$ 1.3483; and 950 g. of CF_2=$CClCF_2I$, b.p. 37–38° (100 mm.), center cut XIX, b.p. 37.5° (100 mm.), 91.4° (737 mm.) (3.5 moles, 70% conversion, 85% yield.)

Anal. Calcd. for C_3ClF_4I: Cl, 12.9; I, 46.3; mol. wt., 274.5. Found: Cl, 12.8; I, 46.4; mol. wt., 274.

Compounds Unreactive to Sodium Iodide in Acetone.—Each of the following compounds was treated with an equivalent amount of sodium iodide in anhydrous acetone at reflux temperature for periods of 24 to 150 hours: Cl_2=$CClCClF_2$, $CClF$=$CFCClF_2$,[57] $C_6H_5CClF_2$ and $CClF_2$-$CClFCClF_2$. No precipitate formation was observed for any of these compounds, a very sensitive sign of reaction, and they were recovered unchanged in substantially quantitative amounts.

Preferential Replacement Reactions of Highly Fluorinated Alkyl Halides. II.[1] Some Reactions of Fluorinated Allyl Iodides[2,3]

BY ARNOLD H. FAINBERG AND WILLIAM T. MILLER, JR.

RECEIVED MARCH 12, 1957

The preferential replacement of iodine in 3-iodopentafluoropropene and in 2-chloro-3-iodotetrafluoropropene by reaction with chlorine and bromine and with chloride and bromide ions is described. Ionic and free radical type reaction mechanisms which involve initial reagent attack at the double bond rather than at the allylic carbon atom are proposed for these reactions. The reactions with halide ion are shown to be reversible. Treatment of the above compounds with metallic zinc results in the replacement of iodine by hydrogen or in the formation of dimeric products with elimination of iodine. The dimerization reaction furnishes a method for the preparation of perfluoro and other highly halogenated 1,5-hexadienes. Perfluoro-1,5-hexadiene on heating undergoes an unusual isomerization to form a saturated compound which is formulated as perfluorobicyclo[2,2,0]hexane.

Introduction

The fluorinated allyl iodides are highly reactive materials which have been found to be versatile intermediates for the preparation of a variety of fluorinated compounds. Illustrative reactions of 3-iodopentafluoropropene and 2-chloro-3-iodotetrafluoropropene are described below. The clean-cut character of the reactions of these compounds, which do not contain hydrogen, is particularly noteworthy. In most cases products of high purity are isolated readily in high yields, without formation of tars and intractable residues. Table I lists

the physical properties of the compounds involved, most of which are new.

Reactions with Halide Ions.—In the preceding paper in this series was described the preparation of the allylic iodides 3-iodopentafluoropropene and 2-chloro-3-iodotetrafluoropropene by treatment of the corresponding fluorinated allyl chlorides with sodium iodide in acetone. The consistent recovery of unreacted allyl chloride in the earlier work suggested that an equilibrium reaction is involved, equation 1, which is displaced toward the formation

$$NaI + CF_2{=}CXCClF_2 \xrightarrow[\text{acetone}]{\text{anhydrous}} ICF_2CX{=}CF_2 + NaCl\downarrow \quad (1)$$

of allyl iodide by virtue of the extremely low solubility of the sodium chloride in the anhydrous acetone.

This equilibrium has been confirmed in the present work. Thus, treatment of perfluoroallyl iodide with sodium chloride in anhydrous acetone gave perfluoroallyl chloride under conditions in which the more volatile chloride was progressively distilled out of the reaction mixture. Furthermore, the rate of formation of the allyl chloride was increased markedly by the addition of water to the acetone; the water increases the solubility of the sodium chloride in the solvent.

In addition, it was shown that the allyl chloride is thermodynamically favored over the bromide. The allyl bromide reacted under equilibrium conditions with lithium chloride in anhydrous acetone, equation 2, to give perfluoroallyl chloride in high yield. Substantially complete reaction occurred

$$Cl^- + CF_2{=}CFCBrF_2 \rightleftharpoons CClF_2CF{=}CF_2 + Br^- \quad (2)$$

in less than five minutes at 0°. Likewise, treatment of the allyl iodide with lithium bromide in acetone, equation 3, gave a 90% yield of 3-bromopentafluoropropene of high purity.

$$Br^- + CF_2{=}CFCF_2I \rightleftarrows CBrF_2CF{=}CF_2\uparrow + I^- \quad (3)$$

All of the above reactions are postulated to proceed *via* an S$_N$2′ mechanism,[1] equation 4. This

$$Y^- + CF_2{=}CFCF_2X \rightleftharpoons [Y\cdots CF_2\cdots CF\cdots CF_2\cdots X]^- \rightleftharpoons YCF_2CF{=}CF_2 + X^- \quad (4)$$

mechanism involves rate-controlling attack by halide ion Y^- on the terminal vinyl carbon atom, with allylic shift and elimination of halide ion X^-. It is striking that such usually mild nucleophiles as chloride and bromide ion are so effective in these reactions with fluoroallyl halides.

Reactions with Elemental Bromine and Chlorine.—3-Iodopentafluoropropene and 2-chloro-3-iodotetrafluoropropene reacted rapidly with bromine in the dark at room temperature to yield the corresponding allyl bromides almost quantitatively. Similarly, perfluoroallyl iodide reacted with chlorine in diffuse light to give the allyl chloride in high yield. In none of the above reactions was any trace of saturated compounds produced.

Heptafluoropropyl iodide does not react with bromine under the same conditions.[13] This result supports the view that the allyl iodides are attacked by the halogen, not at the allylic carbon atom, but at the terminal vinyl carbon atom, a reaction path analogous to that proposed for the reactions with halide ions (4). Inasmuch as some free iodine was always present at the start of these reactions, due to the instability of the allyl iodides, it is considered likely that reaction proceeds largely *via* the inter-halogen compounds, by an S$_N$2′ type of mechanism as shown in equations 5 and 6. A cyclic transition state may be involved which

$$X_2 + I_2 \longrightarrow 2IX \quad (5)$$

$$I^{\delta+}{-}X^{\delta-} + CF_2{=}CX'CF_2I \longrightarrow CF_2XCX'{=}CF_2 + I_2 \quad (6)$$

yields an iodine molecule directly.[14]

Perfluoroallyl bromide did not appear to undergo a dark reaction with chlorine corresponding to that obtained with the allyl iodide. However, photochemical chlorination gave appreciable amounts of at least three other perhalopropanes, in addition to the expected chlorine adduct; see Table II.

TABLE II

PRODUCTS OF THE PHOTOCHEMICAL CHLORINATION OF $CF_2{=}CFCBrF_2$

Compound	Yield, %
$CClF_2CClFCClF_2$	22
$CBrF_2CClFCClF_2$	52
$CBrF_2CBrFCClF_2$	7
$CBrF_2CClFCBrF_2$	14
($CBrF_2CBrFCBrF_2$)	*ca.* 1
Total	96

These products clearly establish that a large amount of carbon–bromine bond cleavage took place, with the formation of bromine atoms. The reaction may well represent the free radical counterpart of the dark reaction of chlorine with perfluoroallyl iodide, as shown in equations 7, 8 and 9.

$$Cl_2 + h\nu \longrightarrow 2Cl\cdot \quad (7)$$

$$Cl\cdot + CF_2{=}CFCBrF_2 \longrightarrow CClF_2\dot{C}FCBrF_2 \quad (8)$$

$$CClF_2\dot{C}FCBrF_2 \longrightarrow CClF_2CF{=}CF_2 + Br\cdot, \text{ etc.} \quad (9)$$

Reactions with Zinc.—Perfluoroallyl iodide, on treatment with zinc dust in methanol, reaction 10, gave the reduction product

$$CF_2{=}CFCF_2I + Zn + MeOH \longrightarrow CF_2{=}CFCHF_2 + Zn(OMe)_2 \quad (10)$$

1,1,2,3,3-pentafluoropropene in high yield. This latter compound added chlorine and bromine readily at low temperatures in the presence of light with no evidence of hydrogen substitution. It was necessary to raise the temperature *ca.* 40° in order to further chlorinate the $CClF_2CClFCHF_2$ to the known trichloride. This sequence of reactions thus constitutes a proof of structure for the initial reduction product and its halogen adducts.

In anhydrous dioxane, the perfluoroallyl iodide reacted with zinc dust to give a good yield of the coupled product, decafluoro-1,5-hexadiene. This diene added two moles of chlorine to give a saturated tetrachloride. The 1,5-positions of the double bonds was proved by oxidation of the diene

(13) A. H. Fainberg and W. T. Miller, Jr., unpublished work.

(14) The relationship of entering and departing groups has been shown to be *cis* for S$_N$2′ reactions of some cyclohexene derivatives; G. Stork and W. N. White, THIS JOURNAL, **75**, 4119 (1953); **78**, 4699 (1956).

to tetrafluorosuccinic acid, isolated as the diethyl ester; see Table I.

Thermal reaction of the diene resulted in the formation of a remarkable isomeric compound, m.p. 41°, boiling only 3° higher, for which the structure decafluorobicyclo[2.2.0]hexane, CF_2–CF–CF_2 / CF_2–CF–CF_2, is proposed. The application of this new ring closure reaction to longer chain terminally unsaturated dienes is under investigation.

Experimental Results

Physical Properties.—Physical properties were determined as previously described.[1,6] Structure assignments were tested in all cases by correlation of physical properties and MR_D in addition to the other evidence cited.

Apparatus.—Unless otherwise indicated, all reactions were carried out in a three-neck round-bottom flask fitted with an all-glass stirrer, thermometer, addition funnel, and a 25 cm. × 1.5 cm. i.d. glass helix packed column surmounted by a water-cooled variable take-off head connected to a receiver and traps cooled in ice and in Dry Ice.

CF_2=$CFCF_2I$ + NaCl in Acetone.—Redistilled CF_2=$CFCF_2I$,[1] 129 g., was added to a suspension of 58 g. of NaCl in 500 ml. of anhydrous acetone and the mixture heated to reflux with stirring for ten days. Slow but continuous evolution of CF_2=$CFCF_2Cl$ occurred to yield a total of 23 g., b.p. 5–9°, center cut b.p. 6.2° (738 mm.), f.p. −141°; previously reported[1] b.p. 7.3° (760 mm.), f.p. −139.8°. In another run, the addition of 1% by wt. H_2O, which increases the solubility of NaCl in acetone by a factor of 10, speeded up the rate of formation of the CF_2=$CFCClF_2$ by a factor of more than 3.

CF_2=$CFCF_2I$ + LiBr in Acetone.—To a well-stirred solution of 104 g. of LiBr (1.2 moles) in 800 ml. of anhydrous acetone at 20° was added, over a ten-minute period, 258 g. of CF_2=$CFCF_2I$ (1.0 mole), which had been cooled to 0°. The temperature rose to 27° during mixing. The reaction mixture was heated to reflux and 204 g. of material, b.p. 27–28°, distilled out during seven hours (180 g. during three hours). Redistillation of the volatile product from 7 g. of P_2O_5 yielded 190 g., 90%, of CF_2=$CFCBrF_2$, b.p. 25.5–25.7°, center cut Ia, b.p. 25.5° (738 mm.).

CF_2=$CFCBrF_2$.—Compound Ia contained bromine, was unsaturated to $KMnO_4$ in acetone, and added one mole of bromine to give a saturated tribromide. The same compound was obtained from the action of bromine on the perfluoroallyl iodide, see below. Molecular weight, molar refraction and boiling point support the molecular formula C_3BrF_5. The allylic position of the bromine was demonstrated by the ready interconvertibility of the compound with the known allyl chloride and iodide.

CF_2=$CFCBrF_2$ + LiCl in Acetone.—To 400 ml. of anhydrous acetone in a 500-ml. Pyrex bottle was added 25.4 g. of LiCl (0.60 mole, a 20% excess). The mixture was equilibrated at 0°, thus giving a saturated solution in which *ca.* 20 g. of LiCl was present as a solid phase.[15] To this mixture was added 105.5 g. of CF_2=$CFCBrF_2$ (0.50 mole), also at 0°. The bottle was tightly stoppered and shaken vigorously. Within five minutes, almost all of the solid phase had gone into solution, about 1 g. of LiCl remaining undissolved. There was no further change during the next three hours. The solution was poured on cracked ice in a separatory funnel with some loss of volatile product. The lower layer was fractionally distilled to give 65 g., 80%, of CF_2=$CFCClF_2$, b.p. 6.3° (739 mm.), f.p. −141°. No trace of unreacted starting material, b.p. 25°, was found.

CF_2=$CFCBrF_2$ and CF_2=$CClCBrF_2$ + NaI in Acetone.—In a qualitative test, CF_2=$CFCBrF_2$ was found to react readily with 10% NaI in anhydrous acetone, a heavy precipitate of NaBr forming in one minute at room temperature. Under the same conditions, CF_2=$CClCBrF_2$ gave a precipitate instantaneously.

CF_2=$CFCF_2I$ + Br_2.—To 985 g. of CF_2=$CFCF_2I$ (3.8 moles) in a one-liter reaction flask at room temperature in the dark was added, with stirring, 400 g. of bromine (2.5 moles) during one hour. Characteristic sharp cracking sounds were produced during the reaction and sufficient heat of reaction was developed to distil about a quarter of the product, b.p. 25 to 30°, out of the reaction flask. The flask then was warmed gently to drive over the rest of the product, leaving free iodine behind. The volatile product was washed with iced aqueous KOH and fractionally distilled to give 730 g., 90% conversion, 95% yield, of CF_2=$CFCBrF_2$, b.p. 25.8–25.9°, center cut Ib, b.p. 25.9° (745 mm.); mol. wt. calcd. 211, found 214. Fifty grams, 5%, of unreacted CF_2=$CFCF_2I$, b.p. 55°, was recovered. No material boiling higher than 55° was found.

CF_2=$CClCF_2I$ + Br_2.—To 147 g. of CF_2=$CClF_2I$[1] (0.53 mole) in a 200-ml. flask in the dark was slowly added 50 g. of Br_2 (0.30 mole). As with the CF_2=$CFCF_2I$, sharp cracking sounds were produced during the addition. The evolution of a large amount of heat necessitated cooling in an ice-bath; most of the reaction was carried out at 30–35°. The reaction mixture, almost solid at this point, was treated with dilute aqueous KOH. The lower layer was separated and fractionally distilled to give 5% of recovered starting material and 100 g., 82% conversion, 87% yield, of CF_2=$CClCBrF_2$, b.p. 63.0–63.5°, center cut II, b.p. 63.5° (736 mm.); mol. wt. calcd. 227.5, found 231.5.

The CF_2=$CClCBrF_2$ added one mole of bromine slowly at room temperature, with illumination furnished by a 100 w. lamp, to give $CBrF_2CBrClCBrF_2$ (III), b.p. 86.9–87.1° (50 mm.).

CF_2=$CClCBrF_2$ and $CBrF_2CBrClCBrF_2$.—The olefin II contained fluorine, chlorine and bromine, but no iodine. Its molecular formula C_3BrClF_4 is supported by its molecular weight, molar refractivity and boiling point as well as by the molar refractivity of its bromine adduct III. Any structures other than CF_2=$CClCBrF_2$ for II and $CBrF_2CBrClCBrF_2$ for III would necessitate postulating rearrangements for which no analogous cases exist.

CF_2=$CFCF_2I$ + Cl_2.—A solution of 108 g. of CF_2=$CFCF_2I$ (0.42 mole) in 200 g. of CCl_2FCClF_2 was placed in a 500-ml. three-neck flask fitted with gas inlet tube, thermometer and Dry Ice-cooled reflux condenser connected to an ice-cooled and a Dry Ice-cooled trap. Chlorine was passed into the solution rapidly in diffuse room light (no light directly on flask). After about four minutes during which the initial purple iodine color was bleached, the liquid became opaque black and evolved sufficient heat to raise the temperature from 30 to 45°. A low-boiling liquid (CF_2=$CFCClF_2$, b.p. +7°) started refluxing back into the flask. The temperature of the reaction mixture fell slowly with the continued rapid addition of chlorine, as the low boiling product built up, and a large amount of free iodine crystallized out of solution. Finally, the solid iodine liquefied rather suddenly (ICl formed), and the chlorine input was stopped. The reaction flask was warmed on a water-bath to distil out material boiling up to the boiling point of the solvent CCl_2FCClF_2 (47°). The product, a clear, light amber colored liquid was shaken with a small amount of mercury to remove traces of free halogen and fractionally distilled to give 58 g. of CF_2=$CFCClF_2$, b.p. 6–8° (85% yield), center cut b.p. 6.3° (739 mm.), f.p. −141°.

CF_2=$CFCBrF_2$ + Br_2.—The CF_2=$CFCBrF_2$ (Ib) added bromine initially rather slowly at its reflux temperature with illumination furnished by a 100-w. incandescent lamp, the bromine being only sparingly soluble in the olefin. The rate of reaction increased rapidly as the product built up, and the reflux temperature rose. The product, obtained in substantially quantitative yield, was the expected tribromide $CBrF_2CBrFCBrF_2$ (IV), b.p. 132.4° (733 mm.); mol. wt. calcd. 371, found 365; Br calcd. 64.7, found 65.0, 64.9.[17]

CF_2=$CFCBrF_2$ + Cl_2.—The CF_2=$CFCBrF_2$ did not appear to react with chlorine at room temperature in diffuse light. It did, however, react rapidly with chlorine when illuminated with 2–15 w. G.E. 360 BL ultraviolet fluorescent lamps. The chlorination product from 422 g. of CF_2=$CFCBrF_2$ (Ib, 2.00 moles) was let stand overnight with dissolved chlorine and illumination. After washing to remove excess chlorine, distillation yielded: 54 g., 13%, of recovered CF_2=$CFCBrF_2$, b.p. 19–25°,

(15) The solubility of LiCl in acetone at 0° is 1.73 g./100 g. of acetone.[16]

b.p. plateau 25.5° (734 mm.); 91 g., 22% yield, of $CClF_2$-$CClFCClF_2$, b.p. 72–74°, center cut Va, b.p. 73.1° (743 mm.); 257 g., 52% yield, of $CBrF_2CClFCClF_2$, see below, b.p. 91–93°, center cut VI, b.p. 92.7° (749 mm.); 120 g., 21% yield, of $C_3Br_2ClF_5$'s, b.p. 111–112°, see below, center cut, b.p. 111.9° (732 mm.); and about 1% higher b.p. material, possibly $CBrF_2CBrFCBrF_2$.

$CBrF_2CClFCClF_2$.—Fraction VI above was shown to have the molecular formula $C_3BrCl_2F_5$. Its cooling curve indicated a single substance. These observations supported the conclusion that it was the expected chlorine adduct $CClF_2CClFCBrF_2$. In addition, VI was found not to react with sodium iodide in acetone. Other work[13] has shown that bromine in terminal $-CBrF_2$ groups is inert toward iodide ion in acetone while internal $-CBrF-$ is readily attacked.

$CBrF_2CBrFCClF_2$ and $CBrF_2CClFCBrF_2$.—The fraction of b.p. 112° formed by chlorination of $CF_2=CFCBrF_2$ was saturated to permanganate in acetone and contained bromine, chlorine and fluorine. It had the following physical properties: b.p. 113.1° (760 mm.), b. range <0.1°, f.p. −115.8°, f.p. depression very large, $n^{20}D$ 1.4026, d^{20}_4 2.1935. The large freezing range showed that the fraction was a mixture of isomers. Its boiling point supports the molecular formula $C_3Br_2ClF_5$. Excluding rearrangement of carbon–fluorine bonds the components of the mixture could be only $CBrF_2CBrFCClF_2$ and $CBrF_2$-$CClFCBrF_2$. It was predicted, on the basis of observations made with other structures,[13] that while the 1,2-dibromide would react with NaI in acetone to give $CF_2=CFCF_2Cl$ plus free iodine the 1,3-dibromide would not react at all under the same conditions. Verification of this prediction, see below, led to the isolation of 1,3-dibromide (VII) in pure form.

The composition of the $C_3Br_2ClF_5$ fraction was thus shown to be about one-third $CBrF_2CBrFCClF_2$ and two-thirds $CBrF_2CClFCBrF_2$.

$CBrF_2CClFCBrF_2$. **Debromination of $CBrF_2CBrFCClF_2$ with NaI in Acetone.**—To a solution of 120 g. of NaI (0.80 mole) in 500 ml. of anhydrous acetone was added 116.5 g. (0.36 mole) of the $C_3Br_2ClF_5$ fraction, b.p. 112°, see above. The solution, initially clear, became cloudy within a minute and a white precipitate settled out on standing. After six days at room temperature, during which time a small amount of low boiling material appeared in the Dry Ice trap, the solution was drowned in ice-water. Titration of the solution with standard aqueous $Na_2S_2O_3$ showed 0.125 mole of free I_2 present. The organic layer was washed with iced aq. $NaHSO_3$ and fractionally distilled to give: 11 g. of material b.p. below room temperature, assumed to be $CF_2=CFCClF_2$, 18% yield; 9 g., 10%, $CF_2=CFCF_2I$, b.p. 51–53°, plateau 53.1° (732 mm.); 68 g., 59%, $CBrF_2CClFCBrF_2$, b.p. 110–112°, center cut VII, b.p. 112.0° (735 mm.), mol. wt. calcd. 326, found 319. The physical properties of $CBrF_2CBrFCClF_2$ differentiate it from $CBrF_2CClFCBrF_2$; previously reported for $CBrF_2$-$CBrFCClF_2$[1] b.p. 113.1° (760 mm.), f.p. −118.0°, $n^{20}D$ 1.4028, d^{20}_4 2.2016.

$CF_2=CFCF_2I$ + Zn in CH_3OH. $CF_2=CFCHF_2$.—To a well-stirred suspension of 120 g. of Zn dust in 700 ml. of anhydrous methyl alcohol in a one-liter flask at reflux was added slowly 194 g. of $CF_2=CFCF_2I$ (0.75 mole). Reaction started immediately, as evidenced by heat evolution, and material boiling from below room temperature up to the boiling point of the methyl alcohol was collected. Distillation of the product gave three fractions: A, b.p. 1.3° (749 mm.); B, b.p. 35.0° (749 mm.); C, b.p. 45° (746 mm.).

Fraction B was tentatively identified as the methyl alcohol azeotrope of $CF_2=CFCF_2OCH_3$, obtained in 0 to 16% conversion. It appeared to undergo decomposition with the evolution of acid fumes when distilled from P_2O_5, and was not treated further. Fraction C appeared to be the methyl alcohol azeotrope of unreacted $CF_2=CFCF_2I$; about 3% was so recovered.

Redistillation of fraction A from P_2O_5 gave $CF_2=CF$-CHF_2, center cut VIII, b.p. 1.2° (746 mm.); mol. wt. calcd. 132, found 133 (74% to 90% conversion).

The $CF_2=CFCHF_2$ added bromine rapidly with illumination at its boiling point to give $CBrF_2CBrFCHF_2$ (IX), b.p. 95.0–95.2° (741 mm.); mol. wt. calcd. 292, found 292; Br calcd. 54.8, found 55.0, 55.0.

Addition of 35 g. of Cl_2 (0.49 mole) to 73 g. of $CF_2=CFCHF_2$ (0.55 mole) with illumination at 0 to 10°, resulted in rapid reaction without evolution of HCl. Fractionation of the product gave 7 g., 10%, of recovered $CF_2=CFCHF_2$, b.p. below room temperature; and 96 g., 92% yield, of $CClF_2CClFCHF_2$, b.p. 52–55°, center cut X, b.p. 55.2° (735 mm.), mol. wt. calcd. 203, found 203. There was no sign of higher boiling material.

Chlorination of $CClF_2CClFCHF_2$ occurred slowly at 45 to 55°, to give in substantially quantitative yield $CClF_2$-$CClFCClF_2$ (Vb), b.p. 72.7° (736 mm.). The formation of this well characterized compound substantiated the structures of compounds VIII and X.

$CF_2=CClCF_2I$ + Zn in C_2H_5OH.—To a well-stirred suspension of 120 g. of zinc dust in 500 ml. of absolute ethyl alcohol at reflux was added, over a half-hour period, 274.5 g. of $CF_2=CClCF_2I$ (1.00 mole). Reaction occurred with sufficient heat evolution to require external cooling during the addition. A low-boiling fraction A, 41 g., slowly accumulated in the Dry Ice trap during the addition and for three hours thereafter. A second fraction B boiling from 40 to 77° was then distilled out of the reaction flask leaving a residue, fraction C, a thick slurry.

Fraction A was fractionally distilled from P_2O_5, with which it appeared to react, for only a trace of material boiling below room temperature was obtained, b.p. <17°. The bulk of the material, 32 g., 25% yield, as yet unidentified, b.p. 32.9–33.6° (745 mm.), center cut b.p. 33.4° (738 mm.), b. range <0.1°, f.p. −105°, f.p. dep. <1.3°, d^{20}_4 1.1980, $n^{20}D$ 1.3342, mol. wt. found 125, MR^{20}_D found 21.5, contained fluorine and chlorine, was unsaturated to $KMnO_4$ in acetone and burned with a smoky flame.

Fraction B, 40 g., was found to be an azeotropic mixture of ethyl alcohol and higher boiling products, all unsaturated to $KMnO_4$ in acetone. It was not treated further.

Fraction C, the residue, was dissolved in water, acidified with HCl, and extracted with benzene using a continuous liquid–liquid extractor. Fractional distillation of the benzene extract gave 60 g., 37% yield, of diethyl malonate, b.p. of center cut XI, 134.4° (100 mm.). The diethyl malonate, in which all that is left of the original perhaloolefin is the three carbon skeleton, may have arisen from hydrolysis of a diether $C_2H_5OCF_2CH_2CF_2OC_2H_5$. The latter would have been produced by a series of basic displacements and base-catalyzed additions accompanying reduction. These interesting reactions are under further investigation.

$CF_2=CFCF_2I$ + Zn **in Anhydrous Dioxane.** $CF_2=CFCF_2CF_2CF=CF_2$.—To a well-stirred suspension of 200 g. of Zn dust in 1500 ml. of anhydrous dioxane (refluxed with and fractionally distilled from Na) at reflux was slowly added 1032 g. of $CF_2=CFCF_2I$ (4.00 moles). Rather sudden heat evolution was observed after about one-third of the iodide was added. From this point on,[18] reaction proceeded smoothly. The reaction mixture was held slightly below reflux for several hours, after which material boiling from 52 to 100° was distilled out. The residue contained no water-insoluble material. Redistillation of the volatile product gave 4% of unreacted starting material and an 83% yield of $CF_2=CFCF_2CF_2CF=CF_2$, b.p. 57–59°, center cut XII, b.p. 58.4° (733 mm.), iodine-free; mol. wt. calcd. 262, found 264.

The 1,5-position of the two double bonds in XII was demonstrated by its oxidation, described below, to the known tetrafluorosuccinic acid.

Photochemical addition of chlorine to XII yielded $CClF_2$-$CClFCF_2CF_2CClFCClF_2$ (XIII), b.p. 89° (50 mm.); mol. wt. calcd. 404, found 405; Cl calcd. 35.1, found 34.8, 35.0.

Oxidation of $CF_2=CFCF_2CF_2CF=CF_2$.—To a well-stirred mixture of 274 g. of $KMnO_4$ (1.7 moles) and 358 g. of $NaHCO_3$[19] (4.3 moles) in 800 ml. of water cooled to 10°, in a 3-l. 3-neck r.b. flask fitted with a Dry Ice-cooled reflux condenser, was added 200 ml. of reagent grade acetone.[20]

(18) The induction period probably can be eliminated by the initial addition of some $ZnCl_2$ to the reaction mixture.

(19) The use of $NaHCO_3$ instead of NaOH or KOH with $KMnO_4$ for oxidation of perhaloölefins has been found generally advantageous in that degradation of the oxidation products is reduced, R. T. Carroll and W. L. Miller, Jr., unpublished work.

(20) On one occasion uncontrolled oxidation of the acetone occurred when the temperature was allowed to rise on mixing. However, no difficulty was encountered when the reaction mixture was kept below 20° after the acetone was added.

To this mixture was added 141.5 g. of $CF_2=CFCF_2CF_2-CF=CF_2$ (0.5 mole) during about one hour with the temperature kept below 20°.[20] Stirring was continued for an additional three hours until the evolution of carbon dioxide ceased. The oxidation mixture was worked up by reducing with SO_2 until there was no further lightening in color, filtering the slurry, acidifying the filtrate with 120 ml. of concd. H_2SO_4, and distilling out material up to the boiling point of water, mostly CO_2, SO_2 and acetone. The residue was extracted with diethyl ether in a continuous liquid–liquid extractor. The ether was then removed and the residue treated with 300 ml. of absolute ethyl alcohol. The excess alcohol was distilled off at atmospheric pressure, and the product fractionally distilled to give 75 g., 60% yield, of $C_2H_5OCOCF_2CF_2COOC_2H_5$ (XIVa), b.p. 96° (20 mm.). The physical properties of this material differed substantially from those reported by Henne and Zimmerschied[10]; see Table I, footnote *k*. For this reason, another sample of $C_2H_5OCOCF_2CF_2COOC_2H_5$ was prepared from $\underbrace{CF=CFCF_2CF_2}$.[10]

Oxidation of $\overbrace{CF=CFCF_2CF_2}$.—The oxidation of this compound, b.p. 0.2° (740 mm.), was carried out at atmospheric pressure, and the diethyl ester of perfluorosuccinic acid isolated by the technique described above for the oxidation of XII. The olefin, 81 g. (0.50 mole), was distilled into the reaction flask containing 137 g. of $KMnO_4$, 179 g. of $NaHCO_3$, 200 ml. of acetone and 800 ml. of water. No external cooling was required, since the refluxing olefin kept the mixture below 12°. Most of the olefin had reacted in 9 hours. From the resulting mixture was obtained 85 g., 70% yield, of $C_2H_5OCOCF_2CF_2COOC_2H_5$ (X), center cut (XIVb) b.p. 95° (20 mm.). The physical properties of XIVb were substantially identical with those of XIVa; see Table I.

$CF_2—CF—CF_2$
| | |
$CF_2—CF—CF_2$

Thermal Reaction of $CF_2=CFCF_2CF_2-CF=CF_2$.—The diene XII was metered from a constant head dropping funnel into a copper coil vaporizer immersed in an oil-bath held at 100° and the vapor passed into a 45 cm. × 3.8 cm. i.d. electrically heated nickel reactor tube. A thermocouple well extended into the center of the reactor tube. The mixture of product and unreacted starting material was condensed by a water-cooled copper condenser with receiver connected to Dry Ice and liquid air-cooled traps. Before and after each run the system was swept out with dry nitrogen. The product, boiling 17° lower than the starting material, was separated readily by fractional distillation. In the first run, 0.84 mole of XII was passed through the tube at 350° with a contact time of two minutes to give less than 1% conversion to product; 97% of the starting material was recovered. In the second run, the temperature was raised to 450°; 0.62 mole of XII gave a 60% conversion to product and 37% of the starting material was recovered. In the third run, with the temperature at 450°, the contact time was increased to 6 minutes; 0.46 mole of XII gave a 70% conversion to product, and 27% of the starting material was recovered.

The product, compound XV, a solid melting at 41°, b.p. 42.6° (732 mm.), mol. wt. calcd. 262, found 262, was saturated to chlorine plus light and to $KMnO_4$ in acetone. It formed an azeotrope with CCl_4, b.p. 41.6° (737 mm.).

The structure proposed for this compound, perfluorobicyclo[2.2.0]hexane, is based on the following considerations. The formation of a single product from the diene XII with the same molecular weight and with more than 97% total weight recovery indicated that XV was formed from XII by thermal isomerization, a process which requires only an electronic rearrangement. The loss of two double bonds necessitates a bicyclo structure for XV. The relatively high freezing point and very small liquid range (about 3° at atmospheric pressure) suggest a high degree of symmetry. The marked ease of formation of four-membered rings by thermal reaction of a variety of olefins containing the terminal $CF_2=$ structure is well known. In addition, a compound analogous to XV, which contains three fused four membered rings, perfluorotricyclo[4.2.0.$0^{2,5}$]-octane, is known to be formed by thermal reaction of perfluoro-1,3-butadiene.[21]

An X-ray investigation of XV[22] failed to shed much light on the structure, because the material was found to show rotational disorder.

$CF_2=CClCF_2I$ + Zn in Anhydrous Dioxane: $CF_2=CCl-CF_2CF_2CCl=CF_2$.—To a well-stirred suspension of 100 g. of Zn dust in 400 ml. of anhydrous dioxane at reflux was added 169 g. of $CF_2=CClCF_2I$ (0.62 mole) over a half-hour period. There was no noticeable heat effect at any time; the mixture was held near reflux for 6 hours, and material was distilled out to the boiling point of dioxane, 100.7° (747 mm.). The distillate contained nothing boiling below room temperature. It contained a small amount of unidentified material boiling at 45°, having a very pungent odor, but was principally a dioxane azeotrope, b.p. 98.5° (747 mm.), n_D^{20} 1.3989, *ca.* 54% dioxane by wt., which gave on drowning in water a 32% yield of $CF_2=CClCF_2CF_2CCl=CF_2$ (XVI), b.p. 112.8° (735 mm.). The structure proposed for this material is based on analogy with that demonstrated for XII.

(21) M. Prober and W. T. Miller, Jr., THIS JOURNAL, **71**, 598 (1949). Evidence for the fused tricyclic structure consists of the isolation of the intermediate compound perfluoro-1,2-divinylcyclobutane and its conversion into the tricycloöctane under conditions similar to those utilized in the present work; R. T. Carroll and W. T. Miller, Jr., unpublished work.

Methyl-fluorinated Methyldiarylcarbinols and Related Compounds

BY ERNST D. BERGMANN, P. MOSES, M. NEEMAN, S. COHEN, A. KALUSZYNER AND S. REUTER

RECEIVED JANUARY 31, 1957

Nine methyl-fluorinated derivatives of diphenylmethylcarbinol have been prepared by the Grignard reaction from suitable substitution products of ethyl fluoroacetate or acetophenone. The ultraviolet and infrared spectra of these carbinols are discussed. Some of the above acetophenones also have been reduced and the corresponding secondary alcohols condensed with chlorobenzene in the presence of fuming sulfuric acid. The chemical reactions of the new substances have been studied. Ethyl fluoroacetate is α-chlorinated by sulfuryl chloride in the presence of benzoyl peroxide.

The interesting biological properties[1–3] of the diaryl-(trifluoromethyl)-carbinols[4,5] made a study of

analogous methyl-fluorinated methyldiarylcarbinols appear worthwhile.

The purification of the products (I) from the Grignard reactions of arylmagnesium bromides (phenyl, *p*-chlorophenyl, *p*-bromophenyl and *p*-methoxyphenyl) with ethyl *difluoroacetate* was made difficult by the presence of the biphenyl derivatives formed as by-products. Combination of distillation under reduced pressure and chromatography gave the pure carbinols, which were oils and showed ultraviolet and infrared spectra similar to those of the corresponding diaryl-(trifluoromethyl)-carbinols. In the infrared spectrum, the OH valency stretching frequency was observed at 3600 cm.$^{-1}$.

$(p\text{-}XC_6H_4)_2(COH)CHF_2$ I $(p\text{-}CH_3OC_6H_4)_2C{=}CF_2$ II

$(p\text{-}ClC_6H_4)_2C(OH)CHFCl$ III $(p\text{-}XC_6H_4)_2C(OH)CF_2Cl$ IV

$(p\text{-}XC_6H_4)_2C(OH)CFCl_2$ V

The *p*-methoxyphenyl compound lost water spontaneously, even under mild conditions, and gave 1,1-di-(*p*-methoxyphenyl)-2,2-difluoroethylene (II), which has practically the same ultraviolet spectrum (λ 241 mμ, log ϵ 4.42) as 1,1-di-(*p*-chlorophenyl)-ethylene.[6] In the infrared, the hydroxyl frequency was absent; instead a band appeared at 1700 cm.$^{-1}$ which may be assigned to the C=CF_2 bond, conjugated with the *p*-methoxyphenyl groups.

The Grignard reaction between ethyl *chlorofluoroacetate* and *p*-chlorophenylmagnesium iodide gave the expected carbinol III, an oily liquid. In this connection it may be worthy of note that ethyl chlorofluoroacetate[7] can be prepared more easily (in 30% yield) by chlorination of ethyl fluoroacetate with sulfuryl chloride in the presence of benzoyl peroxide as catalyst than by the previously reported method.

The esters of *difluorochloro-* and *dichlorofluoro*-acetic acid reacted smoothly with phenylmagnesium bromide, giving the carbinols IV and V (X = H). Surprisingly, the reaction with *p*-chlorophenylmagnesium bromide was extremely sluggish, even under stringent conditions. The main reaction product was 4,4′-dichlorobiphenyl. These two esters, therefore, behave similarly to ethyl trichloroacetate.[8] A detour had to be employed for the preparation of the di-*p*-chloro-derivatives (X = Cl) of IV and V. The corresponding ketones VI and VII were prepared from difluorochloro- and dichlorofluoroacetic acid and an excess of *p*-chlorophenylmagnesium bromide according to the method of Sykes, Tatlow and Thomas.[9] These ketones gave the desired carbinols when treated for a considerable length of time with a twofold excess of *p*-chlorophenylmagnesium bromide.

$p\text{-}ClC_6H_4COCF_2Cl$ VI $p\text{-}ClC_6H_4COCFCl_2$ VII

$(p\text{-}ClC_6H_4)_2C(OH)CH_2F$ VIII $p\text{-}ClC_6H_4COCH_2C_6H_4Cl\text{-}p$ IX

Finally, ethyl *fluoroacetate* was converted, by reaction with *p*-chlorophenylmagnesium bromide, into 1,1-di-(*p*-chlorophenyl)-2-fluoroethanol (VIII). As a by-product, 4,4′-dichlorodesoxybenzoin (IX) was obtained, in analogy with the observations of Bergmann and Kalmus.[10] Dehydration of the carbinol VIII gave 1,1-di-(*p*-chlorophenyl)-2-fluoroethylene (X), whilst the chlorine-free parent compound of VIII gives a hydrindene derivative under these conditions.[10] The structure of X follows from the identity of its absorption spectrum (λ 240 mμ, log ϵ 4.22) with those of 1,1-di-(*p*-chlorophenyl)-ethylene[6] and II, and from its oxidation to *p*,*p*′-dichlorobenzophenone. Upon reduction with iodine and red phosphorus, the carbinol VIII was converted into 1,1-di-(*p*-chlorophenyl)-ethane.

When the ketones VI and VII and *p*-chloro-ω-fluoroacetophenone[11] were reduced with lithium aluminum hydride, the corresponding secondary alcohols were obtained, without loss of the aliphatic halogen atoms. Condensation of the three alcohols with chlorobenzene in the presence of fuming sulfuric acid gave 1,1-di-(*p*-chlorophenyl)-2,2-difluoro-2-chloroethane (XI), -2,2-dichloro-2-fluoroethane (XII) and -2-fluoroethane (XIII).

$(p\text{-}ClC_6H_4)_2C{=}CHF$ X $(p\text{-}ClC_6H_4)_2CHCF_2Cl$ XI

$(p\text{-}ClC_6H_4)_2CHCFCl_2$ XII $(p\text{-}ClC_6H_4)_2CHCH_2F$ XIII

$(p\text{-}ClC_6H_4)_2C{=}CF_2$ XIV $(p\text{-}ClC_6H_4)_2C{=}CClF$ XV

Compound XI melted at 54–55° and was obviously not identical with the product of m.p. 90° which has been obtained by Pouterman and Giraudet[12] by the treatment of DDT with antimony trifluoride and to which they assigned formula XI.

It appeared interesting to compare the behavior of the compounds XI and XII against alkali with that of the corresponding trifluoro compound. Whilst in the latter the CF_3 group is converted into a carboxyl or carbalkoxy group,[13] the former lose hydrogen chloride and give 1,1-di-(*p*-chlorophenyl)-2,2-difluoro- and -2-fluoro-2-chloroethylene (XIV, XV). Both olefins proved to be highly unstable; especially in contact with air they are converted quickly into brown polymers. The same behavior has been noted by Dittman and Wrightson[14] for the analogous 1,1-diphenyl-2,2-difluoroethylene. The fact that II is stable is undoubtedly due to the effect of the *p*-methoxy groups. This may be the same effect which makes 1,1-di-(*p*-methoxyphenyl)-ethylene stable to dimerization reactions.[15]

The **ultraviolet spectra** of the new carbinols show the longest wave length maximum at about

250–270 mμ; it is sometimes split into a doublet. Halogen in the *p*-positions has a distinct, though weak bathochromic affect, an observation which has also been made in the case of the diaryltrifluoromethylcarbinols.[5]

Also the infrared spectra of the tertiary carbinols described are fairly similar. The tertiary hydroxyl group absorbs at 3600 cm.$^{-1}$. In the acetyl derivatives, the carbonyl frequency at 1760 cm.$^{-1}$ is somewhat unusual; its shift from the expected frequency of about 1735 cm.$^{-1}$ may be due to the accumulation of negative substituents in the vicinity, in the same way as malonic esters absorb at 1761 cm.$^{-1}$ and ethyl trichloroacetate absorbs at 1768 cm.$^{-1}$.[16] As in the case of the diaryl-(trifluoromethyl)-carbinols,[5] there is no indication of internal hydrogen bonding. The biological properties of the substances described here will be reported elsewhere; the compounds have not shown any significant insecticidal properties.

Experimental

Difluoromethyl-diarylcarbinols (I).—To the Grignard solution, prepared from 0.1 mole of the aryl bromide in 50 ml. of ether, a solution of ethyl difluoroacetate (0.05 mole) in ether (25 ml.) was added at 0° and with vigorous agitation. The reaction mixture was cooled in an ice–salt mixture and decomposed by the slow addition of a saturated aqueous solution of ammonium chloride. The clear supernatant layer was decanted from a little sludge and the latter treated with a small amount of dilute hydrochloric acid, which was then extracted with ether. The combined ethereal layers were washed with sodium bicarbonate solution and water and dried with sodium sulfate. After removal of the solvent, the product was fractionated under reduced pressure. The crude carbinol fraction was dissolved in light petroleum ether and chromatographed on activated alumina, an ether–petroleum ether mixture (1:4) serving as the eluent. The fraction containing the carbinol was redistilled under reduced pressure. The carbinols gave a strong red-violet color with concentrated sulfuric acid. Their properties are summarized in Table I.

1,1-Di-(*p*-methoxyphenyl)-2,2-difluoroethylene (II).—The reaction with *p*-methoxyphenylmagnesium bromide, carried out as above, gave—after distillation under reduced pressure (123–125° (0.001 mm.))—a solid product of m.p. 54.5–55.5°.

Anal. Calcd. for $C_{16}H_{14}F_2O_2$: C, 69.6; H, 5.1. Found: C, 69.5; H, 5.1.

Ethyl chlorofluoroacetate was obtained by the method of Young and Tarrant[7] or—in 30% yield—by the chlorination of ethyl fluoroacetate with sulfuryl chloride in the presence of benzoyl peroxide.

The mixture of 31.8 g. of ethyl fluoroacetate, 53.6 g. of sulfuryl chloride, 150 ml. of carbon tetrachloride and 0.1 g. of benzoyl peroxide was refluxed until the expected weight loss (30 g.) had taken place. The solution was distilled without further treatment and gave 13 g. (30%) of ethyl chlorofluoroacetate, b.p. 128–130°, $n^{20}D$ 1.3913.

Fluorochloromethyl-di-(*p*-chlorophenyl)-carbinol (III).—To the Grignard solution prepared from 2.4 g. of magnesium and 24 g. of *p*-chloroiodobenzene, an ethereal solution of 5.65 g. of ethyl chlorofluoroacetate was added at 0° within 2 hr. The mixture was kept at room temperature for 2 hr. and decomposed by addition of 10 g. of ammonium chloride in ice-water. The aqueous layer was extracted with ether, and the combined ethereal solutions were washed with sodium thiosulfate solution and water and dried. The carbinol boiled at 140–144° (0.15 mm.); it was a yellowish oil of $n^{21}D$ 1.4763; ultraviolet spectrum in alcohol (log ε): 226 mμ (4.27), 256–266 mμ (3.17).

Anal. Calcd. for $C_{14}H_{10}Cl_3FO$: Cl, 33.0; F, 5.9. Found: Cl, 33.3; F, 5.8.

Ethyl Difluorochloroacetate.[17]—A mixture of difluorochloroacetic acid (General Chemical Division, Allied Chemical and Dye Corp., Morristown, N. J.) (56 g.), absolute ethanol (46 ml.) and concd. sulfuric acid (25 ml.) was heated on the water-bath for 2 hr. The layers were separated and the organic layer was washed twice with water. The acid layer then was added to the aqueous washings, whereupon a further quantity of ester separated. The combined portions of the crude ester were dried over phosphorus pentoxide and distilled in a Vigreux column; b.p. 96–97.5°, yield 62 g. (78.5%), $n^{30}D$ 1.3525, d^{30}_{30} 1.2471; *MR* calcd. 27.43, found 27.45.

Ethyl dichlorofluoroacetate[17a] was prepared by the same procedure from dichlorofluoroacetic acid (General Chemical Division, Allied Chemical and Dye Corp., Morristown, N. J.) (74 g.); b.p. 130–132°, yield 76 g. (86%), $n^{30}D$ 1.4002, d^{30}_{30} 1.307; *MR* calcd. 32.02, found 32.46.

Difluorochloromethyldiphenylcarbinol (IV, X = H).—To a boiling Grignard solution, prepared from magnesium (6 g.) and bromobenzene (39.2 g.) in ether (200 ml.), a solution of ethyl difluorochloroacetate (15.9 g.) in ether (60 ml.) was added, dropwise and with stirring, within 20 minutes. The heating was continued for another 10 minutes and the solution decomposed with ice and hydrochloric acid. The carbinol (IV) distilled at 130–160° (8 mm.), solidified and was recrystallized from petroleum ether; yield 15 g. (56%), m.p. 78–79°. Ultraviolet spectrum in alcohol: (log ε): 259 mμ (2.58), 263 mμ (2.52).

Anal. Calcd. for $C_{14}H_{11}F_2ClO$: C, 62.7; H, 4.1. Found: C, 62.3; H, 4.2.

The acetate was prepared by heating the carbinol (1 g.) with acetic anhydride (5 ml.) and sulfuric acid (2 drops) for 4 hr. at 100°. After hydrolysis of the excess of acetic anhydride with water, extraction with ether, evaporation of the solvent and recrystallization from methanol, the acetate was obtained as colorless prisms, m.p. 82–83°, yield 0.7 g. (61%); ultraviolet spectrum 264 mμ (log ε 2.64).

Anal. Calcd. for $C_{16}H_{13}ClF_2O_2$: C, 61.9; H, 4.2. Found: C, 61.7; H, 4.5.

Dichlorofluoromethyldiphenylcarbinol (V, X = H).—The carbinol V was obtained analogously from ethyl dichlorofluoroacetate (17.5 g.), magnesium (6 g.) and bromobenzene (39.2 g.). It distilled as a heavy yellowish oil at

140–145° (2 mm.) and could not be induced to crystallize; yield 15 g. (52%), $n^{30}D$ 1.5821, d^{30}_{30} 1.342; *MR* calcd. 71.06, found 70.78; ultraviolet spectrum in alcohol (log ε): 254 mμ (3.12).

Anal. Calcd. for $C_{14}H_{11}Cl_2FO$: Cl, 25.0. Found: Cl, 24.6.

The acetate was obtained as described above, m.p. 78–79°, yield 65%; ultraviolet spectrum 257 mμ (log ε 2.53).

Anal. Calcd. for $C_{16}H_{13}Cl_2FO_2$: C, 58.7; H, 4.0. Found: C, 58.2; H, 4.1.

Reaction of *p*-Chlorophenylmagnesium Bromide and Ethyl Difluorochloroacetate.—To the solution prepared from magnesium (5.3 g.) and *p*-chlorobromobenzene (42.2 g.) in ether (200 ml.), toluene (100 ml.) was added and the ether distilled off at 90–100°. The ester (15.85 g.) in toluene (60 ml.) was then added to the hot mixture, dropwise and with stirring, within 15 minutes, and the heating continued for another 15 minutes. After decomposition of the mixture with ice and hydrochloric acid, removal of the solvents and distillation *in vacuo*, the main product proved to be 4,4′-dichlorobiphenyl; the desired carbinol could not be separated in pure form, though the crude reaction product gave the typical color reaction with concentrated sulfuric acid.

ω,ω-Difluoro-ω,*p*-dichloroacetophenone (VI).—A solution of difluorochloroacetic acid (32.6 g.) in ether (70 ml.) was added at 10–15° to a Grignard solution, prepared from *p*-chlorobromobenzene (144 g.) and magnesium (18 g.) in ether (300 ml.), during 90 minutes. After decomposition with ice and hydrochloric acid and removal of the solvent, the reaction product was fractionally distilled *in vacuo;* the ketone VI distilled at 110–125° (25 mm.) and upon redistillation at 211–213° (760 mm.); yield 35 g. (63%), $n^{30}D$ 1.5241, d^{30}_{30} 1.445; *MR* calcd. 45.37, found 47.60; ultraviolet spectrum in ethanol (log ε): 222 mμ (4.00) 1263 mμ (3.03); infrared spectrum: $\nu_{C=O}$ 1710 cm.$^{-1}$.

Anal. Calcd. for $C_8H_4Cl_2F_2O$: C, 42.7; H, 1.8. Found: C, 42.5; H, 2.0.

It is well known[18] that the halogen in α-halogenoketones raises the frequency of the carbonyl group (for liquid acetophenone, $\nu_{C=O}$ is 1682 cm.$^{-1}$). Neither in this case nor in those of VII or of *p*-chloro-ω-fluoroacetophenone have we observed doublets (at about 1700 and 1682 cm.$^{-1}$) as reported, *e.g.*, for ω-chloro- and ω,ω-dichloroacetophenone by Bellamy, Thomas and Williams[19] and ascribed to rotational isomers of the compounds. On the other hand, the observation[19,20] has been confirmed that in such α-halogenations only the first halogen has a major effect on the location of the carbonyl frequency.

ω-Fluoro-ω,ω,*p*-trichloroacetophenone (VII).—The ketone VII was prepared from dichlorofluoroacetic acid (37 g.), *p*-chlorobromobenzene (144 g.) and magnesium (18 g.). It distilled at 110–130° (9 mm.) and upon redistillation, at 245–250° (760 mm.); yield 24 g. (38%), $n^{30}D$ 1.5522, d^{30}_{30} 1.450; *MR* calcd. 50.21, found 52.96; ultraviolet spectrum (log ε): 221 mμ (4.04), 257 mμ (2.32); infrared spectrum: $\nu_{C=O}$ 1700 cm.$^{-1}$.

Anal. Calcd. for $C_8H_4Cl_3FO$: Cl, 44.0; Found: Cl, 43.8.

Difluorochloromethyl-di-(*p*-chlorophenyl)-carbinol (IV, X = Cl).—A solution of VI (16 g.) in ether (50 ml.) was added, dropwise and with stirring, to a boiling Grignard solution prepared from *p*-chlorobromobenzene (15.5 g.) and magnesium (1.9 g.) in ether (100 ml.), over a period of 15 minutes. The heating was continued for 10 minutes and the mixture decomposed with ice and hydrochloric acid. Part of the ketone (2.5 g.) was recovered unchanged; the desired carbinol (IV, X = Cl) distilled at 175–178° (2 mm.) as a colorless oil, yield 7.5 g. (24%), $n^{22}D$ 1.5750; d^{22}_{22} 1.548; *MR* calcd. 76.41, found 76.53; ultraviolet spectrum in alcohol (log ε): 226 mμ (4.20); 266 mμ (2.88).

Anal. Calcd. for $C_{14}H_9Cl_3F_2O$: C, 49.8; H, 2.7. Found: C, 50.3; H, 3.1.

The acetate, prepared as described above, had m.p. 78–79°, yield 72%; ultraviolet spectrum: 227 mμ (4.23), 264 mμ (2.66).

Anal. Calcd. for $C_{16}H_{11}Cl_3F_2O_2$: C, 50.6; H, 2.9. Found: C, 50.7; H, 3.1.

Dichlorofluoromethyl-di-(*p*-chlorophenyl)-carbinol (V, X = Cl) was prepared from a solution of VII (10 g.) in ether (50 ml.) and a Grignard solution, prepared from *p*-chlorobromobenzene (15.5 g.) and magnesium (1.9 g.) in ether (150 ml.). It distilled at 190–195° (2 mm.) and solidified spontaneously. By recrystallization from petroleum ether, waxy prisms of m.p. 79–80° were obtained, yield 9.5 g. (60%); ultraviolet spectrum in alcohol (log ε): 230 mμ (4.14), 260 mμ (2.84), 265 mμ (2.86).

Anal. Calcd. for $C_{14}H_9Cl_4FO$: C, 47.5; H, 2.6. Found: C, 47.7; H, 2.7.

The acetate melted at 100.5–101.5°, yield 72%. *Anal.* Calcd. for $C_{16}H_{11}Cl_4FO_2$: C, 48.5; H, 2.8. Found: C, 48.6; H, 3.0.

1,1-Di-(*p*-chlorophenyl)-2-fluoroethanol (VIII).—To an ice-cold Grignard solution, prepared from magnesium (6.9 g.) and *p*-chlorobromobenzene (57.5 g.) in ether (150 ml.), a solution of ethyl fluoroacetate (17. g.) in ether (150 ml.) was added within 20 minutes. This was followed immediately by a cold saturated solution of ammonium chloride in water. The organic layer was separated, washed and filtered with the help of filter-aid and evaporated. The solid residue was recrystallized from methanol. Thus 4,4′-dichlorodesoxybenzoin (IX) (4 g.), m.p. 113–114°, was obtained; it was identified by its mixed m.p. with an authentic sample. The methanolic mother liquor was evaporated and the residue distilled *in vacuo*. 1,1-Di-(*p*-chlorophenyl)-2-fluoroethanol (VIII) boiled at 173–176° (2 mm.). It solidified and was recrystallized from petroleum ether; m.p. 75–76°, yield 24.6 g. (58%); ultraviolet spectrum in alcohol (log ε): 226 mμ (4.24), 266 mμ (2.60), 275 mμ (2.44).

Anal. Calcd. for $C_{14}H_{11}Cl_2FO$: C, 59.0; H, 3.9. Found: C, 59.5; H, 4.0.

1,1-Di-(*p*-chlorophenyl)-2-fluoroethylene (X).—The mixture of VIII (1 g.) and concentrated sulfuric acid (20 g.) was kept for 12 hr. at room temperature. By addition of ice, extraction with ether, evaporation of the solvent and recrystallization of the solid residue from methanol, 0.5 g. (53%) of X was obtained, m.p. 79–80°; ultraviolet spectrum: 240 mμ (log ε 4.22); infrared spectrum (KBr pellet): 3500, 3000, 1640, 1500, 1400, 1178, 1088, 1070, 1015, 925, 840, 830, 822, 765, 705 cm.$^{-1}$.

Anal. Calcd. for $C_{14}H_9Cl_2F$: C, 63.0; H, 3.4; Cl, 26.6. Found: C, 63.4; H, 3.2; Cl, 26.0.

When the carbinol VIII (2 g.) was refluxed with acetic anhydride (10 ml.) and concentrated sulfuric acid (2 drops) for 3 hr., the ethylene X was obtained in 80% yield.

Oxidation.—The ethylene X (1 g.) was refluxed with chromic acid (2 g.) in glacial acetic acid (10 ml.) for 30 minutes. By addition of water, extraction with ether, evaporation of the solvent and recrystallization of the residue from ethanol, 4,4′-dichlorobenzophenone (0.5 g.) was obtained. It was identified by its melting point and by a mixed melting point with an authentic sample.

1,1′-Di(*p*-chlorophenyl)-ethane.—The carbinol VIII (1.5 g.) was refluxed in glacial acetic acid (10 ml.) with red phosphorus (0.6 g.) and iodine (0.25 g.) for 30 minutes. Water (0.1 ml.) was added and the heating continued for 48 hr. The product was diluted with water, extracted with ether and the extract washed with a solution of sodium thiosulfate and water. Evaporation of the solvent and recrystallization of the residue from methanol gave 1,1-di-(*p*-chlorophenyl)-ethane (0.7 g., 54%), identified by its melting point (54–55°) and by the mixed melting point with an authentic sample.

***p*-Chloro-ω-fluoroacetophenone.**—Finely divided aluminum chloride (250 g.) and subsequently a solution of fluoroacetyl chloride (80 g.) in ethylene dichloride (300 ml.) was added to 1 l. of ethylene dichloride with vigorous agitation which was continued for 30 minutes. The dark solution was decanted into a three-necked flask, cooled at 0° and a mixture of chlorobenzene (90 g.) and ethylene dichloride (75 ml.) added dropwise, with stirring, within 20 minutes; stirring was continued for 15 minutes and the mixture poured onto ice and hydrochloric acid. The

organic layer was separated, washed with water and sodium bicarbonate solution and dried. *p*-Chloro-ω-fluoroacetophenone distilled at 115–119° (8 mm.) and crystallized immediately as plates, m.p. 54–55° (from aqueous ethanol), yield 72 g. (52%). This ketone also has been described by Bergmann, Kalmus and Breuer,[11] who also have carried out the reduction with lithium aluminum hydride, described below; ultraviolet spectrum: 255 mμ (log ε 4.25); infrared spectrum (KBr pellet): $\nu_{C=O}$ 1700 cm.$^{-1}$.

Anal. Calcd. for C_8H_6ClFO: C, 55.8; H, 3.5. Found: C, 55.7; H, 4.5.

1-(*p*-Chlorophenyl)-2-fluoroethanol.—To an ice-cold solution of lithium aluminum hydride (1.5 g.) in anhydrous ether (80 ml.), a solution of *p*-chloro-ω-fluoroacetophenone (12 g.) in ether (50 ml.) was added during 90 minutes. After 10 minutes, the mixture was decomposed with a solution of sulfuric acid (1 ml.) in 30 ml. of ice-water, and the ethereal layer separated, washed and dried. 1-(*p*-Chlorophenyl)-2-fluoroethanol distilled at 124–134° (8 mm.) as a colorless oil; yield 11 g. (90%), $n^{29}D$ 1.5398; infrared spectrum: 3400, 1500, 1100, 1010, 900, 830 and 750 cm.$^{-1}$.

Anal. Calcd. for C_8H_8OClF: C, 55.2; H, 4.6. Found: C, 55.5; H, 4.7.

1,1-Di-(*p*-chlorophenyl)-2-fluoroethane (XIII).—To an ice-cold mixture of 1-(*p*-chlorophenyl)-2-fluoroethanol (2 g.) and chlorobenzene (5 g.), a mixture of concentrated sulfuric acid (20 ml.) and fuming sulfuric acid (4 ml.) was added dropwise. The reaction mixture was shaken mechanically for 2 hr., then poured onto ice and extracted with ether. The ethereal solution was washed, dried, evaporated and the product distilled *in vacuo*. It boiled at 155–165° (2 mm.) and solidified spontaneously; from methanol, m.p. 54–55°, yield 1 g. (32%).

Anal. Calcd. for $C_{14}H_{11}Cl_2F$: Cl, 26.3. Found: Cl, 26.0.

Reaction with Alkali.—The compound XIII (0.3 g.) was refluxed with 1 *N* methanolic potassium hydroxide solution (5 ml.) for 1 hr., hydrochloric acid (2 ml.) and water (30 ml.) added and the product extracted with ether. The ether residue was recrystallized from methanol (0.2 g.) and melted at 84–85°. It was identified as **1,1-di-(*p*-chlorophenyl)-ethylene** by comparison with an authentic sample; infrared spectrum: 3400, 1600, 1500, 1420, 1190, 1120, 1085, 1018, 970, 855, 825, 790, 725 cm.$^{-1}$.

Difluorochloromethyl-*p*-chlorophenylcarbinol.—A solution of the ketone VI (11.3 g.) in ether (30 ml.) was added, dropwise, to a well-stirred ice-cold suspension of lithium aluminum hydride (1.5 g.) in ether (50 ml.). An ice-cold mixture of sulfuric acid (10 ml.) and water (50 ml.) was added cautiously, the ethereal layer separated, washed with water and concentrated and the residue distilled *in vacuo*; b.p. 115–120° (10 mm.), colorless liquid, $n^{28}D$ 1.5144, yield 9 g. (80%).

Anal. Calcd. for $C_8H_6Cl_2F_2O$: C, 42.3; H, 2.7. Found: C, 42.4; H, 2.8.

Dichlorofluoromethyl-*p*-chlorophenylcarbinol.—The ketone VII (4 g.) in ether (15 ml.) was reduced with lithium aluminum hydride (0.5 g.) in ether (20 ml.). The product distilled at 120–125° (2 mm.) as a colorless liquid, $n^{30}D$ 1.543, yield 3.5 g. (87%); infrared spectrum: 3500, 1600, 1400, 1200, 1085, 1010, 950, 870–880, 820, 795, 771, 715 cm.$^{-1}$.

Anal. Calcd. for $C_8H_6Cl_3FO$: Cl, 43.7. Found: Cl, 43.4.

1,1-Di-(*p*-chlorophenyl)-2,2-difluoro-2-chloroethane (XI).—To a well-stirred mixture of chlorobenzene (4.5 g.), concentrated sulfuric acid (10 ml.) and 20% fuming sulfuric acid (3 ml.), was added, slowly and with cooling, *p*-chlorophenyldifluorochloromethylcarbinol (5 g.). The mixture was then shaken for 5 hr., added to crushed ice and extracted with ether. After removal of the ether and excess chlorobenzene by distillation, the ethane XI distilled at 160–165° (2 mm.), yield 6 g. (85%). The product solidified; after recrystallization from methanol, it melted at 54–55°; ultraviolet spectrum: 228 mμ (4.20); 260 mμ (2.60); 267 mμ (2.62); infrared spectrum (KBr pellet): 1500, 1400, 1210, 1170, 1090, 1015, 962, 765 cm.$^{-1}$.

Anal. Calcd. for $C_{14}H_9Cl_3F_2$: C, 52.3; H, 2.8. Found: C, 52.1; H, 2.9.

Reaction with Alkali.—The compound XI (1 g.) was refluxed for 1 hr. with 1 *N* methanolic potassium hydroxide (20 ml.). Water was added and the mixture extracted with ether. After removal of the solvent, **1,1-di-(*p*-chlorophenyl)-2,2-difluoroethylene (XIV)** distilled at 165–169° (2 mm.), yield 0.7 g. (79%), $n^{30}D$ 1.5732. The substance was so unstable that only approximate analyses could be obtained. However, the spectrum indicated (see above) that the compound had structure XIV; ultraviolet spectrum (isoöctane): 228 mμ (4.46); 255 mμ (4.06).

1,1-Di-(*p*-chlorophenyl)-2,2-dichloro-2-fluoroethane (XII).—Condensation of *p*-chlorophenyldichlorofluoromethylcarbinol (2.5 g.) and chlorobenzene (2 g.) in the presence of concentrated sulfuric acid (5 ml.) and 20% fuming sulfuric acid (1.5 ml.) gave XII (2 g., 57%); b.p. 180–185° (2 mm.), m.p. after recrystallization from methanol 78–79°; ultraviolet spectrum (log ε): 232 mμ (4.26), 260 mμ (2.74), 267 mμ (2.76); infrared spectrum (KBr pellet): 1500, 1400, 1120, 1090, 1015, 940, 810, 780 cm.$^{-1}$.

Anal. Calcd. for $C_{14}H_9Cl_4F$: C, 49.8; H, 2.7. Found: C, 50.4; H, 2.8.

Reaction with Alkali.—Upon alkaline hydrolysis of the ethane XII (0.75 g.) as described above, **1,1-di-(*p*-chlorophenyl)-2-chloro-2-fluoroethylene (XV)** (0.55 g., 85%) was very probably obtained. It distilled at 165–166° (3 mm.) as a colorless but unstable oil, of $n^{28}D$ 1.6059.

ω-Fluoroacetophenone. III. Reaction of Fluoroacetyl Chloride with Halobenzenes. On the Mechanism of Side-chain Chlorination by Sulfuryl Chloride

BY FELIX BERGMANN, ABRAHAM KALMUS AND ELI BREUER[1]

RECEIVED FEBRUARY 8, 1957

The synthesis of ω-fluoroacetophenone has been extended to halobenzenes. The mechanism of side-chain chlorination of these ketones by sulfuryl chloride has been studied and a reaction scheme proposed.

The synthesis of ω-fluoroacetophenone (I), which was described previously,[2] was based on the observation that prolonged contact of I with aluminum chloride is responsible for halogen exchange, producing ω-chloroacetophenone (II). Short reaction periods are required to secure sizable yields of I. It remained undecided, however, whether the same type of exchange proceeds with fluoroacetyl chloride, prior to condensation. This possibility was tested by treating the latter with the Friedel-Crafts catalyst in methylene chloride at room tem-

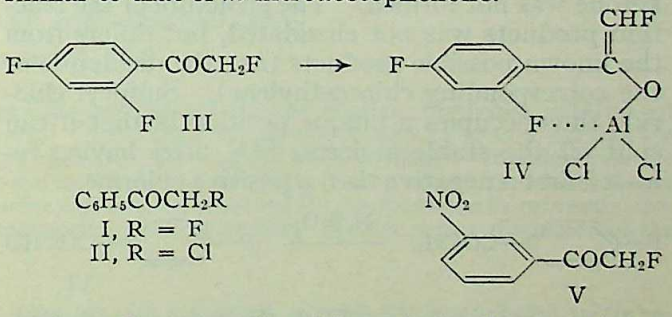
perature for six hours, then cooling the solution to 0°, adding benzene and carrying out the reaction exactly as described previously. The product (50% yield), consisted of about equal parts of I and its chloro analog II. The pretreatment thus decreased the yield of I considerably. However, halogen exchange with fluoroacetyl chloride proceeds at a much lower rate than with the ketone I. The latter, when incubated under similar conditions, is converted almost quantitatively into chloroacetophenone.

When substituted benzenes were submitted to the same reaction, only the halogeno derivatives gave positive results, albeit yields were much inferior to benzene itself (see Table I). Chlorobenzene produced, in addition to 24% of the ω-fluoroketone, also about 3% of *p*,ω-dichloroacetophenone.[3] With fluorobenzene, the yield of ketones was nil when standard conditions were applied. A highly viscous oil was isolated instead, indicating the occurrence of secondary condensation reactions. However, when the reaction was carried out at 0° and interrupted after 10 minutes, a 55% yield of *p*,ω-difluoroacetophenone was obtained. The structure of this compound was established in the way described below. Bromobenzene did not react with fluoroacetyl chloride at 0°. At room temperature, some debromination took place also, in addition to condensation, and no defined product was isolated from the mixture. Anisole gave, even after very short reaction times, a resinous product, which decomposed at about 180° when vacuum distillation was attempted.

In contrast to fluorobenzene, *m*-difluorobenzene had to be exposed to much more drastic conditions in order to promote condensation with fluoroacetyl chloride (30 minutes at 0° and 30 minutes at room temperature). The reaction product is assumed to be III. Although in this case the yield was only 10%, no trace of the ω-chloro derivative accompanied III. The ketone III proved to be rather stable toward halogen exchange, presumably because of competition of the *o*-fluorine with the ω-halogen in complexing the metal atom (as *e.g.* in IV). On this basis it was expected that during a Grignard reaction the intermediate would similarly be protected against rearrangement to a desoxybenzoin[2] by complexing of the metal atom with *o*-fluorine. Therefore, a mixture of phenylmagnesium bromide and 2,4,ω-trifluoroacetophenone (III) in ether was refluxed for four hours. The product, however, was identified as a desoxybenzoin and no trace of its precursor, the tertiary carbinol, was detected.

Nitration of I in acetic acid gave the *m*-nitro derivative V, the point of substitution being proved by oxidation to *m*-nitrobenzoic acid. Likewise, the ultraviolet absorption spectrum of V is quite similar to that of *m*-nitroacetophenone.



$C_6H_5COCH_2R$
I, R = F
II, R = Cl

The *p*-fluoro- and *p*-chloro derivatives of I can be halogenated by the methods available for ω-fluoroacetophenone itself.[4] The chlorination with sulfuryl chloride was studied in more detail. Acetophenone reacts instantaneously at room temperature, and chlorination is completed within 2 hours, giving a practically quantitative yield of II. With ω-fluoroacetophenone—as described previously—reaction starts at room temperature with a marked delay (about 0.5 hour) and requires 16 hours for its completion. With *p*,ω-difluoroacetophenone and *p*-chloro-ω-fluoroacetophenone substitution can be effected only with refluxing sulfuryl chloride. The ketones III and V were not attacked even under these conditions. No trial was made at still higher temperatures.

The outstanding capacity of sulfuryl chloride to chlorinate methyl as well as fluoromethyl, in α-position to the carbonyl, may be interpreted by way of a cyclic mechanism, indicated in scheme A. Here, the reagent is assumed first to polarize the carbonyl group strongly, forming an enol ester and eliminating HCl. In the second phase of the reaction, the electronic cycle swings back and introduces positive chlorine into the α-position.[5]

In order to test this hypothesis, other acid chlorides, capable of forming similar enol esters and carrying out the corresponding electronic cycles, were tried. Oxalyl chloride was found unreactive. Phosphorus pentachloride attacked the carbonyl group, but the expected ω-chloro-ω-fluoro ketone was not formed. The structure of the reaction products was not elucidated, but differs from the known possible products (*i.e.*, the dichloride or the corresponding chloroethylene). Sulfuryl chloride thus occupies a unique position in that it can split off the stable molecule SO_2, after having released first a negative then a positive chlorine.

$$F{-}C_6H_4{-}COCH_3 \xrightarrow{H_2SeO_3} F{-}C_6H_4{-}COCHO$$

VI

In an attempt to establish the point of substitution in the ketone, obtained by fluoroacetylation of fluorobenzene, the usual methods of oxidation of the side chain did not give the expected aromatic acids, suitable for identification. Therefore, the following method was adopted: *p*-Fluoroacetophenone[6a,b] was converted by selenious acid into the glyoxal VI. The bis-dinitrophenylhydrazone of VI decomposes at about 296°. In order to identify unequivocally this compound with the corresponding derivative, obtained from *p*,ω-fluoro-ω-chloroacetophenone (Table II), the X-ray powder diagrams were compared. They were found to be identical, as did also the infrared spectra of the hydrazones from the two sources.

Experimental

All melting points are uncorrected.

p-Chloro-ω-fluoroacetophenone.—Condensation of chlorobenzene (35 g.) with fluoroacetyl chloride (29 g.) was carried out in ethylene chloride (100 ml.), with aluminum chloride (65 g.) as catalyst, exactly under the conditions described previously.[2] The product was fractionated *in vacuo*: (a) b.p. 73–75° (0.4 mm.), yellow oil, which crystallizes spontaneously. From petroleum ether needles of m.p. 53–54°; 13 g. (24%) yield of *p*-chloro-ω-fluoroacetophenone; (b) b.p. 90° (0.4 mm.), yield, 2 g. (3%) of *p*,ω-dichloroacetophenone; from ethanol needles of m.p. 100–101°[3]; oxime m.p. 101°.[7]

p-Chloro-ω-fluoroacetophenone (1 g.) was dissolved in sulfuryl chloride (5 ml.). No evolution of gas occurred at room temperature (26°) during 12 hours, and the starting material could be recovered. Upon refluxing the solution, hydrogen chloride and sulfur dioxide escaped slowly. After 5 hours' heating, the reaction mixture was decomposed with ice and extracted with ether. The ether residue was strongly lachrymatory and tended to decompose during vacuum distillation. It was, therefore, converted directly into a bis-2,4-dinitrophenylhydrazone, which decomposed at about 280° but was so difficultly soluble that no suitable medium for recrystallization could be found.

p,ω-Difluoroacetophenone.—Aluminum chloride (80 g.) was stirred with ethylene dichloride (300 ml.) for 20 minutes and the solution decanted and cooled to 0°. Fluoroacetyl chloride (18 g.) in ethylene dichloride (60 ml.) was added and immediately thereafter fluorobenzene (25 g.) in the same solvent (60 ml.) during 10 minutes. Stirring at 0° was continued for another 10 minutes, and the mixture poured at once into concentrated hydrochloric acid and ice. The ketone was isolated in the usual way and purified by distillation, b.p. 85–90° (4 mm.). The substance crystallized immediately, and after recrystallization from petroleum ether formed sharp-edged plates of m.p. 50–51°. Its 2,4-dinitrophenylhydrazone crystallized from acetic anhydride in deep-red columns.

p,ω-Difluoroacetophone (15 g.) was dissolved in sulfuryl chloride (35 ml.). No reaction occurred at room temperature, but evolution of hydrogen chloride was observed when refluxing the solution. After 5 hours, the mixture was decomposed with ice and extracted with ether. The ether residue distilled smoothly *in vacuo*, b.p. 84–88° (10 mm.). The yellow oil solidified when kept in a refrigerator. The lachrymatory product, *p*,ω-difluoro-ω-chloroacetophenone, melted at 33°, yield, 12.5 g. (68%). The ketone formed a bis-2,4-dinitrophenylhydrazone which crystallized from pyridine–*n*-butyl acetate in red needles of m.p. 295–296°. *Anal.* Calcd. for $C_{20}H_{13}O_8N_8F$: C, 46.8; H, 2.5. Found: C, 46.7; H, 2.4.

Bromination was effected at room temperature by the method described for ω-fluoroacetophenone.[2] *p*,ω-Difluoro-ω-bromoacetophenone was purified by distillation *in vacuo*, b.p. 120–130° (14 mm.), but did not crystallize; yield 65%. The substance is a strongly irritating tear gas. When the ω-bromo ketone was dissolved in ethanol containing an equivalent of sodium iodide, reaction proceeded at room temperature within half an hour. *p*,ω-Difluoro-ω-iodoacetophenone could not be purified, since it is unstable even at room temperature and easily soluble even in petroleum ether. It is a very powerful lachrymator.

2,4-ω-Trifluoroacetophenone (III).—*m*-Difluorobenzene[8] was added to a mixture of fluoroacetyl chloride and aluminum chloride in methylene chloride at 0°. The mixture was stirred for 30 minutes at 0° and an additional half-hour at room temperature. The product was isolated as usual and crystallized immediately after evaporation of the solvent. From ligroin, plates of m.p. 62–63° were obtained. The 2,4-dinitrophenylhydrazone crystallized from *n*-butyl alcohol in rods of m.p. 182–183°.

m-Nitro-ω-fluoroacetophenone (V).—ω-Fluoroacetophenone (10 g.) in concentrated sulfuric acid (22 ml.) was cooled

(5) It should be noted that this is not the only possible way of representation. An alternate possibility is shown in scheme A′ as nucleophilic substitution at the methylene carbon.

to −15°. A mixture of nitric acid (d. 1.42) (10 ml.) and sulfuric acid (10 ml.) was added dropwise, the temperature being kept below −5°. Stirring was continued for 30 minutes and the mixture poured on ice. The solid material was filtered, washed with water and twice with ethanol and recrystallized from methanol or ethanol; yellow rods of m.p. 95–96°, yield 8.8 g. (66%).

p-Fluorophenylglyoxal (VI).—To a solution of selenious acid (43 g.) in dioxane (200 ml.), warmed to 60°, *p*-fluoroacetophenone[6a,b] (46 g.) was added slowly. After 5 minutes, a red precipitate formed. The solution was refluxed for 4 hours and left overnight. It was then decanted from the red precipitate and fractionated. At 105–115° (30–35 mm.) a thick, yellow oil went over which showed no tendency to crystallize; yield 35 g. (78%). The oil was dissolved in benzene and a few drops of water added. This resulted in the formation of a white powder. Recrystallization from water gave the hydrate of VI as glistening, white leaflets, m.p. 80°.

Anal. Calcd. for $C_8H_5O_2F\cdot H_2O$: C, 56.5; H, 4.1. Found: C, 56.9; H, 4.3.

The bis-2,4-dinitrophenylhydrazone crystallized from pyridine–*n*-butyl acetate, decomposition point 296°.

Grignard Reaction with 2,4,ω-Trifluoroacetophenone (III).—To a Grignard solution, prepared from bromobenzene (4.7 g.) and magnesium (0.7 g.) in ether, was added slowly an ethereal solution of 2,4,ω-trifluoroacetophenone (4.5 g.) during 15 minutes. The mixture was refluxed for 2 hours and then left overnight. It was decomposed with ammonium chloride and worked up in the usual way. Fractional distillation gave 5.2 g. of a yellow oil of b.p. 135–138° (4 mm.).

Anal. Calcd. for $C_{14}H_{10}OF_2$: C, 72.4; H, 4.3. Found: C, 72.0; H, 4.7.

The 2,4-dinitrophenylhydrazone crystallized from isopropyl alcohol in pointed plates of m.p. 165–167°.

Anal. Calcd. for $C_{20}H_{14}O_4N_4F_2$: N, 13.6. Found: N, 13.4.

The authors wish to thank Prof. E. Alexander, Department of Physics, for the X-ray spectra and Mrs. Hanna Feilchenfeld, Department of Organic Chemistry, for the infrared measurements used for identification of *p*,ω-difluoroacetophenone.

The Relative Reactivities of Substituted Toluenes toward Chlorine Atoms[1]

BY CHEVES WALLING AND BERNARD MILLER[2]

RECEIVED JANUARY 23, 1957

Competitive halogenations of a series of substituted toluenes have been carried out and relative reactivities determined by the precise deuterium tracer technique of Russell and Brown.[7] For photochlorination the results yield a ρ value for attack of chlorine atoms of −0.76, appreciably smaller than the value of −1.5 reported by Kooyman.[15] Identical relative reactivities and k_H/k_D ratios are observed in photochlorination and in reaction with SO_2Cl_2, giving no evidence for different chain carriers in this system. However, some variation in relative reactivity is observed for reactions run in primarily aromatic media and in carbon tetrachloride. Data on photobromination are also presented, together with a discussion of the importance of polar effects in free radical halogenation.

The reaction of chlorine with aliphatic hydrocarbons and the side-chains of alkyl-aromatics is well established[3] as a radical chain process involving the chain carrying steps.

$$Cl\cdot + RH \longrightarrow HCl + R\cdot \qquad (1)$$

$$R\cdot + Cl_2 \longrightarrow RCl + Cl\cdot \qquad (2)$$

With hydrocarbons containing more than one type of C–H bond (or in mixtures of hydrocarbons) the products formed evidently will depend upon the relative rates of reactions of type (1) of chlorine atoms with the different sorts of C–H bond available. The work of Hass, McBee and Weber[4] has shown clearly that, with aliphatic hydrocarbons, the case of hydrogen displacement lies in the order primary < secondary < tertiary, the selectivity being somewhat greater in the vapor than in the liquid phase and decreasing with increasing temperature. Recently Pritchard, Pyke and Trotman-Dickenson[5] have studied the competitive chlorination of a number of simple hydrocarbons with results leading to similar conclusions, and have actually determined rate constants for hydrogen abstraction by carrying out competitions with the process

$$Cl\cdot + H_2 \longrightarrow HCl + Cl\cdot \qquad (3)$$

for which the rate constant is known over a wide temperature range.[6] Since C–H bond dissociation energies lie in the order primary > secondary > tertiary, decreasing approximately 4 kcal. with each substitution, this weakening, presumably due to resonance stabilization of the resulting radicals, has commonly been given as the explanation of the observed order of chlorine atom substitution.

Unfortunately for this simple picture, more complex molecules do not yield results which indicate a simple parallel between C–H bond strength and ease of attack by chlorine atoms. Competitive chlorination of toluene and *t*-butylbenzene shows[7] that the C–H bonds of the former are only slightly more reactive in spite of the great resonance stabilization (∼ 25 kcal.) of the benzyl radical. More strikingly, the C–H bonds of cyclohexane prove to be *more* reactive than those of toluene by a factor of 2.7.[7,8] Still more anomalous results are observed in the chlorination of molecules containing other

substituent atoms. Brown and Ash[9] have recently summarized data on the chlorination of 1-chlorobutanes and related compounds which show plainly that the presence of a chlorine atom decreases the ease of further chlorine substitution at the same and adjacent carbons, in spite of the fact that the C–H bonds are weakened.[10] In a number of cases the chlorinating agent was actually SO_2-Cl_2; see below. Similarly, radical chlorination of aliphatic acids and their derivatives (acid chlorides, esters and nitriles)[9,11] gives predominantly substitution along the chain with little α-attack in spite of the expected resonance stabilization of the resulting $-\dot{C}H-CO-$ radical, and the known fact that alkyl radicals preferentially attack acid derivatives in the α-position.[12]

In 1950 Mayo and Walling[13] suggested that the anomalous results in the chlorination of alkyl halides and aliphatic acid derivatives might be explained on the basis of the importance of polar contributions to the transition state of the radical displacement, an idea which may be restated by saying that structures such as

$$Cl\cdot \; H\text{—}R \longleftrightarrow Cl^{-}\overset{+}{H}\;\dot{R} \qquad (4)$$

can aid in lowering the activation energy in the attack of chlorine atoms on hydrocarbons but would be relatively unimportant in the presence of strongly electron-withdrawing groups. Brown and Ash[9] have interpreted the situation similarly but less specifically in terms of the inductive effect of –Cl and –COR groups in decreasing electron availability at the adjacent C–H bonds.

One of the most effective techniques for separating such polar effects from others arising from steric and related factors is by studying the effect of *m*- and *p*-substituents on the side-chain reactions of benzene, and treating the results in terms of the Hammett equation

$$\log k/k_0 = \rho\sigma \qquad (5)$$

in which k and k_0 are rate (or equilibrium) constants for reaction of substituted and unsubstituted benzenes, respectively, and ρ and σ are parameters determined, respectively, by the particular reaction under investigation and the substituent involved.[14] Accordingly, we have undertaken a study of the effects of *m*- and *p*-substituents on the liquid-phase, side-chain photochlorination of toluenes, employing a competitive technique, since, as noted above, this method gives directly the relative rates of hydrogen abstraction from different molecules by chlorine atoms, without involving the complicated over-all kinetics of the long-chain processes involved.

Shortly after this work was initiated, Kooyman published a similar study of the side-chain bromination of toluene,[15a] and has subsequently extended his work to the sulfuryl chloride chlorination,[15b] finding that, in both cases, substitution is facilitated by electron supplying and retarded by electron withdrawing groups. Qualitatively, the results of the study reported here are in agreement with Kooyman's sulfuryl chloride data. However, we have employed a more extensive series of derivatives and a more precise analytical method, and have arrived at a somewhat different interpretation which we believe makes a detailed report desirable.

Experimental

Materials

Substituted toluenes—except as indicated—were commercial materials, fractionally distilled (and dried if necessary) before use. ***p*-*t*-Butyltoluene** was prepared by the alkylation of toluene with isobutyl alcohol in the presence of H_2SO_4.[16] ***m*-Phenyltoluene** was prepared by treating *m*-tolylmagnesium bromide with cyclohexanone, dehydrating the resulting alcohol by heating with $KHSO_4$, and dehydrogenating the 1-(*m*-tolyl)-cyclohexene over 10% Pd on charcoal at 280–300° in an over-all yield of 56.5%, b.p. 148–152° (20 mm.), $n^{20}D$ 1.6002. *Anal.* Calcd. for $C_{13}H_{12}$: C, 92.86; H, 7.14. Found: C, 92.87; H, 7.12. ***p*-Phenyltoluene** was prepared similarly from *p*-bromotoluene and recrystallized from petroleum ether, m.p. 46–47°; lit.[17] 47–48°, over-all yield, 44%. **Toluene-α-d_1** was prepared in 76% yield from benzylmagnesium bromide and DCl by the method of Russell and Brown.[7] The reaction product was twice distilled from sodium through a 10-plate helix packed column, b.p. 110–110.5°, $n^{20}D$ 1.4947. The toluene-α-d_1 was combined with its volume of pure toluene for use, and, after completion of a series of runs, combined reaction mixtures were fractionated and combined with fresh toluene-α-d_1 and toluene. All these mixtures are referred to below as *deuterotoluene*.

Solvents.—Carbon tetrachloride was washed three times with a 50% aqueous ethanol solution of KOH, with water, and dried over $CaSO_4$. It was then treated for 15 hours with chlorine and light, dried over $MgSO_4$ and fractionated through a 10-plate column, b.p. 76°. Thiophene-free **benzene** was washed with sulfuric acid and water, dried, distilled from sodium, and fractionally crystallized, m.p. 5.2°, $n^{25}D$ 1.4494. ***o*-Dichlorobenzene** was dried over P_2O_5 and fractionally distilled through a 10-plate column, b.p. 179–180°, $n^{25}D$ 1.5501.

Halogenating Agents.—Chlorine was commercial material, distilled through sulfuric acid before use. **Bromine** was distilled from P_2O_5, and **sulfuryl chloride** was a colorless middle cut obtained by fractionating commercial material. It was stored in an aluminum foil covered flask until used.

Halogenations

Our technique in general involved the halogenation of mixtures of toluene-α-d_1 and substituted toluenes and determining relative reactivities by analysis of the DCl–HCl mixture evolved. This method, which was used by Brown and Russell,[7,8] is capable of high precision, but was checked in several cases by fractional distillation of our reaction mixtures.

Photochlorinations were carried out in the apparatus shown in Fig. 1. With stopcock A open and C closed, chlorine was condensed in B by chilling with a Dry Ice-bath. Trap B was graduated to permit measurement of the volume of chlorine condensed (1.5–2.5 ml.) at its boiling point. With the stirrer, F, running, a gentle stream of prepurified nitrogen was next passed through C, the mixing bulb D, and the rest of the apparatus to remove traces of

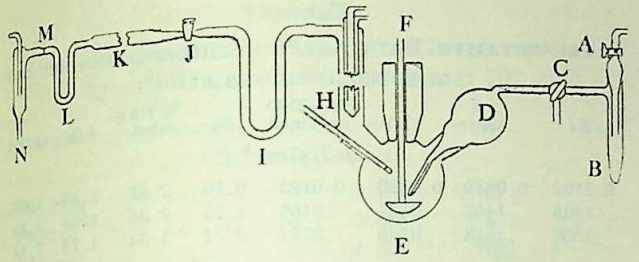

Fig. 1.—Apparatus for competitive liquid-phase halogenation of toluenes.

air. With A closed, and C turned so that all three tubes were connected, the bath around B was lowered and chlorine swept by the nitrogen stream into the reaction flask E which was illuminated by a 200-watt incandescent bulb at the distance of one inch. Both reaction flask and bulb are submerged in a thermostat kept at 69.5 ± 0.5°.

The gases generated passed through an efficient condenser H and Dry Ice trap I where any organic vapors are condensed. They next reached the tube K, packed at both ends with glass wool, and containing a 2-mole excess of tightly packed silver oxide, where the DCl–HCl was converted to D_2O–H_2O. Since this reaction is strongly exothermic, K was cooled and kept from light by a wet towel. Prior to reaction, the entire system beyond J was carefully dried by pumping on a vacuum pump for a half-hour. After all the chlorine had been introduced the stream of nitrogen was continued for 15 minutes to sweep out residual DCl–HCl. The stopcock J was then closed, and the water drawn by a vacuum pump connected to the end of the system into the U-tube L, containing more silver oxide, and cooled by Dry Ice. Next the pump was stopped, the bath lowered, and the water, after melting, shaken with silver oxide. It was then distilled under vacuum through the sintered plate M into the final Dry-Ice trap N where it was weighed and a drop withdrawn and tested for halide with silver nitrate. The water was finally pipetted into a centrifuge tube, centrifuged to remove air bubbles, and the deuterium content measured.

In typical experiments, 0.25–0.35 mole of mixed toluenes was treated with 0.035–0.045 mole of chlorine and E had a volume of 100 ml. In runs using solvents, 100 cc. of solvent and a larger 250-ml. reaction flask were employed, and an additional trap, immersed in an ice-salt bath, was interposed between H and I.

Photobrominations.—A similar apparatus was employed and bromine was pipetted into B, which was maintained at 50° by a water-bath during the reaction.

Sulfuryl Chloride Reactions.—Here the apparatus for halogen introduction was replaced by a pressure equalized dropping funnel, and benzoyl peroxide, rather than light, was used as an initiator. Three ml. of sulfuryl chloride was placed in the funnel, and the system flushed with nitrogen. Next, 0.5 ml. of sulfuryl chloride was dropped into E, and after vigorous reaction began (5–15 min.) the balance introduced over two hours. In operation it was found that the SO_2 and most of the HCl produced condensed in the Dry Ice trap I, so it was necessary to close off the system between H and I by an additional stopcock, and distil the HCl–DCl into K under reduced pressure. The rest of the procedure was similar to that used in photochlorination.

Vapor Phase Reactions.—A mixture of toluene and toluene-α-d_1 was photochlorinated in the vapor phase in order to determine the magnitude of the isotope effect under these conditions. The apparatus used is shown in Fig. 2. In operation, deuterotoluene was placed in B, and chlorine condensed in A by means of a Dry Ice trap. The receiver E was cooled with Dry Ice, while B and the reaction coil D were maintained at 69.5° by a thermostat. During reaction, the pressure in the system was maintained at 85 mm. by a vacuum pump at the end of the usual absorption and conversion train attached at F, and the toluene mixture continually distilled from B through coil D, which was illuminated by a 200-watt incandescent lamp at a distance of one inch, passed into E, and was recycled. Chlorine slowly was introduced by lowering the cooling bath around A, the whole reaction taking 2–3 hours, and the toluene recycling about once every 20 minutes. The absorption of the DCl–HCl mixture and conversion to D_2O–H_2O was accomplished in the same manner as in the liquid-phase experiments.

In addition, we also investigated the competitive chlorination of toluene and cyclohexane in the vapor phase. Here, because of the difference in volatility of the two components, it was not possible to use a recycling system. Accordingly, in place of the flask B, an apparatus was attached consisting of a vaporizer maintained at 100–120° and a coil immersed in the thermostat and intended to bring the vaporized hydrocarbon mixture to thermal equilibrium with the system. The toluene–cyclohexane mixture was dripped slowly into the vaporizer from a pressure-equalized dropping funnel. Considerable difficulty was encountered with this set-up, and only two satisfactory runs were achieved. Accordingly, we have some reservations about the accuracy of our results.

Analytical Methods

Deuterium Determinations.—Measurement of the deuterium content of water was done by the falling drop method[18] in which water density is effectively measured from the time required for uniform droplets to sink a predetermined distance in a carefully thermostated column of *o*-fluorotoluene. A standard curve for sinking time was constructed using known mixtures of D_2O–H_2O, and frequently rechecked. Three or more drops were timed for each sample, the reproducibility being ±0.01% D_2O.

Deuterium analysis in our deuterotoluene was done by burning samples in a conventional apparatus for C–H determination, and collecting the water in a Dry Ice trap protected by a soda-lime tube. On completion of the combustion, the water was distilled into a second trap, and redistillation from a crystal of $KMnO_4$ showed no measurable change in deuterium content.

Total Halogen.—A 2-ml. sample of reaction mixture was refluxed 2–3 hours with xylene and sodium according to the method of Landis and Wichmann.[19] The xylene was distilled from sodium before use and butyl alcohol was used to activate the reaction since commercial amyl alcohol was found to contain significant halogen. The resulting chloride ion was determined by Mohr titration.

Benzyl Halogen.—A 2-ml. sample of reaction mixture was refluxed 2 hr. with 10 ml. of 0.487 *N* NaOH and 30 ml. of ethanol. After neutralization with dilute nitric acid, chloride ion was determined by Mohr titration.

The difference between the two analyses presumably represents non-side-chain substitution, and amounted to 1–4% of the total halogen. Our deuterium concentrations were corrected accordingly, and with chloro- and cyanotoluenes where the method was inapplicable, a correction of 1.5% was used.

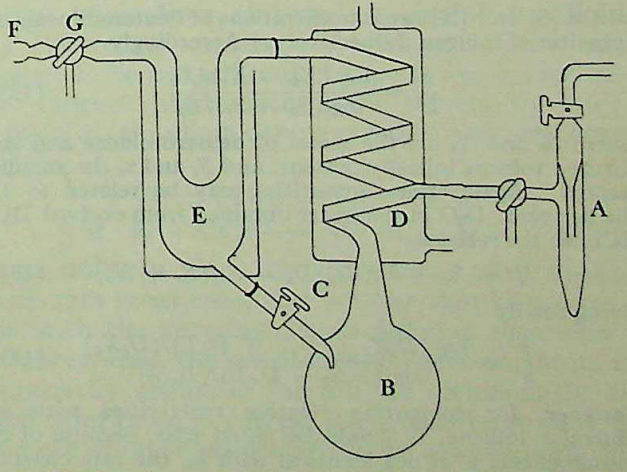

Fig. 2.—Apparatus for vapor-phase halogenation.

Treatment of Data

Isotope Effects.—In a "deuterotoluene" (toluene-α-d_1–toluene mixture) the rate of reaction of halogen with

replaceable hydrogen and deuterium is given by

$$d[HCl]/dt = -d[H]/dt = k_H [Cl\cdot][H] \quad (6a)$$

$$d[DCl]/dt = -d[D]/dt = k_D [Cl\cdot][D] \quad (6b)$$

where [Cl·] represents the concentration of halogen atoms and [H] and [D] of replaceable hydrogen and deuterium, respectively. Division of (6*a*) by (6*b*) gives

$$d[H]/d[D] = (k_H/k_D)[H]/[D] \quad (7)$$

Equation 7 is integrated readily, and, since (6*a*) and (6*b*) are of the same kinetic order, concentrations may be expressed as total moles of material present

$$\frac{k_H}{k_D} = \frac{\log (H_0 - H_r)/H_0}{\log (D_0 - D_r)/D_0} \quad (8)$$

where H_0 and D_0, respectively, represent moles of replaceable hydrogen and deuterium originally present, and H_r and D_r moles reacted. The foregoing derivation assumes that only one hydrogen is substituted in each toluene molecule reacted, a circumstance assured by using an approximately ten-fold excess of deuterotoluene.

The quantities in (8) are related to the analytically determined deuterium concentrations by the relations

$$H_0 = 3S_0 - D_0 \qquad H_r = T(100 - D_s)$$
$$D_0 = 8D_s S_0/100 \qquad D_r = TD_s/100 \quad (9)$$

where S_0 and T represent initial moles of deuterotoluene and halogen employed and D_0 and D_s, respectively, the per cent. D_2O in the water obtained on combustion of the particular sample of deuterotoluene and on conversion of the DCl–HCl evolved to D_2O–H_2O.

Table I lists three runs which illustrate the reproducibility of our data treated in this way.

TABLE I

ISOTOPE EFFECT IN THE PHOTOCHLORINATION OF TOLUENE

D_0 (4 DETERMINATIONS) 2.30, 2.30, 2.31, 2.31, AV. 2.305

T	S_0	D_s	k_H/k_D
0.041	0.271	3.45	2.05
.037	.316	3.40	2.11
.039	.312	3.39	2.08

Determination of Relative Reactivities.—In a similar manner to that above, the rates of halogenation of deuterated toluene and a substituted toluene are given by

$$-d[S]/dt = k' [S][Cl\cdot] \quad (10)$$
$$-d[X]/dt = k [X][Cl\cdot] \quad (11)$$

where [S] and [X] are concentrations of deuterotoluene and substituted toluene, respectively. Accordingly

$$\frac{k}{k'} = \frac{\log (X_0 - X_r)/X_0}{\log (S_0 - S_r)/S_0} \quad (12)$$

where S_0 and X_0 are the moles of deuterotoluene and substituted toluene initially present, and S_r and x_r the amounts reacted. Again, these quantities may be related to D_x, the per cent. D_2O in the water obtained from evolved DCl–HCl, *via* the relations

$$T = S_r + X_r, \; D_x/D_s = S_r/(S_r + X_r) \quad (13)$$

giving finally

$$\frac{k}{k'} = \frac{\log (D_sX_0 - D_sT + D_xT)/(D_sX_0)}{\log (D_sS_0 - D_xT)/(D_sS_0)} \quad (14)$$

However, for comparing relative reactivities with *undeuterated* toluene, it should be noted that, because of the isotope effect, k' is not identical with k_0, the rate constant for reaction of halogen atoms with undeuterated toluene. The ratio k'/k_0, however, may be obtained by applying an equation similar to (14) to mixtures of a deuterotoluene and undeuterated toluene, or calculated from the k_H/k_D ratio *via* the relation

$$\frac{k'}{k_0} = 1 - \frac{F}{3}\left(1 - \frac{k_D}{k_H}\right) \quad (15)$$

where F represents the mole fraction of toluene-α-d_1 in the deuterotoluene, determined by combustion. Table II presents typical data for *p*-xylene and *p*-chlorotoluene.

[a] k ratios corrected by a statistical factor of 2. [b] k'/k_0 = 0.92 for this sample of deuteroluene.

Our technique of determining relative reactivities was also checked for the toluene–*p*-chlorotoluene system by carrying out several larger scale runs using ordinary toluene, and determining the unreacted toluenes by fractional distillation. Data from one experiment appear in Table III, the composition of intermediate fractions being estimated by index of refraction. Three similar experiments, the last two carried out in benzene solution, gave k/k_0 = 0.63, 0.72 and 0.73, average 0.69, which appears within experimental error of the more precise deuterium technique.

Results and Discussion

Our data on relative reactivities of substituted toluenes are summarized in Table IV, and in Fig. 3 our values of log k/k_0 are plotted against Hammett ρ values of substituents, taken from Jaffe's review.[18] A straight line, drawn by the method of least squares through all points with the exception of the phenyl substituents (which are discussed further below) fits the equation log $k/k_0 = -0.76 + 0.03$, whence $\rho = -0.76$. Our results are thus in qualitative agreement with those of Kooyman (who reports $\rho = -1.5$) in that electron supplying groups facilitate, and electron withdrawing groups retard, the attack of chlorine atoms on toluene. This observation we also consider to be a polar effect perhaps best interpreted in terms of resonance structures of the sort indicated in eq. 4. However, before discussing this matter further we should consider the quantitative differences between the two sets of results.

Kooyman's study[15] differs from ours in that he employed sulfuryl chloride as his chlorinating agent, operated in a solvent (benzene), used a different analytical method (competitions were run against *t*-butylbenzene and products analyzed by separation or by differential rates of alkaline hydrolysis) and a somewhat different method of treating his data. Consideration of each of these

[a] A statistical factor of two was used in calculating k/k_0. [b] Average deviation from the mean of individual experiments. [c] This experiment was a competitive vapor-phase chlorination of toluene and cyclohexane, and a statistical factor of 4 was used in computing k/k_0.

points in turn provides a convenient basis for presenting some of the conclusions of this work.

Since discovery of the reaction by Kharasch and Brown in 1939,[20] the radical initiated chlorination of hydrocarbons by sulfuryl chloride has generally been considered as a chain process involving chlorine atoms as the chain carriers, and hence it should be identical in selectivity to photochlorination. However, Russell and Brown[21] have recently reported a significantly higher selectivity for tertiary *vs.* primary C–H bonds in the sulfuryl chloride reaction. They have suggested that, at least under some conditions, the $\cdot SO_2Cl$ radical may be the attacking species,[22] and have used the discrepancy between the preliminary report of our work[11] and that of Kooyman to support this interpretation. However, as shown in Table IV, competitive experiments with *p*-chloro- and *m*-cyanotoluene, in our hands, yield results indistinguishable from our photochlorinations. Chlorine and sulfuryl chloride also give indistinguishable k_H/k_D ratios, so we conclude that our substituted toluene experiments give no evidence for different carrier species in the two reactions.

On the other hand, Russell and Brown[7] have reported a k/k_0 value in the competitive chlorination of toluene and cyclohexane of 3.5 at 80°, compared with 2.8 for photochlorination. We have carried out the photochlorination in the vapor phase, obtaining $k/k_0 = 2.12$, which may be within experimental error of the liquid phase reaction, but certainly differs significantly from the SO_2Cl_2 result, particularly since, as observed by Hass,[3] chlorine atom selectivity is generally greater in the vapor than in the liquid phase.

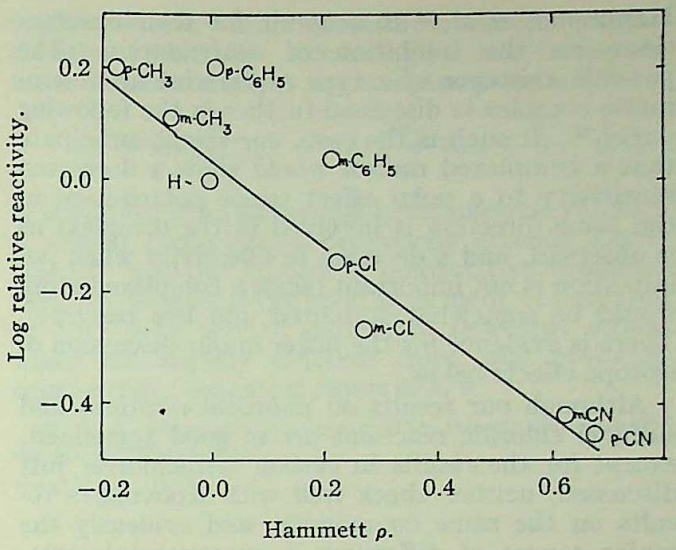

Fig. 3.—Relative reactivities of substituted toluenes toward chlorine atoms *vs.* Hammett ρ values for substituents.

To see if change of solvent plays any role in our systems, we have determined the relative reactivity of *p*-chlorotoluene in benzene and carbon tetrachloride, the systems being approximately 3 *M* in mixed toluenes. In benzene (the solvent used by Kooyman) no significant change occurs, but in carbon tetrachloride selectivity is increased about 50%, a result which has been checked by fractionation of larger runs (two experiments give $k/k_0 = 0.49, 0.43$, in excellent agreement with the isotope method). This then appears to be one of the very few examples of a significant variation in the relative rates of two radical reactions with change of medium and we are unable to afford any convincing explanation, although there also appears to be a significant change in k_H/k_D, see below. Direct interference of the solvent by interaction with the chain carrying radicals by processes such as

$$Cl\cdot + CCl_4 \longrightarrow Cl_2 + \cdot CCl_3 \qquad (16)$$

$$\text{or} \quad R\cdot + CCl_4 \longrightarrow RCl + \cdot CCl_3 \qquad (17)$$

seems unlikely since the reverse of (16) should occur with great ease, and neither should compete well with the very fast chain carrying reactions.[23]

Conceivably, the properties of a chlorine atom in a primarily aromatic solvent are significantly altered from those in carbon tetrachloride, so that, in the bulk of our measurements, we are studying the properties of a complexed radical. Such a suggestion has been made by Russell and Brown,[21] and the possibility of such complexes of peroxy radicals (with more strongly electron donating aromatic systems) has been advanced by Boozer,

(20) M. S. Kharasch and H. C. Brown, THIS JOURNAL, **61**, 2142 (1939).

(21) G. A. Russell and H. C. Brown, *ibid.*, **77**, 4031 (1955).

(22) M. S. Kharasch and A. F. Zavist, *ibid.*, **73**, 964 (1951), have also suggested the participation of $\cdot SO_2Cl$ radicals in SO_2Cl_2–olefin reactions to account for the formation of β-chlorosulfones when terminal olefins are employed.

(23) Reaction 16 would compete with hydrogen abstraction which has a rate constant of $>10^{10.6}$ while the rate constant for (17) may be estimated as <1 from values of chain-transfer with CCl_4 and chain propagation in styrene polymerization where a similar radical is involved.

Hammond, *et al.*,[24] to account for their observations on the inhibition of autoxidation. The possible existence of a type of chlorine atom–aromatic complex is discussed further in the following paper.[25] If such is the case, one might anticipate that a complexed radical would show a decreased sensitivity to a polar effect (since polarization in the same direction is involved in the complex) as is observed, and a decrease in selectivity when polarization is not important (since a complexed atom would be somewhat stabilized and less reactive). There is evidence for the latter in our discussion of isotope effects below.

Although our results on photochlorinations and sulfuryl chloride reactions are in good agreement, except for the results in carbon tetrachloride just discussed, neither check well with Kooyman's results on the same compounds, and evidently the major source of difference is experimental error. Although Kooyman has used a plausible experimental technique, with the exception of *p*-chlorotoluene (run in duplicate with an experimental error given as 14%) his data represent single experiments. Accordingly, in view of our excellent reproducibility and the good check given by fractionation of reaction mixtures, we believe our results give, at present, the best measure of relative reactivity of substituted toluenes toward chlorine atoms. Actually, it should be pointed out that part of the difference lies in the manner of treatment of data. Kooyman has determined ρ by a "best line" passing through the origin (toluene point), and the resulting slope is heavily influenced by the point for *p*-nitrotoluene for which the "usual" value of 0.778 was employed. In some other radical reactions, better Hammett plots have been obtained by using 1.27, the value for polar reactions involving anilines and phenols.[26] If the larger value is used (or if the *p*-nitrotoluene point is disregarded) and the toluene point is not given special weight, a value of $\rho \cong -1.0$ is obtained.

The negative sign of ρ in our series again points to the importance of polar effects in halogen atom reactions, particularly since any contribution to the transition state due to radical stabilization should produce an effect in the opposite direction.[12] However, our value now indicates a lower selectivity and smaller effect of polar contributions to the transition-state in chlorination than in bromination. For photobromination, Kooyman has reported $\rho = -1.05$, and, from Table IV, our results on three substituted toluenes are in good agreement with his. Actually, there is some uncertainty as to the significance of bromination data due to the reversibility of hydrogen abstraction, but deferring this point for the moment, the difference appears in a reasonable direction. Hydrogen abstraction from toluene by chlorine atoms occurs at a rate comparable to attack on ordinary secondary aliphatic C–H bonds,[8] and, from Pritchard, Pyke and Trotman-Dickenson's work,[5] the latter reaction (in the gas phase, at least) has an activation energy of ~ 1 kcal. In contrast, the bromine atom reaction has a reported[27] activation energy of 7 kcal. One would anticipate that, other things being equal, a low-activation energy process would show less sensitivity to a polar, or any other sort of, effect due to structural variation of the reactants.

Kooyman[15a] has suggested a simple correlation between ρ in radical reactions involving the toluene side-chain and the electronegativity[28] of the attacking atom, based on data involving chlorine and bromine atoms and $\cdot CCl_3$ and succinimide radicals. Our results with photochlorination indicate that the correlation was fortuitous, and it seems implausible to use an electronegativity value for a simple atom for highly substituted species such as the $\cdot CCl_3$ and succinimide radicals, particularly since copolymerization results[13] and recent data on aromatic substitution[29] show plainly that polar effects in the selectivity of carbon radicals vary markedly with the radical structure. Rather, it appears to us that the magnitude of polar effects depends upon an "effective electronegativity" of a radical, markedly influenced by substituents, and the size of the energy barrier to the reaction involved.

As is evident from Fig. 3, our data on phenyl-substituted toluenes indicate anomalously high reactivities. Berliner[30] has reviewed evidence for the value of the *p*-phenyl group, and suggests that at least two different sigma values should be assigned since ". . . effects are much greater where strong resonance interaction of the substituent group is possible, or where it can be enhanced in the transition state." Apparently participation of the *p*-phenyl group in resonance structures of type (4) here represents such a case. The value for *m*-phenyl was given originally on the basis of a single reaction,[14] and has been recalculated by Lichtin and Leftin,[31] from the ionization of *m*-phenylbenzoic acid, as 0.06 ± 0.03, a result which is in better agreement with our data. Thus nei-

ther of our phenyl results appear particularly inconsistent with our picture.

Finally, a series of k_H/k_D ratios for halogen atom attack on toluene are collected in Table V. Results for photochlorination in no solvent, vapor, benzene and *o*-dichlorobenzene are experimentally indistinguishable from each other and from the sulfuryl chloride reaction, in accord with our other data on relative reactivities, but the value in CCl_4 is significantly lower, further evidence for some difference in this solvent.

Our value of 3.08 for photobromination is larger than for chlorination, as might be anticipated for a process of higher activation energy,[32] but is actually too low,[33] since photobromination is significantly reversible. Accordingly, the measurement actually involves the complex process

$$RH + Br\cdot \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} R\cdot + HBr \xrightarrow[k_2]{Br_2} RBr + \cdot Br \quad (18)$$

in which k_2 and k_{-1} have roughly comparable values.[27] A similar complication necessarily attends Kooyman's[15a] and our studies of competitive brominations, so, in spite of the good agreement, it may well be that both sets of data here represent values which are slightly different from, and probably smaller than, the actual ratios of k_2's.

The Displacement of Aromatic Substituents by Halogen Atoms[1]

BY BERNARD MILLER[2] AND CHEVES WALLING

RECEIVED JANUARY 23, 1957

The reaction of chlorine with bromobenzene to give chlorobenzene and bromine is apparently a radical chain process on the basis of the following evidence: (1) the reaction is light catalyzed; (2) the analogous reaction using sulfuryl chloride is accelerated by benzoyl peroxide; (3) the reaction is inhibited by nitro-, azo- and azoxybenzene; (4) reactions run in competition with the side-chain chlorination of toluene yield comparable ratios of products in light and dark. Similar reactions of substituted bromobenzenes have been studied and competitive experiments show that the displacement is retarded by electron withdrawing groups. Benzenesulfonyl chloride and diphenylsulfone also undergo ready photochemical reaction with chlorine to give chlorobenzene and SO_2, and the photochemical exchange of bromobenzene and Br_2[82] has been demonstrated. Radical chain sequences are proposed, and the critical step, $Cl\cdot + C_6H_5Br \rightarrow C_6H_5Cl + Br\cdot$, is suggested as possibly involving the rearrangement of an intermediate radical–substrate "pi complex."

The difficulty with which aromatic halogen is replaced by polar reagents is well known[3] and chlorination of bromobenzene in the presence of ferric or aluminum chloride proceeds smoothly to give chiefly *o*- and *p*-chlorobromobenzene.[4] However, in 1903 Eibner[5] reported that bromobenzene, on standing with chlorine at room temperature in the absence of catalysts, gave 50% chlorobenzene, together with polyhalogenated products. Molecular bromine was produced, and the reaction was stated to be favored by moisture and direct light.

Similar displacements have been reported in attempts to chlorinate bromotoluenes. Although the successful preparation of *ortho*-,[6] *meta*-[7] and *para*-bromobenzyl chlorides[8] by this route have all been claimed, in 1890 Srpek[9] reported that room temperature chlorination of *p*-bromotoluene gives an inseparable mixture of products with chlorine and bromine in both ring and side-chain. These reactions have been reinvestigated by Asinger,[10] who found that extensive nuclear substitution of chlorine for bromine occurred in all cases.

More recently, Goerner and Nametz reported similar nuclear displacement of bromine during the reaction of bromotoluenes with sulfuryl chloride and benzoyl peroxide at 93°.[11]

While our work was in progress, Voegtli, Muhr and Langer[12] have also described similar displacements on substituted bromobenzenes during photochlorination in refluxing carbon tetrachloride, the three isomeric chlorobromobenzenes giving 82–90% of the corresponding dichlorobenzenes. *p*-Fluorobromobenzene gave *p*-fluorochlorobenzene in similar yield, but under these conditions bromobenzene yielded only 68% chlorobenzene together with a dark residue.

Interestingly, iodine apparently is not replaced as is bromine, chlorination of iodobenzene producing only iodobenzene dichloride,[13] and similar dichlorides are reported from *p*-bromoiodobenzene and *sym*-tribromoiodobenzene.

The reported effect of light, and the efficacy of the sulfuryl chloride–peroxide, a well-recognized radical halogenating system,[14] in these displacements, made it appear very likely that they are radical processes, and this paper reports work intended to settle this point, and characterize this sort of reaction more fully.

Results and Discussion

Bromobenzene.—Preliminary experiments confirmed literature reports of the ease of the exchange. When chlorine was bubbled slowly through a slight excess of bromobenzene at 90° under strong illumination, bromine was liberated and chlorobenzene produced in 81% yield based on the equation

$$2C_6H_5Br + Cl_2 \longrightarrow 2C_6H_5Cl + Br_2 \qquad (1)$$

In the dark under similar conditions, but using excess chlorine, the yield was only 39%. The photo-induced reaction also occurs at room temperature, but is accompanied by the formation of a small amount of halogen addition to give mixed polychlorobromocyclohexanes. The presence of bromine at the start of a reaction leads to no reduction in yield, but the photochemical reaction was found to be inhibited completely in the presence of nitrobenzene, azobenzene or azoxybenzene. With sulfuryl chloride, yields of chlorobenzene were low (12–20%) at room temperature or reflux, either in the presence or absence of benzoyl peroxide, but peroxide was observed to eliminate a marked induction period before the appearance of the bromine color.

All of these observations, notably the increase in yield in the presence of light, the accelerating effect of peroxide on the sulfuryl chloride reaction, and the inhibition of the reaction by nitrobenzene, azobenzene and azoxybenzene are consistent with a radical chain process involving halogen atoms. However, in order to obtain more conclusive evidence, and also get an idea of the rate of the displacement step, the competitive reaction of bromobenzene and toluene with chlorine was investigated. Fractionation of the products, and treatment of the data as arising from competitive processes first order in halogen atom and substrate, essentially as described in the preceding paper,[15] yielded a value of k_1/k_2 in the equation

$$\frac{\mathrm{d} \ln [C_7H_8]}{\mathrm{d} \ln [C_6H_5Br]} = \frac{k_1}{k_2} \qquad (2)$$

of 4.0 for a reaction run at 90° in the dark and 5.6 for one run under strong illumination. The difference is probably within experimental error, and, since the chlorination of toluene under these conditions yields almost entirely benzyl chloride by a strongly photocatalyzed radical chain process, in which chlorine atoms are the chain carriers,[15,16] we consider this a crucial experiment establishing that chlorine atoms are involved in the displacement on bromobenzene as well.

Substituted Bromobenzenes.—We have also investigated bromine displacement in the presence of chlorine and light in a number of substituted bromobenzenes, both alone and in competitition with bromobenzene. In the latter case, a deficiency of chlorine was used and relative reactivities (again calculated as arising from competitive first-order processes) calculated from product analyses. Results are summarized in Table I, and indicate that, while displacement still occurs in the presence of electron withdrawing groups, reactivity is reduced and the reaction fails with *p*-nitrobromobenzene.

TABLE I

REACTIONS OF BROMOBENZENES WITH CHLORINE AND LIGHT (IN CCl_4 OR $CHCl_3$ AT 65–70° UNDER ILLUMINATION)

p-Cl	98	0.91
o-COOH	~100	.23
m-COOH	...	.26
p-SO_2Cl	97[b]	< .12
p-NO_2	0	....

[a] Of corresponding chlorobenzene. [b] Of *p*-dichlorobenzene (see below). [c] Relative reactivities compared with bromobenzene from competitive experiments.

Other Displacements.—In our investigation of the photochemical reaction of chlorine with *p*-bromobenzenesulfonyl chloride (Table I) we observed that both bromine and sulfonyl chloride groups were displaced to give a 97% yield of *p*-dichlorobenzene. A similar displacement of the sulfonyl chloride group occurs with benzenesulfonyl chloride to give chlorobenzene (97%). Since chlorine is regenerated in the over-all reaction

$$C_6H_5SO_2Cl + Cl_2 \xrightarrow{h\nu} C_6H_5Cl + SO_2 + Cl_2 \qquad (3)$$

less than stoichiometric quantities are required and slow passage of only 25 mole % of chlorine into benzenesulfonyl chloride at 70° in carbon tetrachloride under illumination gave chlorobenzene in 92% yield. This facile displacement was surprising since the only analogous cases in the literature involve reactions of *o*-toluenesulfonyl chloride and fluoride to give *o*-chlorobenzyl and benzal chlorides at higher temperatures, and have been attributed to the *ortho* orientation of the two reaction sites.[17]

Our results with sulfonyl chlorides led us to investigate the chlorine atom displacement of other groups, and we find that diphenylsulfone reacts smoothly with excess chlorine on illumination in carbon tetrachloride to give chlorobenzene[18]

$$C_6H_5SO_2C_6H_6 + Cl_2 \longrightarrow 2C_6H_5Cl + SO_2 \qquad (4)$$

However, phenyl and methyl benzenesulfonates showed no displacement, even at temperatures of

(17) W. Davies and J. H. Dick, *J. Chem. Soc.*, 2042 (1932). The usual technique for conversion of a $-SO_2Cl$ group $-Cl$ involves the use of PCl_5 at 200–220°; C. M. Suter "The Organic Chemistry of Sulfur," John Wiley and Sons, Inc., New York, N. Y. 1944, p. 500.

(18) The reaction at 120–130° to give chlorobenzene and benzenesulfonyl chloride has been described by R. Otto, *Ann.*, 141, 93 (1867), who also noted the reaction of 1,2-dichlorosulfonylethane with chlorine at 180° to give 1,2-dichloroethane, chlorobenzene, benzenesulfonyl chloride and other products, R. Otto *J. prakt. Chem.*, [2] 30, 179 (1884).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

150–170°. Displacements also were attempted with N-phenylphthalimide, azobenzene and azoxybenzene. The first was chosen since displacement should yield a presumably rather stable phthalimide radical, and the latter two since the reaction might gain driving force by the elimination of nitrogen. However, in no case were we able to detect any trace of chlorobenzene in the products.

Using Br^{82} as a tracer, we have also been able to show that bromine atoms displace bromine from bromobenzene. At room temperature under strong illumination, exchange between molecular bromine and bromobenzene is approximately 30% complete in 17 hours, while in the dark the reaction is negligible. The ease of this sort of halogen exchange evidently decreases as one ascends the periodic table, iodine showing very little photochemical exchange at room temperature, although a thermal exchange occurs at elevated temperatures.[19]

Reaction Mechanism.—The properties of the reactions we have observed are certainly consistent with a radical chain process which, for the photochemical chlorine–bromobenzene reaction, we may write as

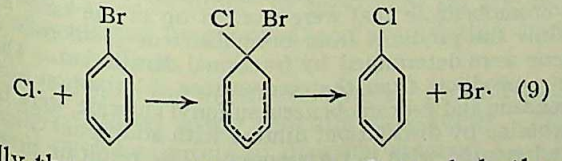
$$Cl_2 \overset{h\nu}{\rightleftharpoons} 2Cl\cdot \quad (5)$$

$$Cl\cdot + C_6H_5Br \longrightarrow BrCl + Cl\cdot \quad (6)$$

$$Br\cdot + Cl_2 \longrightarrow BrCl + Cl\cdot \quad (7)$$

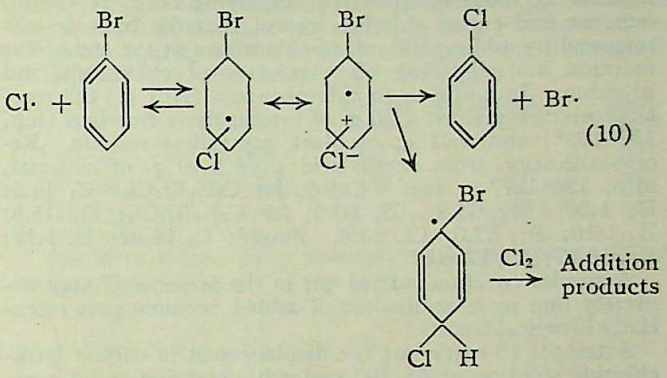
$$2BrCl \rightleftharpoons Br_2 + Cl_2 \quad (8)$$

with additional or alternative steps possible to account for the regeneration of chlorine atoms and the formation of molecular bromine. The interesting and critical step in the sequence is the displacement (6), which at first glance might be pictured either as addition to the aromatic ring followed by bromine atom loss, or as a direct displacement, analogous to the S_N2 displacements observed with negatively substituted halobenzenes.[3] However, either formulation presents difficulties.[20] Addition appears well established as the usual path of attachment of halogen atoms or alkyl or aryl radicals on aromatic systems.[21] However, here, addition would have to occur to the already substituted carbon



(9)

actually the most unlikely point of attack, both on grounds of steric hindrance and resonance stabilization of the resulting radical. Conceivably, of course, addition could be essentially at random, but highly reversible (as actually appears to be the case in the first step of chlorine addition to benzene) with the result that only that fraction of addition which occurs as indicated in (9) leads to displacement. The alternative of direct displacement cannot be ruled out, but would represent one of the very few examples of a direct radical displacement on carbon, and is accordingly somewhat suspect. A third alternative also exists, namely, that both displacements of the sort described here and the more familiar halogen additions to aromatics arise through rearrangement of an initial loose "pi-complex," *i.e.* analogous to the complexes of aromatics with electrophilic reagents discussed by Brown.[22]



(10)

In the case of our sulfonyl chloride and sulfone displacements analogous chains are plausible

$$C_6H_5SO_2Cl + Cl\cdot \longrightarrow C_6H_5Cl + \cdot SO_2Cl \quad (11a)$$

$$\cdot SO_2Cl \longrightarrow SO_2 + Cl\cdot \quad (11b)$$

$$C_6H_5SO_2C_6H_5 + Cl\cdot \longrightarrow C_6H_5Cl + C_6H_5SO_2\cdot \quad (12a)$$

$$C_6H_5SO_2\cdot + Cl_2 \longrightarrow C_6H_5SO_2Cl + Cl\cdot \quad (12b)$$

or

$$C_6H_5SO_2\cdot \longrightarrow C_6H_5\cdot + SO_2 \quad (12c)$$

$$C_6H_5\cdot + Cl_2 \longrightarrow C_6H_5Cl + Cl\cdot \quad (12d)$$

but we have no convincing explanation for the relative stability of benzene sulfonate esters.

Finally, two properties of these displacements need to be pointed out which must be accounted for in any complete reaction scheme. The first is the retarding effect of electron withdrawing groups (Table I) which is certainly consistent with a "pi-complex" scheme, but is actually a general characteristic of all chlorine atom processes.[15] The second is the extremely high *rate* of the displacement step, established by competition with the side-chain chlorination of toluene. Our results indicate that reaction 6 has approximately the same rate constant as that for the attack of a chlorine atom on a single benzyl C–H bond, a process which, as discussed further in our preceding paper,[15] probably has a rate constant of 10^{10}, and an activation energy of < 2 kcal. These displacements are thus extremely facile processes, with rates considerably higher than most radical–substrate reactions, and this, to us, makes them of particular interest.

Experimental

Reaction of Bromobenzene with Chlorine.—Fifty-nine grams (0.376 mole) of bromobenzene was placed in a 3-necked flask fitted with gas inlet tube, stirrer, reflux condenser and thermometer. The flask was illuminated by a 200 watt light bulb at a distance of three inches and maintained at 90°. Chlorine (0.156 mole, obtained by evapor-

ating 3.5 ml. of liquid chlorine) was bubbled through the system during one hour. Within five minutes the reaction mixture turned orange and then red, and soon bromine refluxed in the condenser. The cooled reaction mixture was stirred with sodium bisulfite solution, extracted with ether, dried over NaOH pellets and fractionated through a 10-plate Fenske column. The yield of chlorobenzene was 31.5 g. (0.254 mole, 81% based on chlorine). A similar reaction carried out in the dark (with the system wrapped in aluminum foil) gave a yield of only 39%.

The photochemical reaction was carried out in a similar manner at room temperature employing 30 g. of chlorobenzene and excess chlorine, except that the bromine was removed by adding 100 ml. of chloroform at the end of the reaction and distilling off a mixture of chloroform and bromine. In addition to chlorobenzene (20.1 g.) the reaction mixture yielded 2.26 g. of intermediate fractions (b.p. 136–160°) and 4.41 g. of black crystalline residue. Recrystallization from acetic acid gave 2.00 g. of material, m.p. 126–127°. *Anal.* Calcd. for $C_6H_5Br_4Cl_3$: C, 14.3; H, 1.00; Br, 63.8; Cl, 20.9; for $C_6H_5Br_3Cl_4$: C, 15.8; H, 1.10; Br, 52.0; Cl, 30.8. Found: C, 14.62; H, 1.19; Br, 59.87; Cl, 22.90

A similar reaction carried out in the presence of approximately one mole equivalent of added bromine gave essentially identical results.

Attempts to carry out the displacement in carbon tetrachloride solution at 65–70° under illumination in the presence of nitrobenzene, azobenzene or azoxybenzene gave no material boiling between 125 and 135° or indication of the liberation of bromine.

Reaction of Bromobenzene with Sulfuryl Chloride.—Bromobenzene (35.1 g.) and freshly distilled sulfuryl chloride (20 ml.) were mixed and allowed to stand at room temperature. After two hours the initially light yellow solution turned light orange, and, 15 minutes later, dark red. After standing overnight the reaction mixture was poured into aqueous sodium bisulfite solution, extracted with ether, and the ether layer dried over calcium chloride and distilled to give a 12% yield of chlorobenzene and 85% recovered bromobenzene. A similar experiment carried out in the presence of 0.207 g. of benzoyl peroxide turned deep red within 11 minutes, but the yield of chlorobenzene was still only 15%. When the same quantities of bromobenzene and sulfuryl chloride were refluxed together the deep bromine color developed in 35 minutes, and, after 6 hours, the mixture yielded 12% chlorobenzene. Addition of benzoyl peroxide gave the bromine color within three minutes and 16% chlorobenzene after six hours.

Reaction of Substituted Bromobenzenes with Chlorine.—*p*-Chlorobromobenzene (31.0 g.) was dissolved in 200 ml. of carbon tetrachloride and heated to 70° under a reflux condenser. A rapid stream of chlorine was passed through the solution while it was illuminated by a 200 watt light bulb at a distance of three inches. The solution soon turned red, and after 90 minutes the solvent was evaporated to give 23.7 g. (98%) of *p*-chlorobenzene, m.p. 46–49°. Two recrystallizations from ethanol gave 20.0 g., m.p. 51–53°: other displacements on substituted bromobenzenes were carried out similarly using either chloroform or carbon tetrachloride as solvent with results listed in Table I. With *o*- and *p*-nitrobromobenzene, no bromine color developed, and starting materials were recovered unchanged.

Competitive Reaction of Toluene and Bromobenzene.—A mixture of 0.645 mole of toluene and 0.694 mole of bromobenzene was placed in a stirred reaction-flask and heated to 90° while illuminated by a 200 watt incandescent light. Chlorine (0.376 mole) was introduced over 90 minutes, and the mixture first turned yellow, but then became colorless. The product was fractionally distilled through a 12-plate glass helix packed column, using dicyclohexyl as a chaser, and the composition of intermediate fractions determined by index of refraction. In a parallel experiment in the dark, chlorine was introduced over two hours, and the product compositions shown in the following table were determined. Relative reactivities were calculated from the relation

$$\frac{k}{k_0} = \frac{\log [C_7H_8]_{initial}/([C_7H_8]_{initial} - [C_7H_7Cl])}{\log [C_6H_5Br]_{initial}/([C_6H_5Br]_{initial} - [C_6H_5Cl])} \quad (13)$$

Since material balances were not quantitative, the values of k/k_0 are subject to considerable uncertainty but it seemed

	Light (moles)	Dark (moles)
Cl_2 (initial)	0.376	0.400
C_6H_5Br (initial)	.649	.720
C_7H_8 (initial)	.645	.747
C_6H_5Br (recovered)	.549	.572
C_7H_8 (recovered)	.264	.373
C_6H_5Cl	.069	.074
C_7H_7Cl	.297	.263
C_6H_5Br unaccounted for	.031	.074
C_7H_8 unaccounted for	.034	.054
k/k_0	5.6	4.0

that the best way of determining the amount of unreacted toluene and bromobenzene (the denominators in the fractions of eq. 13) was by subtracting the amount of isolated products from the accurately known initial quantities of reactants. Accordingly the values for k/k_0 reported are probably a little high. The alternate method of using values for recovered toluene and bromobenzene (corrected for the small amount of benzyl bromide formed), since it involves larger numerical quantities presumably subject to the same percentage error as those for chlorobenzene and benzyl chloride, appears less accurate and gives k/k_0's of 3.1 and 2.4 for the light and dark reactions, results which must be considerably too low.

Competitive reactions of bromobenzenes were carried out under illumination in chloroform solution at approximately 65° with over-all results summarized in Table I. In a typical experiment 0.175 mole of *m*-bromobenzoic acid and 0.185 mole of bromobenzene in 300 ml. of chloroform were treated with 0.095 mole of chlorine during two hours. The solution was cooled, the solid acids filtered off, and washed free of bromine with fresh chloroform. The filtrate and washings were stirred with aqueous sodium sulfite–sodium hydroxide, washed with water, and the aqueous extracts acidified. The resulting precipitate was combined with the acids originally isolated, and recrystallized from chloroform to give 33 g. of mixed acids containing 35.9% Br and 2.28% Cl by analysis. Bromobenzene and chlorobenzene were determined by fractionation of the chloroform layer, and the following material balance obtained

	Mole
C_6H_5Br (initial)	0.185
$C_6H_4BrCOOH$ (initial)	.175
C_6H_5Br (recovered)	.092
$C_6H_4BrCOOH$ (recovered)	.148
C_6H_5Cl	.074
$C_6H_4ClCOOH$	.021
C_6H_5Br unaccounted for	.019
$C_6H_4BrCOOH$ unaccounted for	.004

Relative reactivities were calculated in the same manner as for the toluene–bromobenzene experiment. The products from the competitive chlorination of bromobenzene and *o*-bromobenzoic acid were worked up in the same manner, while the products from bromobenzene–*p*-chlorobromobenzene were determined by fractional distillation. The reaction products from the competitive chlorination of bromobenzene and *p*-bromobenzenesulfonyl chloride were freed of bromine by distillation, diluted with additional chloroform, and treated with dry ammonia. The resulting precipitate was recrystallized from benzene and found to be chlorine-free *p*-bromobenzenesulfonamide, m.p. 165–166°. The difference between the amount obtained and the amount of *p*-bromobenzenesulfonyl chloride initially present was taken as the quantity of the former which underwent bromine displacement. Since some of the material was necessarily consumed by displacement of the sulfonyl chloride group, the resulting calculated reactivity for displacement of bromine represents merely an upper limit, and is so indicated in Table I.

Reaction of Chlorine with Benzenesulfonyl Derivatives.—*p*-Bromobenzenesulfonyl chloride (32.4 g.) was dissolved in 250 ml. of carbon tetrachloride and kept at 70° in an illuminated flask while a rapid stream of chlorine was passed through the solution for two hours. Evaporation of the solvent and bromine gave 18.1 g. (97%) of *p*-dichlorobenzene, m.p. 47–50°. A similar experiment using benzenesulfonyl chloride gave 97% chlorobenzene. When a limited

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

amount of chlorine (0.078 mole for 0.308 mole of benzenesulfonyl chloride) was employed, the mixture at the end of the reaction showed no peak in the infrared spectrum at 8-9 μ, characteristic of sulfonyl chlorides, and gave 92% chlorobenzene on distillation.

Under the same conditions diphenylsulfone also gave chlorobenzene in essentially quantitative yield, but phenyl benzenesulfonate and methyl benzenesulfonate gave no chlorobenzene and good yields of starting material when treated with chlorine and light, either at 70° in carbon tetrachloride or at 150–170° in absence of solvent.

Other Attempted Displacements.—Treatment of azobenzene, azoxybenzene and N-phenylphthalimide with chlorine and light at 70° in carbon tetrachloride solution gave only starting material and no trace of chlorobenzene. Similarly no displacement was observed when iodobenzene was refluxed with sulfuryl chloride in the presence of benzoyl peroxide, or when benzenesulfonyl chloride or diphenylsulfone was illuminated in the presence of bromine.

Exchange of Br^{82}_2 with Bromobenzene.—Twenty-five ml. of bromine containing Br^{82}, 50 ml. of bromobenzene and 75 ml. of carbon tetrachloride were mixed and then divided into three equal portions placed in stoppered flasks. One flask was kept for 18 hours at room temperature while being illuminated at a distance of 8 inches by a 200 watt incandescent light, the others were stored in the dark. The contents of the illuminated flask and one other were washed with sodium bisulfite solution and then three portions of water, and the radioactivity of the organic layer determined, using a Geiger counter of the type described by Sibbett.[23] The contents of the third flask were used to determine total radioactivity. In a second experiment a similar mixture was irradiated for four hours at 50° and overnight at room temperature. The bromine was then washed out, and the radioactivity of the organic layer determined. In order to establish that the radioactivity was confined to bromobenzene, the organic layer was next carefully fractionated and the radioactivity of the bromobenzene fraction determined. Results of both experiments are shown below.

Run	Total	Activity (counts/min.) Organic	C_6H_5Br	Background
1 (light)	12,344	2272	...	50
1 (dark)	12,344	90	...	50
2 (light)	21,317	4211	4110	62

Structure and Properties of Cyclic Compounds. IX.[1] Hemiketal Formation of Cyclic Ketones

BY OWEN H. WHEELER

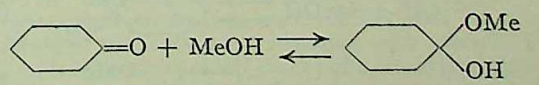
RECEIVED SEPTEMBER 20, 1956

Cyclohexanone has been found to undergo acid-catalyzed hemiketal formation with methanol in dioxane solution. The extent of hemiketal formation of a number of cyclic ketones in pure methanol is in agreement with I-strain prediction and is reduced by steric effects. Less reaction takes place with ethanol and no reaction is observed with isopropyl alcohol or water.

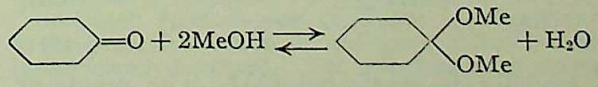
During the course of routine spectroscopic measurements,[2] it was observed that the intensity of absorption of cyclic ketones in methanol depended on the sample of methanol used as solvent. Addition of a drop of concentrated hydrochloric acid greatly reduced the intensity. The decreased absorption of aldehydes in polar solvents has been noted by many workers[3] and has been attributed to hemiacetal formation. This suggests that the above results may be due to a similar reaction. A decrease in the refractive index of solutions of acetone and cyclohexanone in methanol on the addition of acids has been noted[4] and is probably caused by the same effect.

The reaction between cyclohexanone and methanol was studied using dioxane as solvent. Solutions of cyclohexanone in dioxane showed λ_{max} 290 mμ (ϵ 15.8 ± 0.1, mean of five readings). In the presence of 0.05 *M* hydrogen chloride the absorption was unchanged. Similarly the absorption intensity of cyclohexanone in dioxane containing 0.07, 0.12 and 0.26 *M* methanol was ϵ 15.85, 15.75, 15.8, respectively, with the maxima at the same wave length. These solutions showed no change in absorption on standing. Thus the decrease in intensity in methanolic hydrogen chloride solution cannot be due to reaction between the ketone and the acid or to a non-acid-catalyzed reaction between the ketone and methanol.

The most probable reactions of cyclohexanone and methanol catalyzed by acids are those of hemiketal (1) and ketal (2) formation. Both reactions are first order in ketone but reaction 1 is first order



(1)



(2)

and reaction 2 second order in alcohol. The reaction was studied in dioxane containing 0.05 *M* hydrogen chloride using varying concentrations of ketone and alcohol (Table I). The concentration of unreacted ketone was calculated from the extinction coefficient of the solution and the known extinction of cyclohexanone in dioxane in the absence of acid. The concentration of the addition compound is then the difference between this and the initial ketone concentration. In the first case the final methanol concentration is the difference between the initial concentration and the concentration of addition compound and in the second the difference with twice the addition compound concentration. The dissociation constants K^1_D and

[a] In the presence of 0.05 M hydrogen chloride at 25.0 ± 0.2°. [b] ϵ at 290 mμ.

K^2_D for the first and second reactions were calculated, and it can be seen that while K^1_D is sensibly constant, K^2_D varies considerably and thus the reaction must be first order in both ketone and alcohol and is the hemiketal equilibrium (1).[5] That the only function of the hydrogen chloride is to act as an acid catalyst is shown by the fact that the dissociation constants of the hemiketals of cyclopentanone and cyclohexanone are independent of acid concentration over a range of 50-fold (Table II).

TABLE II

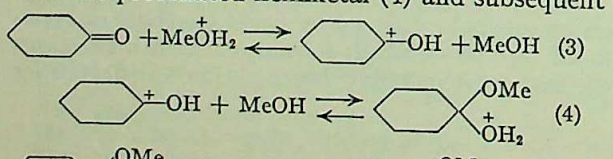
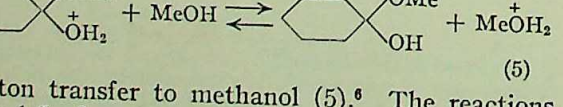
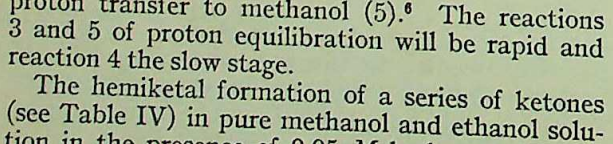
[a] In methanol at 25.0 ± 0.2°.

Equation 1 only represents the stoichiometry of the reaction. The mechanism probably will involve initial formation of the protonated ketone (3), followed by nucleophilic attack of methanol to form the protonated hemiketal (4) and subsequent







proton transfer to methanol (5).[6] The reactions 3 and 5 of proton equilibration will be rapid and reaction 4 the slow stage.

The hemiketal formation of a series of ketones (see Table IV) in pure methanol and ethanol solution in the presence of 0.05 M hydrogen chloride has been measured. The concentration of unreacted ketone [Ket.$_f$] is proportional to the extinction coefficient (ϵ_a) of the acid solution, and the concentration of hemiketal [Hemiket.] is proportional to the difference between the extinction coefficients of the neutral (ϵ_0) and acidified solutions.

The concentration of methanol and ethanol was taken as the molarity of the pure solvent.[7]

$$K_D = [\text{Ket.}_f][\text{ROH}]/[\text{Hemiket.}] = 32 \text{ (or } 46)\epsilon_a/\epsilon_0 - \epsilon_a$$

The results with cyclopentanone and cyclohexanone are in agreement with the I-strain concept of Brown.[8] Cyclohexanone is reactive since addition to the double bond relieves angle strain in the ring and the small interference of the α-hydrogen atoms with the keto group, while addition to the carbonyl grouping of cyclopentanone gives a product in which there is considerable interaction with the ring hydrogen atoms and these additions are not favored. In the case of cyclobutanone this ketone is highly strained[8c] and addition reactions will be facilitated. However, the hemiketal will be a crowded molecule, and ring hydrogen interactions will tend to decrease its stability. Thus though cyclobutanone methyl hemiketal is more stable than cyclohexanone methyl hemiketal, the reverse is true for the ethyl hemiketal where repulsion of the bulky ethoxy group decreases the stability of the cyclobutanone addition compound. Addition to the ketone groupings of cycloheptanone and cycloöctanone will also not be favored because of the hindered nature of the hemiketals, and no reaction was observed between these ketones and ethanol.

The presence of methyl groups in cyclic ketones at positions not adjacent to the ketone grouping has been found[1,9] to decrease the reactivity toward cyanohydrin formation due to steric repulsion across the ring between the methyl and cyano groups. Similarly in methyl hemiketal formation 3-methylcyclopentanone is less reactive than cyclopentanone itself, and 3,3,5,5-tetramethylcyclohexanone is very unreactive, and neither compound reacts with ethanol. Bridge ring ketones are also unreactive toward addition reactions,[10] and the methyl hemiketal of camphor is very unstable, and no reaction occurs with ethanol. Di-*n*-propyl ketone has the same number of carbon atoms as cycloheptanone, but the chains are staggered in space and not confined in a ring, and accordingly steric hindrance to addition is greater. In the case of diisopropyl ketone, the two bulky isopropyl groups prevent any reaction from taking place.

The methyl hemiketal formation of di-*n*-propyl ketone, cyclobutanone, cyclopentanone and cyclohexanone was also measured at 1.5° and the heat of formation of the hemiketals (ΔH) calculated (see Table III). Since it was difficult to measure the small amounts of unreacted ketone in the case of cyclobutanone and cyclohexanone, the results are only approximate, but addition to the ketone grouping of cyclohexanone involves less energy change than in di-*n*-propyl ketone, whereas additions to

(5) The initial rapid formation of hemiketal may be followed by slow formation of a ketal, but this could not be detected since on long standing the absorption intensity increased and the maximum was shifted to shorter wave length, the ketones probably undergoing self-condensation.

(6) Cf. C. A. MacKenzie and J. H. Stocker, *J. Org. Chem.*, **20**, 1695 (1955).

(7) No appreciable error is involved in this assumption since the ketone concentration was never greater than 0.1 M.

cyclobutanone and cyclopentanone are more difficult due to the steric repulsions produced in the hemiketals.

The spectra of di-*n*-propyl ketone, cyclopentanone and cyclohexanone were measured in water and 2-propanol containing 0.05 *M* hydrogen chloride (Table IV). In neither case was there

TABLE IV

SPECTRA IN WATER AND ISOPROPYL ALCOHOL

	Water		Isopropyl alcohol

any decrease in absorption intensity as compared with the spectra in neutral solution.[11] This difference in the behavior of methanol and ethanol, on the one hand, and water and 2-propanol on the other, cannot be due to the differing nucleophilic properties of the solvents since water is a stronger nucleophile than methanol. The unreactivity of water probably is due to its high self-solvation and the high free energy necessary for its "desolvation," before solvation of a ketone can take place. In the case of 2-propanol, steric hindrance to the formation of a bulky isopropoxide derivative probably prevents reaction. The non-reactivity of cyclobutanone is interesting in that cyclopropanone is known only as its hydrate,[12] but in the latter case I-strain in the ketone is so great that hydrate formation is favored.

The closest analogous addition reaction to that of hemiketal formation is the cyanohydrin reaction, and it is interesting to compare the results for the two series (Table V). Comparing di-*n*- and diisopropyl ketone and cycloheptanone and cyclooctanone in the two reactions, the hemiketal appears to have larger steric requirements, and this is to be expected since the methoxy group with the lone pair of electrons on the oxygen atom and the hydrogen atoms of the methyl group will be larger than the linear cyano group. The cyclization of open chain hydroxyaldehydes to form intramolecular cyclic hemiketals has been investigated.[13] In this case the stabilities will depend on both the ease of ring closure and the resulting I-strain in the ring,

and the large dissociation constant of the seven-membered cyclic hemiketal probably is due to an unfavorable combination of these effects.

Experimental

The ketones used were specimens which had been fractionally distilled or purified through their semicarbazones.

Methanol and ethanol were dried by refluxing with and distilling from their magnesium alkoxides[14] and isopropyl alcohol by distilling with sodium. Dioxane was refluxed with potassium hydroxide and fractionated from a fresh quantity and this treatment repeated with metallic sodium. The first fraction contained traces of aromatic hydrocarbons which made it unsuitable for spectroscopic work.[15]

Hydrogen chloride was generated by dropping A. R. hydrochloric acid into A. R. sulfuric acid and was absorbed in the required solvent. The solutions were standardized with carbonate-free sodium hydroxide and used immediately after preparation.

The spectroscopic measurements were made using a Beckman DU spectrophotometer fitted with thermospacers, through which water was circulated at 25.0 ± 0.2° from a constant temperature bath or at 1.5 ± 0.2° from an ice–water-bath.

The solvents were kept in the constant temperature baths until needed; 1-cm. quartz cells were used and the comparison cell contained solvent of the same composition. Readings were taken after 10 min. and again after 0.5 hr., but no differences were noted. However, after about 1 hr. the readings began to increase. The determinations were carried out in duplicate or triplicate using different solu-

3α-(2-Diethylaminoethyl)-aminotropane and Related Compounds[1,2]

BY S. ARCHER, T. R. LEWIS AND M. J. UNSER

RECEIVED, FEBRUARY 20, 1957

Tropinone was reductively aminated in the presence of diethylaminoethylamine and the resulting triamine was quaternized to furnish a bismethiodide in which the secondary amine function was still present. The compound is a tropane and not a pseudotropane as was shown by converting 3α-benzylaminotropane to the known 3α-aminotropane. The corresponding triamine derived from pseudopelletierine was prepared by catalytic reduction of the Schiff base. Evidence is presented which lends additional support to the view that in the reductive amination process it is the Schiff base and not the carbinolamine which is hydrogenated. The triamines in the pseudo series were prepared by sodium–alcohol reduction of the Schiff bases from diethylaminoethylamine and tropinone or pseudopelletierine.

The proven clinical utility of "hexamethonium" in the control of malignant hypertension has stimulated further investigation of many bis 'onium types of peripheral ganglionic blocking agents.[3] More recently it has been shown by Cavallito and his coworkers[4] that by appropriate manipulation of the length of the chain separating the 'onium centers and the groups attached to the quaternary nitrogen atoms, it was possible to prepare hypotensive agents whose action was predominantly central rather than peripheral.

As a part of a chemical–pharmacological program, we have prepared a series of compounds of which the prototypes are the quaternary salts III and IV. Since the pharmacological aspects of this work already have been published,[5] we will confine our discussion to the more interesting chemical features of the joint endeavor.

The general method of synthesis is shown in the equation chart.

Since isomerism is possible at C-3 in the triamine I, it became necessary to establish which stereoisomer was formed in the reductive amination. Willstätter[6] prepared 3β-aminotropane by sodium–alcohol reduction of tropinone oxime. The same oxime furnished 3α-aminotropane upon reduction with sodium amalgam. We were able to obtain 3α-aminotropane by catalytic reduction of tropinone oxime. After our work was completed, a similar preparation was reported by Stoll.[7]

Hydrogenation of tropinone affords tropine[8] which has been isomerized to pseudotropine under alkaline conditions.[9] Similarly, 3α-aminotropane was isomerized to 3β-aminotropane with the aid of

sodium amoxide.[6] The configuration of the tropines has been established,[10] and in view of the marked similarities in preparation and isomerization of the two aminotropanes, it seems clear that

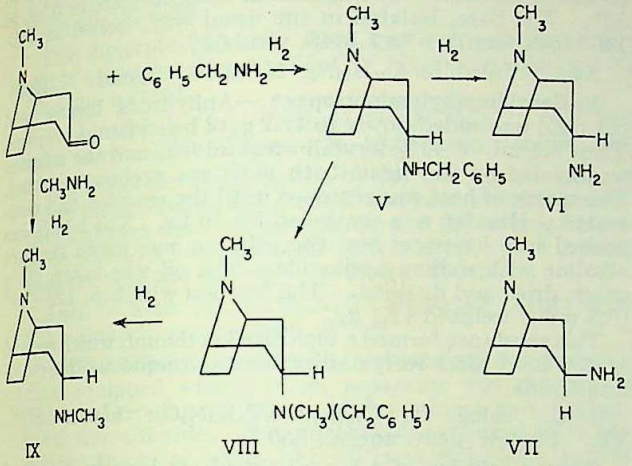
3α-tropylamine is best represented as shown in VI and 3β-aminotropane is VII.

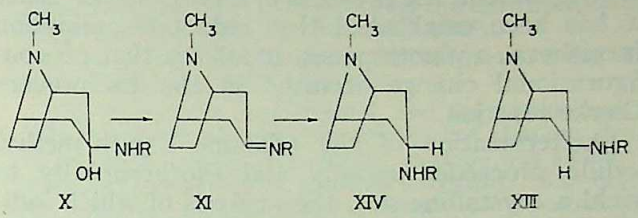


The reductive amination of tropinone in the presence of benzylamine led to 3α-benzylaminotropane (V) which was catalytically hydrogenolyzed to give 3α-aminotropane (VI). Thus the amine V is a member of the tropane group and by analogy the triamine I is also a member of the tropane and not the pseudotropane family.

The question whether it is the intermediate carbinolamine or the Schiff base which is hydrogenated in the reductive amination of ketones with primary amines, has never been completely answered. The consensus seems to be that it is the Schiff base that is hydrogenated.[11] Cope[12] found that in the reductive amination of carbonyl compounds with ethanolamine it was best to pre-reduce the platinum oxide catalyst in order to avoid induction periods. In our study of the preparation of the triamine I we were able to confirm this observation, but further investigation revealed that this induction period could be eliminated by premixing the ketone and amine and that it was not necessary to pre-reduce the Adams catalyst. Furthermore if the platinum oxide were reduced and the reagents were added separately to the hydrogenation vessel containing the catalyst, the induction period re-appeared.

Since the conditions necessary to effect reductive amination would serve also to reduce tropinone to tropine, the above results are in harmony with the suggestion that the carbinolamine forms rapidly and protects the ketone from attack by hydrogen. This is followed by a slower dehydration to the Schiff base and, as soon as a sufficient quantity of this species is formed, hydrogenation begins.

Further support for this suggestion can be found in a consideration of the stereochemistry of the reduction process. Alder[13] has pointed out that addition to the carbonyl group of tropinone or pseudopelletierine takes place in the "exo" sense. On conformational grounds it would be expected that the larger group would occupy the less hindered equatorial positions.[14] For these reasons the carbinolamine would be expected to have the structure X. Bonner[15] showed that hydrogenolysis of a carbon–oxygen bond proceeded with retention of configuration. Thus the amine which would be formed as the result of cleavage of the carbinolamine by hydrogen would be a 3β-aminotropane XIII.



This is contrary to the observed fact (see above) On the other hand, if it is the Schiff base XI which is reduced, one can predict the correct stereochemistry, XIV, by the invocation of Alder's principle[13] of "exo" addition of hydrogen.

We were unable to reductively aminate pseudopelletierine under conditions that were more strenuous than required for the tropinone series. It was found necessary to prepare and isolate the Schiff base[16] prior to catalytic hydrogenation in order to prepare the required 3-(2-dialkylaminoalkylamino)-9-methylgranatolines. The slow rate of formation of Schiff bases in the pseudopelletierine series is a reflection of the higher degree of hindrance that results from the interpolation of an additional methylene group in the bridge. Obviously, in this series it is not the carbinolamine which is being hydrogenated. The evidence adduced in this work lends further support to the belief that it is the Schiff bases and not the carbinolamines which are attacked by hydrogen in the reductive amination reaction.

In order to prepare the corresponding members in the pseudo series the ketimines derived from both tropinone and pseudopelletierine were reduced with the aid of sodium and either hexanol or ethanol. The mixture of triamines (I and its epimer at C-3) in the tropine series was separated as the phenylthioureides. The β-form predominated in the ratio of 25:1. In the pseudopelletierine series metal–alcohol reduction afforded a mixture in which a very substantial amount of the normal (axial) isomer was present. This is in accord with the presumed greater hindrance at C-3 in the granatoline.[17]

The conversion of the triamine I to the methylated amine II was accomplished by the formaldehyde–formic acid methylation. Although Parham[18] showed that inversion at carbon does not accompany methylation in the Eschweiler–Clarke reaction, we thought it advisable to confirm this

(17) Reduction of hindered ketones in the carbocyclic series by metal–alcohols frequently furnishes axial carbinols (Barton, ref. 9). Alder (ref. 8) reported that reduction of pseudopelletierine afforded the equatorial isomer, but from inspection of the experimental details it is apparent that appreciable quantities of another substance were present in the crude reduction mixtures.

point since we were working in the thermodynamically less stable series. Accordingly, 3α-benzylaminotropane (V) was converted to the methylated amine VIII. The latter was catalytically debenzylated to 3α-methylaminotropane (IX). This same amine was prepared by reductive amination of tropinone in the presence of methylamine. Since it has been established that reductive amination furnishes α-aminotropanes, it follows that no configurational change occurred in the Eschweiler–Clarke reaction.

Quaternization of the triamine I with methyl iodide proceeded rapidly and exothermically to yield a crystalline salt, the analysis of which indicated the formation of a bis-methiodide. That this substance was best represented by formula III follows from the analogous results obtained by Marxer and Miescher,[3] the fact that the infrared spectrum displayed a strong NH band and no significant absorption in the 4.0 μ region characteristic of ammonium salts.[19] Similarly the fully alkylated amine II furnished a bis-methobromide (IV, X = Br) when treated with methyl bromide.

Higher homologs of the triamine III were prepared by acylation of the secondary amine I with the appropriate anhydride and reduction of the corresponding amides with lithium aluminum hydride. Quaternization of these homologs proceeded at a noticeably slower rate in acetonitrile.

Experimental[20]

3α-Aminotropane.—A solution of 23 g. of tropinone oxime[5] in 150 ml. of methanol was reduced in the presence of 0.5 g. of Adams platinum oxide catalyst. After seven hours at 50° the reduction was stopped and the catalyst was filtered. After the solvent was removed, the residue furnished 5.5 g. of 3-aminotropane, b.p. 98–102° (20 mm.), $n^{25}D$ 1.5018. A large high-boiling residue (ditropylamine?) was not investigated.

The above amine (0.5 g.) in 3 ml. of methanol was treated with 1.0 ml. of phenyl isothiocyanate. A crystalline solid separated almost immediately. The thioureide melted at 160–161°[21] after recrystallization from ethyl acetate.

Anal. Calcd. for $C_{15}H_{21}N_3S$: N, 15.26. Found: N, 15.20.

The 3β-aminotropane prepared by sodium–amyl alcohol[6] reduction of tropinone oxime boiled at 104–106° (22 mm.), $n^{25}D$ 1.4995, and furnished a thioureide, m.p. 173–175°.[22]

3α-Methylaminotropane.—A solution of 45 g. of tropinone in 100 ml. of methanol was mixed with a solution of 40 ml. of 7.9 *N* methylamine in methanol. Adams catalyst was added and the mixture was heated to 50° to initiate the hydrogenation which then proceeded to completion in 90 minutes. The catalyst and solvent were removed and the residue was distilled to give a fraction, b.p. 59–60° (0.5 mm.), wt. 43.5 g.

Anal. Calcd. for $C_9H_{17}N_2$: N, 18.3. Found: N, 17.6.

When a sample of the above amine was treated with excess alcoholic picric acid, a dipicrate separated which melted at 255° dec., after recrystallization from ethanol.

Anal. Calcd. for $C_9H_{18}N_2 \cdot 2C_6H_3N_3O_7$: neut. equiv., 306.2. Found: neut. equiv., 305.

The phenyl thioureide was prepared in methanol solution with the aid of phenyl isothiocyanate; m.p. 160–161° after recrystallization from ethyl acetate.

Anal. Calcd. for $C_{16}H_{22}N_3S$: N, 14.9. Found: N, 14.5.

3α-Benzylaminotropane.—A solution of 45 g. of tropinone and 32 g. of benzylamine in 80 ml. of ethanol was added to 1.5 g. of pre-reduced Adams platinum oxide suspended in 30 ml. of ethanol. Hydrogenation was complete in 3 hr. at 50°. The base, isolated in the usual way, boiled at 143–146° (0.05 mm.), $n^{25}D$ 1.5445, yield 63%.

Anal. Calcd. for $C_{15}H_{22}N_2$: N, 12.16. Found: N, 12.14.

3α-Benzylmethylaminotropane.—Anhydrous formic acid (21.6 g.) was added slowly to 19.2 g. of benzylaminotropane. Then 8.4 ml. of 40% formalin was added, and the solution was heated on the steam-bath until gas evolution started. The source of heat was removed until the reaction had moderated. Heating was continued for 16 hr. The whole was poured into ice-water and the solution was made strongly alkaline with sodium hydroxide. The oil was taken up in ether, dried and distilled. The fraction with b.p. 126–129° (0.3 mm.) weighed 11.1 g.

This substance formed a **dipicrate** in ethanol, which melted at 230–232° after recrystallization from aqueous dimethylformamide.

Anal. Calcd. for $C_{16}H_{24}N_2 \cdot 2C_6H_3N_3O_7$: neut. equiv., 351. Found: neut. equiv., 350.[23]

When a solution of 4.3 g. of the above base in 30 ml. of dry ethanol was treated with 3.5 ml. of methyl iodide, crystals of the **monomethiodide** started to separate within 15 minutes. The whole was left overnight and filtered. The salt was crystallized from methanol, wt. 3.9 g., m.p. 233–237° dec.

Anal. Calcd. for $C_{17}H_{27}IN_2$: I, 32.84; N, 7.25. Found: I, 32.55; N, 7.26.

Catalytic Debenzylation of 3α-Benzylmethylaminotropane. Ten grams of 3-benzylmethylaminotropane in 100 ml. of ethanol was hydrogenolyzed in the presence of 10% palladium-on-charcoal. Distillation of the oil that remained after removal of the catalyst and ethanol furnished an oil, b.p. 116–118° (18 mm.). When this base was treated with phenyl isothiocyanate in methanol, a phenyl thioureide separated which melted at 160–161°, after crystallization from ethyl acetate. When admixed with an authentic sample there was no depression in melting point.

Catalytic Debenzylation of 3α-Benzylmethylaminotropane.—In a similar fashion 22.8 g. of 3α-benzylaminotropane was hydrogenated in the presence of 10% palladium-on-charcoal. The tropylamine that was formed boiled at 118–120° (43 mm.), $n^{25}D$ 1.5014. The phenyl thioureide, m.p. 158–160°, did not depress the melting point of an authentic sample.

3α-(2-Diethylaminoethyl)-aminotropane.—A solution of 30 g. of tropinone and 24 g. of diethylaminoethylamine in 100 ml. of dry ethanol was allowed to stand for 2 hr. During this time 1.2 g. of platinum oxide catalyst was reduced in 50 ml. of ethanol. The solution of the bases was added to the catalyst and the reduction which proceeded without delay was 80% complete in 1 hr. The mixture was heated to 50° to finish the reaction. After the usual work-up there was obtained 33.2 g. (66%) of the desired triamine, b.p. 111–115° (0.5 mm.).

In another experiment the catalyst was pre-reduced, and the tropinone and diethylaminoethylamine were added separately without mixing. In this case no reduction occurred at room temperature. The contents of the hydrogenation vessel were heated to 50° whereupon the required amount of hydrogen was consumed within the next few hours. There was obtained, in 70% yield, the desired base, b.p. 115–118° (0.5 mm.).

In our preferred procedure, 204 g. of tropinone and 174 g. of diethylaminoethylamine in 1 liter of methanol was allowed to stand overnight. The solution was added to 2.0 g. of Adams catalyst (*under nitrogen*), and the reduction was allowed to proceed at room temperature and 1000 p.s.i. Over 75% of the required amount of hydrogen was absorbed within the first hour at room temperature. The remainder was consumed at 60°. The triamine was collected at 99–101° (0.2 mm.), wt. 273 g., $n^{25}D$ 1.4842.

The phenyl thioureide was prepared by dissolving 3.8 g. of the above base in 30 ml. of methanol and treating the solution with 2.2 g. of phenyl isothiocyanate. After 1 hr. 5.0 g. of crystals was collected. Recrystallization from

(19) B. Witkop, THIS JOURNAL, **76**, 5597 (1954).

(20) Analyses were carried out under the supervision of Mr. K. D. Fleischer. The infrared spectra were determined under the supervision of Dr. F. C. Nachod. Melting points are corrected.

(21) Willstätter (ref. 5) reported the m.p. as 142–143° (typographical error?). Stoll (ref. 6) reported the m.p. was 153–154°.

(22) Willstätter (ref. 5) reported the m.p. to be 171–172°.

(23) The neutral equivalent was determined by titrating the picric acid with sodium methoxide in anhydrous methanol. The value for the unmethylated base is 344.

ethanol and ethyl acetate furnished the pure compound, m.p. 168–170°, wt. 3.7 g.

Anal. Calcd. for $C_{21}H_{34}N_4S$: N, 14.95; S, 8.56. Found: N, 14.96; S, 8.29.

The dipicrate prepared from two equivalents of picric acid in ethanol melted at 168–170° after crystallization from the same solvent.

Anal. Calcd. for $C_{14}H_{29}N_3 \cdot 2(C_6H_3N_3O_7)$: N, 18.00; neut. equiv., 350. Found: N, 18.06; neut. equiv., 350.[23]

The tripicrate was prepared by (a) treating the base with excess picric acid in hot ethanol and recrystallizing the salt from aqueous dimethylformamide and (b) adding alcoholic picric acid to a hot alcoholic solution of the above dipicrate. In either case the derivative melted at 230–232°.

Anal. Calcd. for $C_{14}H_{29}N_3 \cdot 3(C_6H_3N_3O_7)$: neut. equiv., 310. Found: neut. equiv., 307.[23]

3-(N-2-Diethylaminoethyl)-tropinoneimine.—A one-liter flask equipped with a water separator was charged with 69.5 g. of tropinone, 500 ml. of dry toluene and 500 mg. of fused zinc chloride. The mixture was refluxed for 1 hr. to remove traces of water (0.2 ml. was collected), and then 63.8 g. of diethylaminoethylamine was added. Reflux was resumed and in 12 minutes 50% of the theoretical amount of water was collected, and in 4 hr. the reaction was complete. On cooling, the mixture deposited a few crystals which were filtered off. The clear filtrate was distilled to yield 92.2 g. (78%) of the Schiff base, b.p. 117–131° (0.6 mm.), mainly at 128–131° (0.6 mm.).

A tripicrate, prepared in ethanol, melted at 184–185° after recrystallization from the same solvent.

Anal. Calcd. for $C_{14}H_{27}N_3 \cdot 3(C_6H_3N_3O_7)$: neut. equiv., 308. Found: neut. equiv., 312.[23]

Hydrogenation of the Schiff base in the presence of Raney nickel catalyst occurred at 60° and 1,000 p.s.i. The oil that resulted after removal of the nickel and the ethanol was converted directly to the phenyl thioureide. The crude derivative melted at 167–169° and did not depress the m.p. of the sample prepared as above. No appreciable quantity of the isomeric base was present.

Similarly, reduction of 24.6 g. of the Schiff base in the presence of Adams catalyst (0.6 g.) occurred in 75 minutes at room temperature. Distillation afforded 21.5 g. (85%) of 3α-(2-diethylaminoethyl)-aminotropane, b.p. 100–105° (0.2 mm.), $n^{25}D$ 1.4832.

When 11.8 g. of the Schiff base in 100 ml. of dry ether was reduced with the aid of 2.0 g. of lithium aluminum hydride, there was obtained 7.8 g. of a colorless oil. This was converted to a crude phenyl thioureide, m.p. 166–169°, which did not depress the m.p. of the previously prepared sample.

3β-(2-Diethylaminoethyl)-aminotropane.—To a hot solution of 47.4 g. (0.2 mole) of the Schiff base in 375 ml. of absolute ethanol, 22.0 g. of freshly cut sodium was added in small pieces in a 2-hr. period. After all the metal had been added, the suspension was refluxed for 1 hr. The clear solution was cooled, and just enough concentrated hydrochloric acid was added slowly to neutralize the sodium ethoxide. The salt was removed by filtration, and the clear filtrate was concentrated to leave an oil which was dissolved in a small quantity of water. The desired amine was thrown out of the aqueous solution with solid potassium carbonate. It was collected with ether, dried and distilled to give a yellow base, b.p. 108–112° (0.3 mm.), wt. 26.5 g.

A solution of 11.1 g. of the above crude amine was dissolved in 75 ml. of methanol and treated with 6.75 g. of phenyl isothiocyanate in 25 ml. of methanol. The solution warmed slightly, but no crystals separated. The reaction mixture was left in the refrigerator overnight. The crystalline solid that deposited was collected on a filter, m.p. 165–168°, wt. 0.8 g. This compound did not depress the m.p. of the phenyl thioureide of 3α-(2-diethylaminoethyl)-aminotropane.

The filtrate was concentrated to leave a yellow gum (wt. 17.4 g.) which was dissolved in 100 ml. of ethyl acetate. The solution was concentrated to 60 ml. and cooled. The crystals were filtered; wt. 12.7 g., m.p. 136–138°. After one recrystallization from ethyl acetate, the phenyl thioureide of 3β-(α-diethylaminoethyl)-aminotropane melted at 138–139.5°.

Anal. Calcd. for $C_{21}H_{34}N_4S$: N, 14.95; S, 8.56. Found: N, 15.06; S, 8.38.

Addition of pentane to the filtrate caused the separation of an additional 2.6 g. of crystals, m.p. 110–115°. This was not further investigated.

A solution of 11.7 g. of the above phenyl thioureide, m.p. 136–138°, in 50 ml. of ethanol was mixed with 25 ml. of 8 *N* alcoholic hydrogen chloride and allowed to stand at room temperature for 2 hr. The solid that separated was filtered and a small portion was recrystallized from methanol. The compound, which proved to be the dihydrochloride of the phenyl thioureide, melted at 219–221°.

Anal. Calcd. for $C_{21}H_{34}N_5S \cdot 2HCl \cdot H_2O$: S, 6.88; H_2O, 3.87. Found: S, 6.80; H_2O, 4.11.

The filtrate was concentrated, and the residue together with the above salt were dissolved in hot absolute alcohol; 25 ml. of 8 *N* alcoholic hydrogen chloride was added, and the solution was allowed to stand overnight. The crystals were filtered and the above process was repeated. The first and second crop of crystals were united (wt. 8.0 g.) and recrystallized from a large volume of ethanol to give the pure trihydrochloride, m.p. 268° dec.

Anal. Calcd. for $C_{14}H_{29}N_3 \cdot 3HCl$: C, 48.3; H, 9.22; Cl, 30.5. Found: C, 48.0; H, 9.33; Cl, 30.1.

3β-(2-Diethylaminoethyl)-aminotropane Bis-methiodide.—An aqueous solution of the above trihydrochloride was treated with potassium carbonate, and the liberated base was removed with the aid of ether and dried. Distillation furnished the free base, b.p. 117–119° (1.5 mm.), $n^{25}D$ 1.4839.

One hundredth mole of the base (2.4 g.) was dissolved in 50 ml. of absolute ethanol; 2 ml. of methyl iodide was added, and the solution was allowed to stand at room temperature for 5 hr. The crystals (3.0 g.) were filtered and recrystallized from methanol, m.p. 270.5–271.5°.

Anal. Calcd. for $C_{16}H_{35}N_3I_2$: N, 8.03; I, 48.5. Found: N, 8.09; I, 48.4.

3α-(α-Diethylaminoethyl)-aminotropane Bis-methiodide.—Six grams of the triamine I dissolved in 30 ml. of dry ethanol was chilled to 0°, and 3.5 ml. of methyl iodide was added. The solution was left at room temperature overnight. The solid which separated (wt. 10.4 g.) was crystallized from aqueous ethanol to give 7.5 g. of the bis-methiodide, m.p. 265–266°. The infrared spectrum (KBr pellet) showed a strong NH band.

Anal. Calcd. for $C_{16}H_{35}I_2N_3$: I, 48.5. Found: I, 48.2.

N,N-Diethyl-N′-(3-[9-methylgranatanyl])-ethylenediamine Phenyl Thioureide.—A solution of 15.7 g. of pseudopelletierine hemihydrate[24] in 100 ml. of dry toluene was refluxed under a water separator. The dried solution was treated with 12.0 g. of diethylaminoethylamine and 100 mg. of zinc chloride. After 4 hr. only 50% of the theoretical amount of water was collected and after 12 hr. only 83% (*cf.* the same reaction with tropinone). The mixture was distilled to give a small fore-run (b.p. 90–120°, 1.0 mm.) which contained pseudopelletierine and the main fraction, b.p. 130–135° (0.5 mm.), wt. 13.7 g. (57%). On redistillation the Schiff base boiled at 131–139° (0.7 mm.), $n^{25}D$ 1.5050.

Reduction of 10.5 g. of the redistilled Schiff base in ethanol with 0.5 g. of Adams catalyst took 5 hr. at 60°. The triamine, isolated in the usual way, boiled at 116–122° (0.2 mm.) and weighed 9.0 g. (85%). On redistillation the base boiled at 128–130° (0.6 mm.), $n^{25}D$ 1.4920.

When 600 mg. of the base was treated with 320 mg. of phenyl isothiocyanate, the corresponding phenyl thioureide separated, which melted at 188–190° after recrystallization from ethyl acetate.

Anal. Calcd. for $C_{22}H_{36}N_4S$: N, 14.42; S, 8.25. Found: N, 14.49; S, 8.22.

N,N-Diethyl-N′-(3-pseudo-[9-methylgranatanyl])-ethylenediamine Phenyl Thioureide.—To a suspension of 7.5 g. of sodium sand in 175 ml. of refluxing toluene there was added over a 5.5-hr. period a solution of 20.5 g. of the Schiff base derived from pseudopelletierine and diethylaminoethylamine in 32.8 g. of 4-methyl-2-pentanol. After all had been added, the mixture was stirred for an additional half hour. The cooled reaction mixture was treated cautiously with 30 ml. of 10% sodium carbonate. The organic layer was separated, and the water layer was satu-

(24) A. C. Cope, *et al.*, This Journal, **73**, 3416 (1951).

Digitized by Arya Samaj Foundation Chennai and eGangotri

rated with potassium carbonate. The aqueous phase was extracted with benzene and the united organic portions were dried and distilled *in vacuo* to leave 22.8 g. of a residue. This was combined with 7.0 g. of a similar preparation, and the resulting 29.8 g. of mixed bases was dissolved in 100 ml. of ethanol and treated with 17.5 g. of phenyl isothiocyanate. After 1 hr. the mixture was chilled in ice and filtered. This was called fraction A. The filtrate was evaporated to leave a red oil which was called fraction B.

Fraction A was crystallized from a large volume of ethyl acetate. There deposited 20.3 g. of a phenyl thioureide, m.p. 189–191°, undepressed when mixed with the same derivative obtained from the triamine prepared by catalytic reduction of the Schiff base. The filtrate was concentrated to 300 ml. and cooled. The crop that separated weighed 2.0 g., m.p. 185–187°. The combined yield of the normal isomer was 22.3 g.

The above filtrate was further concentrated to 25 ml. On cooling 1.8 g. of the phenyl thioureide of the pseudo isomer, m.p. 133–135°, separated. Fraction B was dissolved in 50 ml. of ethyl acetate. On cooling 12.0 g. of the same isomer separated, m.p. 131–133°. The combined yield of the pseudo isomer was 13.8 g. Further crystallization from ethyl acetate raised the m.p. to 135–136°.

Anal. Calcd. for $C_{22}H_{36}N_4S$: N, 14.42; S, 8.25. Found: N, 14.70; S, 7.96.

N,N-Diethyl-N′-(3-pseudo-[9-methylgranatanyl])-ethylenediamine Trihydrochloride.—A suspension of 10.2 g. of the phenyl thioureide described directly above (m.p. 135–136°) in 100 ml. of absolute alcohol was mixed with 15 ml. of 8 *N* alcoholic hydrogen chloride and left overnight at room temperature. A small amount of insoluble material was removed by filtration and the filtrate was carefully treated with 150 ml. of dry ether to precipitate the crude trihydrochloride, wt. 9.1 g. After recrystallization from equal parts of methanol and ethanol, the salt melted at 264–267° dec.

Anal. Calcd. for $C_{15}H_{31}N_3 \cdot 3HCl$: C, 49.7; H, 9.45; Cl, 29.3. Found: C, 49.9; H, 9.54; Cl, 29.2.

The bis-methiodide was prepared from 2.6 g. of the trihydrochloride. The base was liberated from an aqueous solution of the salt with potassium carbonate and dissolved in ether. The dried ether solution was evaporated to an oil which was dissolved in 10 ml. of methanol. The solution was treated with 1.2 ml. of methyl iodide, left overnight and then filtered. The bis-quaternary salt was purified by crystallization from methanol; m.p. 270–272° dec.

Anal. Calcd. for $C_{17}H_{37}I_2N_3$: I, 47.2; N, 7.82. Found: I, 47.3; N, 7.88.

3α-(N-Diethylaminoethyl)-methylaminotropane.—Sixty-nine grams of 3α-(2-diethylaminoethyl)-aminotropane was cooled, and 76 ml. of 98% formic acid was added slowly. The solution was allowed to warm to room temperature before 29 ml. of 37% formalin was added. The solution was heated on the steam-bath for 17 hr., cooled, poured into ice-water and made strongly basic with 35% sodium hydroxide. The oil was removed and the aqueous layer was washed twice with methylene chloride. The united oil layers were dried over Drierite and distilled to give a fraction, b.p. 120–124° (0.9 mm.), $n^{25}D$ 1.4873, which was taken as the methylated base, wt. 59.7 g.

Twenty grams of this base was dissolved in 250 ml. of absolute alcohol, and to it was added a freshly prepared solution of alcoholic hydrogen bromide to *p*H 3. The mixture was allowed to stand 18 hr. and was filtered. The trihydrobromide which weighed 34 g. was recrystallized from methanol. It was quite hygroscopic and melted unsharply in the range 135–145°.

Anal. Calcd. for $C_{15}H_{31}N_3 \cdot 3HBr$: C, 36.3; H, 6.91; Br, 48.3. Found: C, 35.9; H, 7.09; Br, 47.9.

The bis-methobromide was prepared by adding gaseous methyl bromide to 5.0 g. of the base in 50 ml. of acetonitrile for 4 minutes. The temperature rose from 23 to 30°, and the product started to separate during this time. After 3 hr. at room temperature the mixture was filtered and the salt was crystallized from isopropyl alcohol; wt. 4.4 g., m.p. 230–232° dec.

Anal. Calcd. for $C_{17}H_{37}Br_2N_3$: Br, 36.1. Found: Br, 35.7.

3α-(N-2-Diethylaminoethyl)-acetylaminotropane.—A solution of 24 g. of N,N-diethyl-N′-(3-tropanyl)-ethylenediamine in 20 ml. of acetic anhydride was heated on the steam-bath for 2 hr. The mixture was allowed to stand overnight and then it was poured into ice-water. The solution was rendered strongly alkaline. The oil was taken up in benzene, dried by azeotropic distillation and then distilled to give 20.1 g. (73%) of a viscous oil, b.p. 143–150° (0.05–0.15 mm.). Upon redistillation it boiled at 142–144° (0.09 mm.), $n^{25}D$ 1.4980.

A portion was converted to the dipicrate which melted at 194–195° after recrystallization from ethanol.

Anal. Calcd. for $C_{16}H_{31}N_3O \cdot 2(C_6H_3N_3O_7)$: N, 3.70. Found: N, 3.74.[25]

3α-(N-2-Diethylaminoethyl)-ethylaminotropane Bis-methiodide.—The above amide (10.3 g.) was reduced in 100 ml. of dry ether with 4.0 g. of lithium aluminum hydride. The mixture was refluxed for 2 hr. after all the amide had been added. Excess reducing agent was destroyed with ethyl acetate followed by 10 ml. of water. The inorganic matter was filtered off and washed thoroughly with ether. The combined ethereal fractions were dried and distilled. The product boiled at 142° (2.0 mm.) and weighed 10.0 g., $n^{25}D$ 1.4845.

A solution of the base (470 mg.) in 10 ml. of acetonitrile was treated with 0.5 ml. of methyl iodide. No temperature rise was noted, but in two minutes crystals of the bis-methiodide started to separate. After 2.5 hr. the solid was collected and dried, wt. 630 mg., m.p. 217.5–219.5° dec.

Anal. Calcd. for $C_{18}H_{39}I_2N_3$: I, 46.0; N, 7.63. Found: I, 45.4; N, 7.74.

3α-(N-2-Diethylaminoethyl)-propionylaminotropane.—3α-(2-Diethylaminoethyl)-aminotropane (48 g.) was cooled under the tap as 50 ml. of propionic anhydride was added. The temperature rose to 70°. The mixture was allowed to stand for 2.5 hr. and then worked up as in the case of the lower homolog. The viscous propionyl derivative boiled at 160° (0.5 mm.), $n^{25}D$ 1.4945, wt. 45.8 g.

The dipicrate prepared in ethanol melted at 173–176° after recrystallization from aqueous dimethylformamide.

Anal. Calcd. for $C_{17}H_{33}N_3O \cdot 2(C_6H_3N_3O_7)$: neut. equiv., 377. Found: neut. equiv., 373.[23]

3α-(N-2-Diethylaminoethyl)-propylaminotropane Bis-methiodide.—One-tenth mole of the propionamide (29.5 g.) was reduced with 4.0 g. of lithium aluminum hydride in 100 ml. of ether. The mixture was worked up as in the previous case to furnish an oil, b.p. 119–126° (0.1 mm.), $n^{25}D$ 1.4835, wt. 23.6.

Two grams of the above base in 30 ml. of acetonitrile was treated with 2.0 ml. of methyl iodide. The solution warmed noticeably, but crystals did not appear until about 10 minutes after the halide was added. The mixture was allowed to stand overnight, cooled to 5° and filtered. The salt was washed successively with acetonitrile, absolute alcohol and pentane; m.p. 193–195° dec.

Anal. Calcd. for $C_{19}H_{41}I_2N_3$: I, 44.9; N, 7.44. Found: I, 44.5; N, 7.56.

Interconversion of Chalcones and Flavanones of a Phloroglucinol-type Structure

BY MASAMI SHIMOKORIYAMA

RECEIVED DECEMBER 14, 1956

Naturally occurring flavanone glycosides with a phloroglucinol-type structure were converted to the corresponding chalcone glycosides. The method of preparation and the properties of the latter compounds are described. Some preliminary evidence was obtained for the existence of an enzyme, "flavanone synthease," which converts phloroglucinol-type chalcone glycosides to flavanone glycosides. It is postulated that a chalcone glycoside may in certain cases serve as an intermediate in the biogenesis of a flavanone glycoside.

In a previous paper[1] it was shown that the flavonoid pigments of *Coreopsis tinctoria* consist of a chalcone, a flavanone and a benzalcoumaranone derivative of corresponding structure. It was found that the chalcone, marein, is oxidized easily to the corresponding aurone, maritimein, but at the same time it has a great tendency to isomerize into the related flavanone, flavanomarein. The unusual behavior shown by marein suggests that there may be a close relationship among the three types of flavonoid pigments. This finding, in addition to a number of reports in the literature which are summarized below, prompted us to investigate the interconversion of chalcones and flavanones; flavanone glycosides with a phloroglucinol type of structure, *viz.*, naringin, poncirin, hesperidin and isosakuranin, were used for this purpose.

A majority of the naturally occurring flavanones have a phloroglucinol structure. However, no chalcone possessing a phloroglucinol or a 2′,6′-dihydroxy structure with free hydroxyl groups in the 2′- and 6′-positions is known in nature. Salipurposide found in *Salix purpurea*[2] is fairly stable in the chalcone form (isosalipurposide); it has a glucosidoxy residue in place of one of the *o*-hydroxyl groups. Other examples of the co-existence of a flavanone with a corresponding chalcone have been reported by Seshadri.[3]

Narasimhachari and Seshadri,[4] in their study of a number of substituted flavanones, found that naringenin, isosakuranetin, naringenin 4′,7-dimethyl ether, etc., dissolve readily in cold 10% sodium hydroxide and are precipitated unchanged by acidification, whereas 5-methoxy- and 5,7-dimethoxyflavanone dissolve in this reagent only on warming and give only the corresponding 2′-hydroxy chalcones on acidification. From these experiments they pointed out that when the 5-hydroxyl group is present in the flavanone, the equilibrium in the chalcone–flavanone isomerization is shifted in favor of the flavanone because of hydrogen-bonding stabilization between the 5-hydroxyl group and the carbonyl.[4]

Of particular interest are optically active flavanones, a few of which have been found in nature.[5]

In 1942, Zemplén and co-workers[6] synthesized an isosakuranetin glucoside (m.p. 214°, $[\alpha]_D$ −73.4° in pyridine) through its chalcone form and ascribed to it the structure of a 7-glucoside. Natural isosakuranetin-7-glucoside (m.p. 190°, $[\alpha]^{13}_D$ −41.4° in 60% acetone) was isolated from the wood of *Prunus donarium* var. *spontanea* by Hasegawa and Shirato[7] who attributed the discrepancy in the two preparations to the difference in the optical activity of the aglycon.

Wawra and Webb[8] reported the preparation of hesperidin chalcone by dissolving hesperidin in cold alkali; upon neutralization the chalcone crystallized. Their preparation melted at 251–252° and showed ultraviolet absorption maxima at 332 and 308 mμ. Almost the same procedure was repeated by the author, giving pale yellow crystals, which did not show any of the absorption characteristics of chalcones. It will be shown below that, under the comparatively mild conditions used by Wawra and Webb, the equilibrium, flavanone ⇄ chalcone, is not shifted to the right.

The existence in nature of optically active flavanones suggests that an enzyme may be involved in the chalcone–flavanone isomerism; various sources were tested for the presence of such an enzyme.

Experimental[9]

Isosakuranin from Poncirin.—Poncirin isolated from *Poncirus trifoliata*[5e] was partially hydrolyzed by refluxing a solution of 2 g. in 25 ml. of 50% ethanol and 0.5 ml. of 20% hydrochloric acid for 3 hr. Paper chromatography revealed that the poncirin had almost disappeared, while the isosakuranetin spot was still weak and a spot of intermediate R_f was most prominent. In agreement with this finding, a marked spot of rhamnose was detected, whereas glucose showed a weak spot. When the hydrolyzate was allowed to stand overnight, colorless needles of isosakuranin separated almost completely; yield 0.4 g. The isosakuranin was repeatedly recrystallized from 50% ethanol; m.p. 172–178°, $[\alpha]^{20}_D$ −48.4° (*c* 0.25, 90% ethanol).

Anal. Calcd. for $C_{22}H_{24}O_{10}\cdot 1.5H_2O$: C, 55.57; H, 5.72; H_2O, 5.69. Found: C, 55.76; H, 5.43; H_2O, 5.60.

Chalcones.—The following procedure exemplifies the preparation of the chalcones from the corresponding flavanones:

(A) **Isosakuranin.**—Isosakuranin (1 g.) was heated with 2 g. of potassium hydroxide and 4 ml. of water on a boiling water-bath for 2 minutes. On cooling, the mixture was acidified with 20% hydrochloric acid. The resulting orange-yellow crystalline precipitate was recrystallized from 40 ml. of 30% ethanol as yellow needles, m.p. 172–175°, yield 0.55 g.

Anal. Calcd. for $C_{22}H_{24}O_{10}\cdot 1.5H_2O$: C, 55.57; H, 5.72; H_2O, 5.69. Found: C, 55.80, 55.52; H, 5.93, 6.01; H_2O, 5.80.

(B) Poncirin.—The reaction mixture, obtained by similar treatment of 1 g. of poncirin, was acidified to *p*H 2. Treatment of the oily precipitate with ethyl acetate gave crystals which, upon three recrystallizations from 50% ethanol, yielded yellow needles, m.p. 195–205°, yield 0.45 g.

Anal. Calcd. for $C_{28}H_{34}O_{14}\cdot H_2O$: C, 54.90; H, 5.92; H_2O, 2.94. Found: C, 55.02; H, 5.64; H_2O, 3.00.

(C) Naringin.—Naringin (1.3 g.) isolated from the peel of *Citrus natsudaidai*[10] was treated as described for poncirin. The chalcone was obtained as yellow needles, m.p. 185–200°, yield 0.7 g.

Anal. Calcd. for $C_{27}H_{32}O_{14}\cdot H_2O$: C, 54.18; H, 5.73; H_2O, 3.01. Found: C, 54.15; H, 5.51; H_2O, 3.20.

(D) Hesperidin.—Yellow needles of the chalcone were obtained from hesperidin isolated from *Citrus nobilis* peel. The hesperidin chalcone melted at 180° and the melted mass, gradually losing color, solidified as colorless crystals which melted at 250°, the melting point of hesperidin.

Anal. Calcd. for $C_{28}H_{34}O_{15}\cdot 2.5H_2O$: C, 51.30; H, 6.00; H_2O, 6.87. Found: C, 51.19; H, 5.49; H_2O, 7.12.

These chalcones dissolved instantly in cold, dilute aqueous alkali giving an orange color; their ethanolic solutions gave a brown color with ferric chloride.

Preparation of Racemic Flavanones from Chalcones. (A) Isosakuranin.—Isosakuranin chalcone (1.0 g.) was heated on a water-bath with 0.3 g. of sodium acetate and 3 ml. of water according to the method of Zemplén.[6] The separation of colorless crystals of the flavanone, which occurred after a few minutes, was almost complete in 15 minutes. The product was recrystallized from 50% ethanol; m.p. 210–214°, $[\alpha]^{20}D$ −39.2° (*c* 0.25, 90% ethanol).

Anal. Calcd. for $C_{22}H_{24}O_{10}\cdot 1.5H_2O$: C, 55.57; H, 5.72; H_2O, 5.69. Found: C, 55.94; H, 5.82; H_2O, 5.42.

(B) Poncirin.—A mixture of 0.1 g. of the chalcone, 1 ml. of 50% ethanol and 0.1 ml. of McIlvaine buffer solution of *p*H 7 was heated on a water-bath for 3 minutes. The reaction mixture was extracted with ethyl acetate, the extract evaporated *in vacuo* and the residue crystallized from absolute ethanol; yield 40 mg. The crystals softened at 160° and melted at 170–175°, $[\alpha]^{20}D$ −82.5°; natural poncirin, $[\alpha]^{20}D$ −93.8° (*c* 0.8, 90% ethanol).

(C) Naringin.—The chalcone (0.1 g.) was heated with 1 ml. of 50% ethanol and 0.1 ml. of McIlvaine buffer solution (*p*H 6). The mixture was added to an equal volume of water and allowed to stand overnight. The crystals which separated were recrystallized from 20% ethanol as colorless needles, m.p. 80–83°, yield 80 mg., $[\alpha]^{20}D$ −72.1°; natural naringin, $[\alpha]^{20}D$ −82.0° (*c* 1, 90% ethanol).

(D) Hesperidin.—Racemic hesperidin, prepared by the procedure described for racemic naringin, was recrystallized from pyridine as colorless needles, m.p. 250°.

Enzymatic Hydrolysis of Isosakuranin with Emulsin.—Isosakuranin (0.1 g.) suspended in 6 ml. of water was added to 6 ml. of a solution containing 60 mg. of emulsin, prepared from Japanese apricot. The mixture was covered with toluene and incubated at 30°. The hydrolysis was almost complete in three days. The aglycon was filtered and recrystallized from dilute ethanol; m.p. 170°, reported[7] m.p. 170°; $[\alpha]^{20}D$ −13.8° (*c* 1, 90% ethanol).

Anal. Calcd. for $C_{16}H_{14}O_5\cdot{}^1/_2H_2O$: C, 65.08; H, 5.12. Found: C, 65.35; H, 5.36.

The filtrate, separated from the aglycon, was evaporated to about 1 ml. and chromatographed with 1-butanol–acetic acid–water (4:1:1) as the solvent and a benzidine solution as the developer. The concentrate gave a single spot, which corresponded to glucose (R_f 0.17).

When racemized isosakuranin was hydrolyzed by emulsin, an optically inactive isosakuranetin (m.p. 190°) was obtained.

Stability of Chalcones at Various *p*H Values.—The behavior of chalcones in dilute ethanolic solution was studied at various *p*H's. The times required for the complete decolorization of the buffered solutions, *i.e.*, for the complete conversion of the chalcone to flavanone, are given in Table I.

TABLE I

DECOLORIZATION TIME IN MINUTES OF CHALCONES AT VARIOUS *p*H VALUES

To 0.2 ml. of ethanolic solution of chalcones (0.01 *M*) were added 0.5 ml. of water and 0.3 ml. of McIlvaine buffer solution (22°) ppt and PPT indicate the presence of crystals of chalcone and flavanone, respectively.

Chalcone	*p*H 3	4	5	6	7	8
Isosakuranin	ppt ∝	ppt ∝	ppt ∝	70	PPT 22	PPT 15
Poncirin	ppt ∝	ppt ∝	ppt ∝	65	22	16
Naringin	ppt ∝	∝	PPT 400	PPT 70	PPT 20	PPT 15
Hesperidin	∝	∝	PPT 420	PPT 80	PPT 21	PPT 15

This isomerization reaction also was followed by measuring the changes in the absorption of buffered chalcone solutions at 370 mμ with a spectrophotometer against an appropriate buffer blank; the data are recorded in Fig. 1. This isomerization is a monomolecular reaction. The rate constant *k* was calculated from the formula

$$k = \frac{2.303}{t} \log \frac{E_0}{E_t}$$

where E_0 and E_t represent the optical densities of the solution at 370 mμ at zero time and at *t* minutes, respectively. The following values were obtained for *k*: 0.150 at *p*H 7, 0.055 at *p*H 6, 0.018 at *p*H 5, 0.001 at *p*H 4 and 0.000 at *p*H 3.

Preparation of an Enzyme Solution from the Peel of *Citrus aurantium*.—One hundred grams of the peel was macerated twice with 300 ml. of cold ethanol, and the almost colorless powder obtained was then extracted with 300 ml. of water. The aqueous solution was mixed with one-tenth volume of a saturated ammonium sulfate solution and then centrifuged. The supernatant was saturated with ammonium sulfate and the resulting precipitat was filtered, redissolved and reprecipitated by the same procedure as above. The precipitate was then dissolved in 20 ml. of water, dialyzed and filtered. In order to test the activity of the "flavanone synthease," 10 mg. of the chalcone glycoside suspended in 0.5 ml. of water (in some cases buffered with McIlvaine solution) was added to 0.5 ml. of the above enzyme solution. The mixture was covered with toluene and incubated at 30°. A blank test was always run on the same quantity of the chalcone suspended in 1 ml. of water. The conversion of the chalcone to flavanone was readily detected by disappearance of the chalcone or by appearance of the resulting flavanone in crystals.

TABLE II

THE ACTIVITY OF "FLAVANONE SYNTHEASE" FROM VARIOUS SOURCES

Species	Tissue	Relative activity[a]
Citrus aurantium	Peel	+ + +
	Leaf	−
C. natsudaidai	Peel	+ +
	Leaf	−
C. junos	Peel	±
C. nobilis	Peel	±
C. pseudoparadisi	Peel	±
Poncirus trifoliata	Peel	+
	Leaf	−
Cosmos sulphureus	Ray	−
	Leaf	−
Coreopsis lanceolata	Ray	−
	Leaf	−
C. tinctoria	Ray	−
	Leaf	−
Dahlia variabilis	Ray	−
(a white variety)	Leaf	−

[a] + + + denotes almost complete conversion of the chalcone glycoside (10 mg. in 0.5 ml. of water plus 0.5 ml. of enzyme solution) in 3 days, + + in 5 days, + signifies partial conversion, ± slight activity and − no activity.

Some other plant materials were tested for enzymatic activity in the same way; the results are summarized in Table II.

No isomerization reaction was observed if the enzyme solution had been boiled for about 10 minutes. The activity also was inhibited completely by mercuric chloride (0.002*M*) but not affected by potassium cyanide (0.002*M*). The cyclization did not occur at *p*H 3–4. The spontaneous reaction, however, occurs so readily at *p*H 5 and so rapidly at *p*H 6–7 that it was impossible to find the optimum *p*H for the enzyme. If an unbuffered aqueous suspension was used, the chalcone was almost perfectly stable during a week's incubation, owing to its insolubility in water. When these chalcones were subjected to the oxidizing action of the chalconase[11] in *Cosmos* or *Coreopsis*, the conversion into the corresponding aurones was not, however, observed. As chromatographic analysis showed, the marein from *Coreopsis tinctoria*[1] and the coreopsin from *Cosmos sulphureus*[12] were not isomerized by the "flavanone synthease"; flavanomarein[1] and flavanocoreopsin, obtained as described below, served as controls.

Enzymatic Resynthesis of Flavanones. (A) **Naringin.**—A mixture of the chalcone (0.5 g.), suspended in 25 ml. of water, and 25 ml. of the enzyme solution prepared from the peel of *Citrus aurantium* was covered with toluene and incubated at 30°. The reaction was complete in 3–4 days; by that time no yellow crystals of chalcone remained and colorless needles of naringin had appeared. The mixture was cooled in a refrigerator overnight, and the flavanone was filtered and recrystallized from 20% ethanol; m.p. 80–83°, $[\alpha]^{20}D$ −74.3° (*c* 1, 90% ethanol).

(B) **Isosakuranin.**—Isosakuranin prepared from the chalcone in the same way melted at 175–190°, $[\alpha]^{20}D$ −43.0° (*c* 0.25, 90% ethanol).

(C) **Poncirin.**—Poncirin chalcone, which had been incubated with the enzyme, gave an almost clear, pale brown solution which was extracted with ethyl acetate. The extract was evaporated *in vacuo* and the residue crystallized twice from absolute ethanol to yield colorless crystals of the flavanone, m.p. 160–170°, $[\alpha]^{17}D$ −84.2° (*c* 0.8, 90% ethanol).

Flavanocoreopsin.—Coreopsin (1.2 g.) was heated on a water-bath with 3.6 g. of sodium acetate and 18 ml. of water for about 2 hr. Then the solution was slightly acidified with a few drops of 20% acetic acid and extracted with ethyl acetate. The acetate solution was evaporated and the residue was dissolved in 10 ml. of ethanol. The pale yellow needles which separated were recrystallized repeatedly from ethanol to yield almost colorless needles which melted at 166–168° and gave a green color with ferric chloride. The flavanocoreopsin gave an R_f value of 0.62 (1-butanol–acetic acid–water, 4:1:2; Whatman No. 1; 20°); that of coreopsin was 0.54.

Anal. Calcd. for $C_{21}H_{22}O_{10}\cdot H_2O$: C, 55.75; H, 5.35; H_2O, 3.98. Found: C, 55.81; H, 5.84; H_2O, 4.04.

The conversion did not, however, occur under the conditions used for the cyclization of phloroglucinol-type chalcones. Flavanocoreopsin could not be detected even in trace amounts in the fresh extract of the ray flowers of *Cosmos sulphureus*.

Discussion

All of the chalcones obtained from phloroglucinol-type flavanone 7-glycosides as described above are fairly stable even when dissolved in ethanol, either concentrated or dilute. They are readily soluble in strong ethanol and recrystallizable from dilute ethanol. That these substances have a chalcone structure is indicated by the following experiments and considerations: They are bright yellow, while the original as well as the reconverted flavanones are colorless. They dissolve instantly in cold, dilute aqueous alkali giving an orange color. They gave a brown color with ferric chloride, whereas the flavanones studied in the present work gave a purple color. The chalcones gave well-sepa-

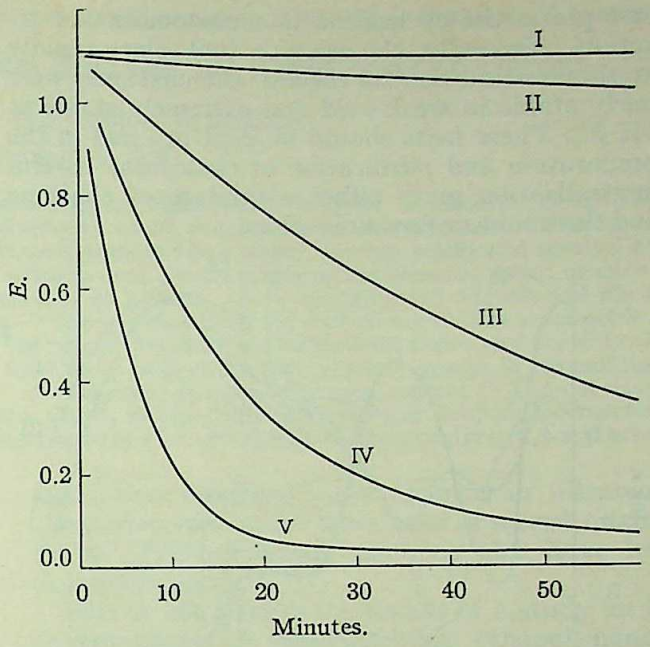

Fig. 1.—Isomerization of naringin chalcone to the flavanone at various *p*H values (22°). To 1.0 ml. ethanolic solution of the chalcone (0.003 *M*) were added 1.0 ml. of McIlvaine buffer solution and 8.0 ml. of water. rated yellow spots on a paper chromatogram, not accompanied by even a faint spot of corresponding flavanones; while the mother liquor of recrystallization, after being allowed to stand a few days, gave both spots. The R_f values are shown in Table III. Their ultraviolet absorption spectra, two examples of which are shown in Fig. 2 with one typical flavanone curve, confirm the chalcone structure assigned to these compounds. An imperfect chalconization or careless treatment gave a pale yellow preparation which had an absorption curve between that of the chalcone and the flavanone.

The stability of the chalcones at various *p*H values exceeded our expectation. An equilibrium may exist in the interchange, chalcone ⇄ flavanone, and this equilibrium is shifted to the left in an alkaline medium and to the right in an acid medium. Our study of the behavior of chalcones in a dilute ethanolic solution of various *p*H values (Table I and Fig. 1) is noteworthy in two respects. In the

(11) M. Shimokoriyama and S. Hattori, THIS JOURNAL, 75, 2277 (1953).

first place, the cyclization is a monomolecular reaction. Secondly, the reaction took place rapidly in alkaline and neutral media; the chalcones were fairly stable in weak acid and extremely stable at *p*H 3. These facts should be kept in mind in the preparation and purification of chalcones; careful neutralization gives either a mixture of chalcone and flavanone or flavanone alone.

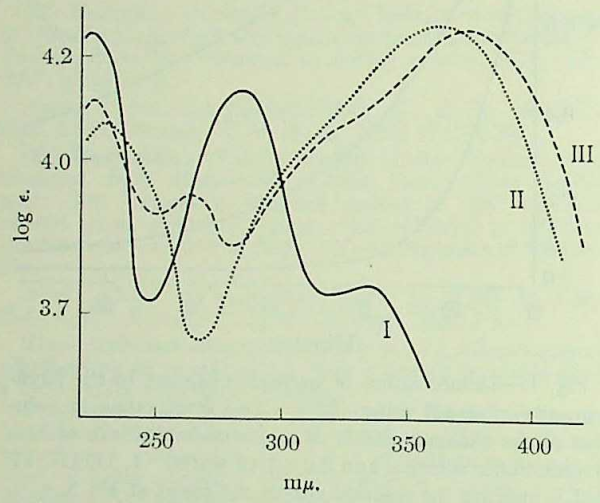

Fig. 2.—Ultraviolet absorption spectra: I, pocirin and isosakuranin; II, poncirin chalcone and isosakuranin chalcone; III, hesperidin chalcone (in 98% ethanol).

The existence of optically active flavanones in nature suggested that if a chalcone was produced as a precursor in the biosynthesis of a flavanone, an enzyme may be involved in the chalcone–flavanone isomerism. The fact that the phloroglucinol-type chalcone glycosides are unstable in the *p*H range prevailing in living cells and form optically inactive flavanones supports this hypothesis. Some evidence for the existence of such an enzyme, "Flavanone synthease," was obtained. The aqueous, cell-free extract of the peel of *C. aurantium* proved to be the most active preparation. The enzyme in the peel of *Citrus* fruits acted in almost the same way on all the phloroglucinol-type chalcones tested, but it did not seem to exert any effect on the coreopsin from *Cosmos sulphureus* and the marein from *Coreopsis tinctoria*. No activity was detected in the ray and the leaves of *Cosmos*, *Coreopsis* and *Dahlia*.

Few optically active forms of flavanone glycosides have been found in nature. By the usual procedure for the hydrolysis of a glycoside, however, some racemization always takes place. Consequently, enzymatic hydrolysis is the best method for obtaining an optically active aglycon from a flavanone glycoside. Isosakuranin prepared from poncirin was hydrolyzed readily by an emulsin from Japanese apricot to give optically active isosakuranetin; Hasegawa and Shirato[7] obtained the same results with isosakuranin from *Prunus*. When isosakuranin chalcone was recyclized, it gave isosakuranin (m.p. 210–214°) which is regarded as identical with the isosakuranin described by Zemplén and co-workers.[6] A mixture of racemic isosakuranin and the original preparation gave on recrystallization a preparation which melted between 180 and 200°. Enzymatically resynthesized isosakuranin melted in the same temperature range, a finding which suggests that it contains some optically active isosakuranetin. The specific rotation values of these preparations are in good accord with these facts: $[\alpha]^{20}D$ for isosakuranin prepared from poncirin was −48.4°, that of the completely racemized glucoside was −39.2°, and that of the enzymatically recyclized preparation −43.0°. Although the isosakuranin from poncirin is, of course, partially racemized during hydrolysis and purification, the isosakuranin enzymatically resynthesized from the chalcone is fairly rich in optically active isosakuranetin.

In the case of poncirin and naringin, there was almost no difference between the melting points of the completely racemized compounds obtained *via* the chalcone and those of the original flavanones. However, the specific rotation powers of the recyclized flavanones were about 10° less than those of the original compounds, a difference which indicates that the aglycon occurs in the plant in an optically active form; it would necessarily be partly racemized during extraction and purification. The specific rotation values of the enzymatically resynthesized glycosides indicate that the products contain optically active aglycon to some extent.

Acknowledgment.—The author is grateful to Professor S. Hattori for his kind advice and to the Ministry of Education for a grant given to Professor S. Hattori, with which the cost of this study was defrayed. Thanks are also due to Dr. M. Hasegawa of the Government Forest Experiment Station who supplied isosakuranin isolated from *Prunus*.

Lignin Structure. XI. A Quantitative Study of the Alcoholysis of Lignin[1]

By Kyosti Sarkanen and Conrad Schuerch

Received November 9, 1956

The following changes occur on re-ethanolysis of ethanol–spruce lignins, isolated in 57% yield: a maximum of 42 to 57% of the guaiacylpropane units become ethoxylated by a rapid reaction which seems to be independent of the liberation of phenolic groups. New phenolic hydroxyl and α-carbonyl groups are generated by a slower cleavage reaction in nearly 1-to- 1 molar ratio. The concurrent decrease in molecular weight indicates that the liberation of the phenolic group usually results in fission of the molecule but that some cyclic structures may be present. Both unconjugated phenols and phenols with a carbonyl in the α-position are formed by the cleavage. The α-carbonyl groups formed are mainly responsible for the change in the ultraviolet spectrum during ethanolysis. The rate of the phenolic liberation decreases more rapidly than would be expected if only a single structure were reacting. Only about 60% of the para-phenoxy groups in ethanol lignin are converted to free phenols by acid-catalyzed ethanolysis. An extensive decrease in oxygen content (0.3 to 0.6 oxygen atom per guaiacyl propane unit) takes place and is apparently due to independent intramolecular dehydration reactions. Most of these observations correspond closely to similar changes occurring on ethanolysis of guaiacylglycerol β-aryl ethers.

Alcoholysis is one of the important degradative reactions which can be used to dissolve lignin from the tissues of woody plants. Although the reaction can be considered formally analogous to the alcoholysis or hydrolysis of proteins or polysaccharides, there are marked differences between the degradation of lignin by this reaction and the degradation of other polymers. For example, the final products even from a softwood lignin, which apparently is derived almost exclusively from a single monomeric skeleton, are always a complex mixture of oligomers. Furthermore, that small fraction of lignin which has been degraded to propylguaiacyl monomers has had the functional groups on the aliphatic side chains extensively rearranged.

Four monomeric ethanolysis products from spruce lignin have been isolated and identified by Hibbert.[2] These are probably degradation and rearrangement products derived from a single structure, such as a derivative of α-oxyconiferyl alcohol[3] or guaiacylglycerol,[4–8] which exists as a part of the lignin macromolecule in wood. The reactions occurring in that part of lignin which resists degradation to the monomeric state are, however, less clear. The introduction of ethoxyl groups,[9] the formation of phenolic hydroxyl[10] and C-methyl groups,[11] the increase in structures capable of yielding benzene tetra- and pentacarboxylic acids by direct oxidation[12] or *m*-hemipinic acid by oxidation of the methylated product,[13] depolymerization reactions[14] and changes in ultraviolet absorption spectrum[15] have been observed qualitatively. Polymerization reactions also have been claimed to occur.[14]

This article reports the results of a study on the re-ethanolysis of ether-insoluble ethanol lignins, isolated under mild conditions[16,17] from spruce wood. The formation of monomeric products by re-ethanolysis from analogous preparations has been shown to be almost negligible (less than 3%).[14] Therefore, these results describe reactions which occur on that portion of lignin which remains almost exclusively as a complex mixture of low polymers.

It is quite possible that several independent reactions occur on re-ethanolysis of ethanol lignin. The interpretation of analytical data is therefore not as obvious as in the case of simple homogeneous materials. For example, if two functional groups are formed or destroyed in a simple molar ratio (1:1 or 2:1) after some period of time, it is not justified to conclude that the changes are caused by a single reaction. However, there is little likelihood that two independent reactions would have exactly the same rate and therefore if such a ratio is constant throughout the reaction it is very probable that the two molecular changes are caused by the same reaction. Therefore by following changes in analysis over a period of time, it is possible to distinguish which changes are independent and which are probably interrelated. As will be shown in detail, changes in light absorption and in number-average molecular weight may similarly be interrelated with changes in functional group content. For correlations of this type, it is obviously necessary to recover quantitatively and analyze carefully a number of samples allowed to react for varying periods of time. The method used in this investigation seems suitable for application to the reactions of many substrates, the homogeneity of which is doubtful.

It seemed advantageous to isolate fractions of the whole substrate as soon after solution as practicable in order to follow the ethanolysis through as large a fraction of the whole reaction as possible. Therefore samples SI, SII and SIII were isolated

as ether-insoluble fractions of ethanol lignins in that order from a single batch of spruce wood meal by successive, mild ethanolyses. In all essential aspects, the characteristics of SII were intermediate between SI and SIII. The study on this sample was therefore less comprehensive than that of the other two fractions. Sample NI is a part of SI, separated from it by countercurrent distribution in 10% yield. It differs from the rest of sample SI by the fact that its phenolate is extracted from aqueous alkali by chloroform–ethanol. It is called NI to indicate its apparently "neutral" character. The "neutral" parts of SII and SIII were negligibly small and were not investigated separately.

Experimental

Preparation of Ethanol–Spruce Lignins.—The ethanol lignins used in this study were those prepared as described previously[17] by a three-step ethanolysis of Norway spruce woodmeal in anhydrous chloroform–ethanol (volume ratio 4/1) using 0.2 *N* hydrogen chloride as catalyst. The ether-insoluble powders SI, SII and SIII were extracted in that order and amounted to 28, 14 and 15% of the original Klason lignin. An ether-insoluble fraction poor in phenolic groups, NI, was separated in about 10% yield from SI, or 2.8% of the original Klason lignin, by countercurrent distribution between chloroform–alcohol and alkali as previously.[16]

Re-ethanolysis Experiments.—Lignin samples (1 g.) were dissolved in 100 ml. of ethanolysis solution (0.38 *N* hydrogen chloride in chloroform–ethanol 4:1) and heated in sealed round-bottomed flasks for different periods of time in a constant-temperature bath adjusted to 65 ± 0.02°. The reaction was stopped by cooling the flask in crushed ice. The flask was opened and the contents shaken with a saturated sodium bicarbonate solution to neutral reaction and finally with distilled water. If some cloudiness appeared during the extraction, ethanol was added until the solution became clear. The solution was dried with sodium sulfate and evaporated in water-pump vacuum under nitrogen atmosphere. Ten ml. of dioxane (freshly distilled over sodium) was added to the residue and evaporated again. The residue was dissolved in 8 ml. of dioxane and transferred for freeze drying into a test-tube (diam. 6/8″, length 3.5″) with a small indentation in the middle. The contents were thoroughly frozen in an acetone–Dry Ice-bath, placed inside the evaporation flask of a freeze-drying apparatus and the solvent sublimed for 21 hr. under oil-pump vacuum. The final drying was done *in vacuo* over phosphorus pentoxide at 40° for three days.

Because of the tendency of hydrogen chloride to evaporate from chloroform–ethanol, the ethanolysis stock solution was frequently rechecked by titration and the acid concentration corrected by adding a proper amount of a more concentrated ethanolysis solution.

Analysis of Samples.—The methods used for the determination of methoxyl, ethoxyl, phenolic hydroxyl content and ultraviolet absorption spectra have been given previously.[17] Carbon and hydrogen analyses were carried out by Dr. K. Ritter, Basel, Switzerland. The number average molecular weight determinations were made by Dr. Sonja K. Gross in this Laboratory using a cryoscopic determination in ethylene carbonate.[18] A standard Beckmann freezing point apparatus was used. Lignin concentrations were 2%, and molecular weights were found to be nearly concentration independent.

The analytical data are given in Table I. It may be noted that dissolving sample SI in cold ethanolysis solution and recovering it immediately caused a slight change in composition. Samples SII and SIII, on similar treatment, remained unchanged. It seems probable that, in the preparation of SI, the removal of carbohydrates was incomplete and therefore the data on SI_0 were used in subsequent calculations.

ethoxyl and phenolic hydroxyl content of samples NI, SI and SIII occurring during re-ethanolysis are shown in Fig. 1. First, it is obvious that the ethoxylation reaction has been completed in sample SIII before it is isolated from the woodmeal and is nearly complete in the fractions SI and NI isolated earlier. A rapid rate previously has been reported for the ethoxylation of black spruce "native lignin."[19]

The ethoxyl content reaches a maximum value of about 0.55 ethoxyl group per monomer unit in lignin SI after a few hours of re-ethanolysis and thereafter decreases slightly. The ethoxyl content of fraction SIII may also decrease very slowly on re-ethanolysis from an initial value of 0.41 unit per monomer.

While the ethoxyl content is thus remaining almost unchanged, the phenolic hydroxyl content is increasing substantially. It is clear, therefore, that these changes are not connected and the cleavage reaction at this stage of the process should properly not be called ethanolysis at all. The assumption that phenolic liberation and ethoxyl introduction are related during[20] the original isolation from wood therefore appears unlikely.

Liberation of Phenolic Groups.—Just as the ethoxyl content reaches a nearly constant value which is much less than one ethoxyl group per propylguaiacyl unit, the phenolic content also reaches a constant value of 0.55 to 0.65 phenolic group per monomer (Fig. 1). Since every propylguaiacyl unit contains either a phenoxy derivative such as a phenolic ether or a free phenolic hydroxyl group, there are present in the completely reacted samples 0.35–0.45 "unreactive" phenolic ether group per monomer unit that cannot be cleaved by the ethanolysis reaction.

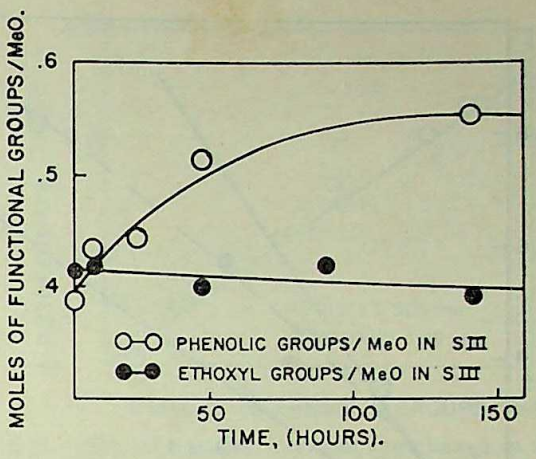
Some information regarding the structure of the "reactive" phenoxy derivatives in ethanol lignin can be obtained by a study of the rate of their ethanolysis. In most acid-catalyzed reactions the rate is known to be first order with respect to the substrate.[21] The rate constant k can therefore be computed using the equation

$$\ln (A_0/A) = kt$$

where A_0 and A are the amounts of the reactant at the start of the reaction and after time t, respectively. For the liberation of phenolic groups, A can be defined as the moles of "reactive" phenolic ether groups per mole methoxyl. These are not directly determinable. However, if no side-reactions occur, the number of "reactive" phenolic ether groups at the beginning of the reaction equals the total number of phenolic hydroxyl groups liberated after infinite time of reaction. The latter quantity can be estimated from the experimental data with a reasonable accuracy and the above equation thus assumes the form

$$\ln \frac{(\Delta C_6H_5OH)_\infty}{(\Delta C_6H_5OH)_\infty - (\Delta C_6H_5OH)_t} = kt$$

where ΔC_6H_5OH denotes the amount of phenolic



Change in phenolic hydroxyl and ethoxyl contents in the re-ethanolysis of sample SIII.

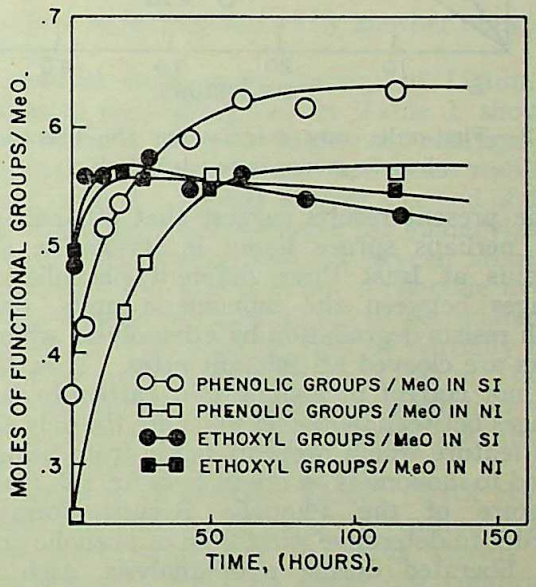


Fig. 1.—Change in phenolic hydroxyl and ethoxyl contents in the re-ethanolysis of samples SI and NI.

groups liberated in moles per mole methoxyl, t is time in hours and subscripts ∞ and t refer to infinite time and time t, respectively.

If the formation of phenolic groups in ethanolysis were due to the cleavage of one single reactive phenolic ether structure, the logarithmic plot of the data against time in Fig. 2 should form a single straight line, regardless of the ethanolic lignin preparation. This condition is obviously not fulfilled. The rate of liberation of phenolic groups in sample SIII is clearly less than the initial rate in sample SI or NI and the data on sample SI suggest that its first-order rate constant becomes less as the reaction proceeds.

The observed kinetic behavior would be expected if phenolic hydroxyl groups were liberated from two (or more) "reactive" phenolic ether structures. As the reaction proceeded the constant decrease in the ratio of rapidly reacting phenolic ether groups to those reacting slowly would result in a decrease in the over-all rate, as was observed in case of sample SI. Since sample SIII, when isolated, had been subjected to ethanolysis for a longer period of time than SI, it would be expected to contain proportionately less of the rapidly reacting groups and would have a lower rate as is observed.

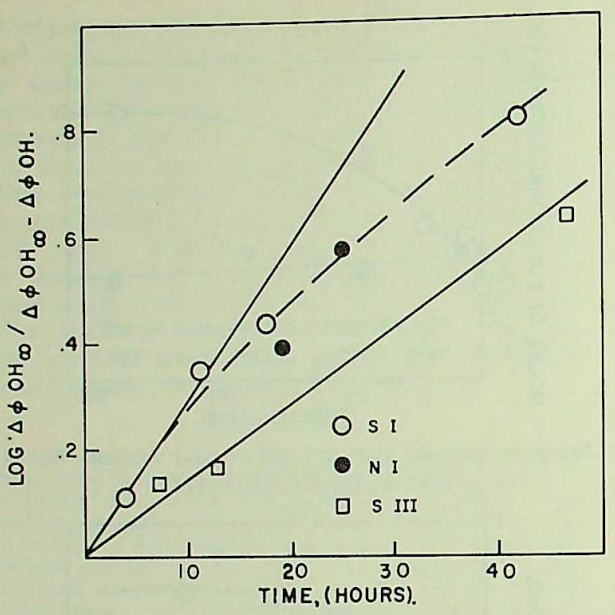

Fig. 2.—First-order rate diagram for the liberation of phenolic groups in re-ethanolysis.

The present results suggest that ethanol lignin (and perhaps spruce lignin in its native state) contains at least three different phenolic ether linkages between the monomeric units, one of which resists degradation by ethanolysis, while the others are cleaved at different rates. It is, therefore, not correct to assume that carbon-to-carbon linkages between monomer units are the only structural feature which prevents lignin from being degraded to monomers on ethanolysis (*cf.* ref. 14).

Nature of the Phenolic Groups Formed.—In order to determine what kind of phenolic groups were liberated during re-ethanolysis, each individual product from re-ethanolysis of SI was dissolved in neutral and alkaline solution, and the difference in the spectra of the two solutions was determined by the method of Goldschmid.[22] The height of the two maxima of the difference spectra of these products at various stages of reaction are given in Table II. The increase in the peak at

Table II

Maxima in the Difference Spectra between Neutral and Alkaline Solutions of Reacted SI Samples

Time of reacn., hr.	Absorptivity, l. g.$^{-1}$ cm.$^{-1}$[a] At 300 mμ	At 350 mμ
0	0.45	1.80
4.1	1.27	4.01
13.0	0.96	6.49
17.5	..	7.55
59.8	0.40	11.60

[a] Because of the low solubility of samples 30% of ethanol was used in *p*H 12 and 6 buffer solutions.

350 mμ during re-ethanolysis can be interpreted[23] to mean that phenols with a carbonyl group in the α-position of the side chain are formed throughout the re-ethanolysis. The increase in the 300 mμ peak during the first 5-hour period of the same reaction indicates the formation of unconjugated phenols early in the reaction. The disappearance of the peak later may be due either to the formation of more α-carbonyl groups, from a previously unconjugated side chain, or may simply be due to the formation of more conjugated phenols, since the values of their difference spectra are generally negative in the 300 mμ region.[23]

Changes in the Ultraviolet Spectra.—Ultraviolet spectral changes occurring during ethanolysis were determined by subtracting the spectra of neutral solutions of the original lignin samples SI or SIII from the neutral solutions of the same products after re-ethanolysis for various periods of time. In both series the spectral change was greatest at 255 and at 305 mμ (Fig. 3a). Since there is little difference between the molar absorptivity of a phenol and its simple derivatives at these wave lengths, the change in spectrum must indicate the formation of another functional group than the phenolic hydroxyl. It must be unsaturated and conjugated with the aromatic ring because guaiacylpropane derivatives show absorption at wave lengths higher than 305 mμ only when such groups are present. In order to establish the nature of this group, comparison was made to similar spectral changes in known model compounds.

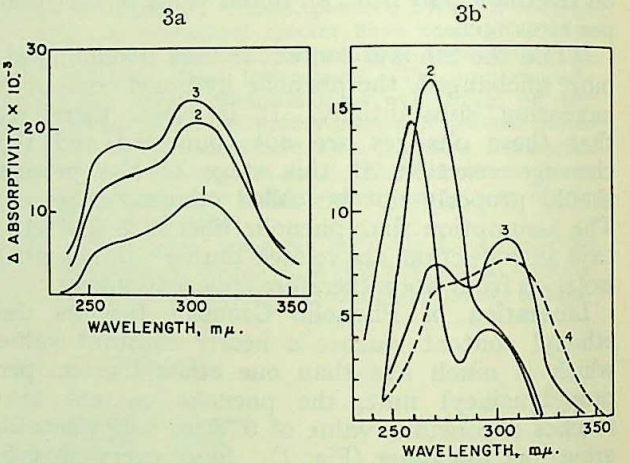

Fig. 3a.—Change in ultraviolet spectrum in the re-ethanolysis of sample SI; time of reaction: curve 1, 11.2 hr.; curve 2, 43.0 hr.; curve 3, 85.9 hr.

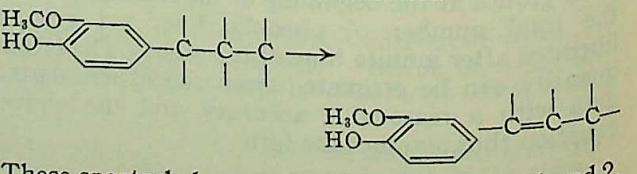
Fig. 3b.—Spectral changes caused by the introduction of a conjugated ethylenic bond (curves 1 and 2) or a conjugated carbonyl group (curves 3 and 4) to guaiacyl derivatives.

By subtracting the reported absorption spectrum of *p*-propylguaiacol from that of isoeugenol and of dihydro-dehydrodiisoeugenol from that of dehydrodiisoeugenol,[24] typical spectral changes were obtained for the transformation



These spectral changes are shown as curves 1 and 2, respectively, in Fig. 3b. Similarly, by subtracting the reported spectrum of guaiacylglycerol-β-guaiacyl ether from that of ketone I[25] and of dihydroeugenol from that of II (on a methoxy basis), spec-

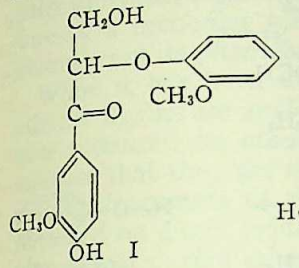
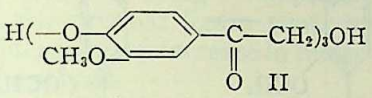
tral changes were obtained for the following trans-

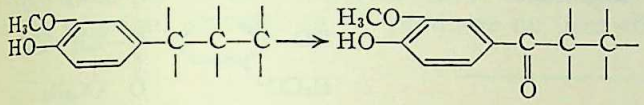


I



II

formation (curves 4 and 3, respectively, in Fig. 3b).



The spectral change for the formation of a conjugated ethylenic bond in this series is characterized by a strong main peak at 260–270 mμ and a shoulder or low maximum at 300 mμ. The spectral change corresponding to the formation of an α-carbonyl, however, contains a main peak at 305 mμ and a somewhat lower maximum in the 270 mμ region (Fig. 3b) and is thus very similar to that produced during ethanolysis (Fig. 3). The absorptivity change at 305 mμ is therefore almost certainly due to the formation of an α-carbonyl group during ethanolysis.

Furthermore, when the change in absorptivity at 305 mμ (ΔA_{305}) is plotted as a function of change in phenolic content, a single linear correlation between the two changes is found for the products from both SI and SIII (Fig. 4). This appears to be strong evidence that a phenolic hydroxyl and an α-carbonyl group are produced in the same reaction.

It can be shown by the following reasoning that these two functional groups must also be produced in nearly equivalent amounts rather than in some non-stoichiometric ratio. The maxima of curves 3 and 4 (Fig. 3b) at 305 mμ are 8.7×10^3 and 7.8×10^3 l. mole^{-1}cm.$^{-1}$, respectively. The average of these two values, 8.3×10^3, gives the approximate change in absorptivity at 305 mμ, caused by the introduction of one mole of α-carbonyl in a guaiacylpropane derivative. On the other hand, the liberation of one mole of phenolic group in the ethanolysis of lignin corresponds to a change in absorptivity of 9.17×10^3 l. (mole CH_3O)$^{-1}$cm.$^{-1}$ (Fig. 4). By comparing this figure with the average value given above, it can be concluded that for every liberated phenolic hydroxyl group approximately 1.1 α-carbonyl groups are formed. The 10% variation between these numbers is well within the range of uncertainty introduced by ignoring those functional groups in the model substances which contribute less to ultraviolet absorption.

The formation of an α-carbonyl very largely explains the ultraviolet spectral changes during re-ethanolysis, but the rate of formation of the 255 mμ peak differs somewhat from that at 305 mμ. Furthermore, the 255 mμ peak continues to grow as long as ethanolysis continues while the change at 305 mμ is very slight in those later periods of ethanolysis during which there is little or no phenolic liberation. The 255 mμ peak must therefore be formed in part by another unexplained reaction.

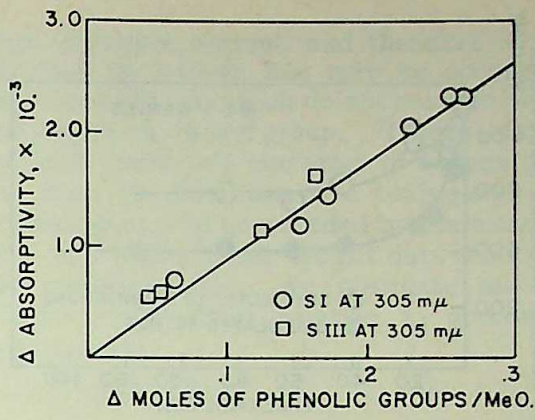


Fig. 4.—The relationship between the change in absorptivity at 305 mμ and the change in phenolic hydroxyl content in the re-ethanolysis of samples SI and SIII.

Decrease in Oxygen Content of Lignin.—The molecular formulas given in Table I show that quantitatively the most important reaction occurring during re-ethanolysis is one which results in a loss of oxygen. Sample SI over a period of 116 hr. loses about 0.6 atom of oxygen per guaiacylpropane unit and SIII loses about 0.3 oxygen atom. For comparison the total number of phenolic hydroxyl groups formed are 0.28 and 0.16 per guaiacylpropane unit. This reaction may be partially related to the increase in absorptivity at 255 mμ, but it is not possible to make any linear correlation such as was possible with phenolic hydroxyl liberation and change in absorptivity at 305 mμ.

Change in Molecular Weight (With Sonja K. Gross).—In the past, repolymerization reactions have been postulated to occur during lignin ethanolysis.[14] However, under our conditions of high dilution in a good solvent system, the number average molecular weight at first decreased and then, like the phenolic hydroxyl content, remained constant (Fig. 5). It seemed possible, therefore, that the fission of phenolic ether linkages might be the only reaction altering the lignin molecular weight.

Now in linear or branched polymers, it is obvious that a cleavage reaction will be accompanied by a decrease in number average molecular weight corresponding to the formation of two molecules from one. This relationship can be expressed by the equation

$$M_n = \frac{G_o \bar{M}_{no}}{G(1 + \Delta F_s \bar{M}_{no})} \qquad \text{(III)}$$

where G represents the content of some stable functional group (in the case of lignin, methoxyl expressed as per cent.), and ΔF_s is the *increase* in the number of moles of *product* functional group per gram (in the case of lignin ethanolysis, phenolic hydroxyls).

If during a cleavage reaction the molecular weight decreases less than this equation predicts, the molecular structure cannot be linear but must contain cycles of some size which are opened by the reaction, or side reactions must be occurring.

Theoretical number average molecular weights

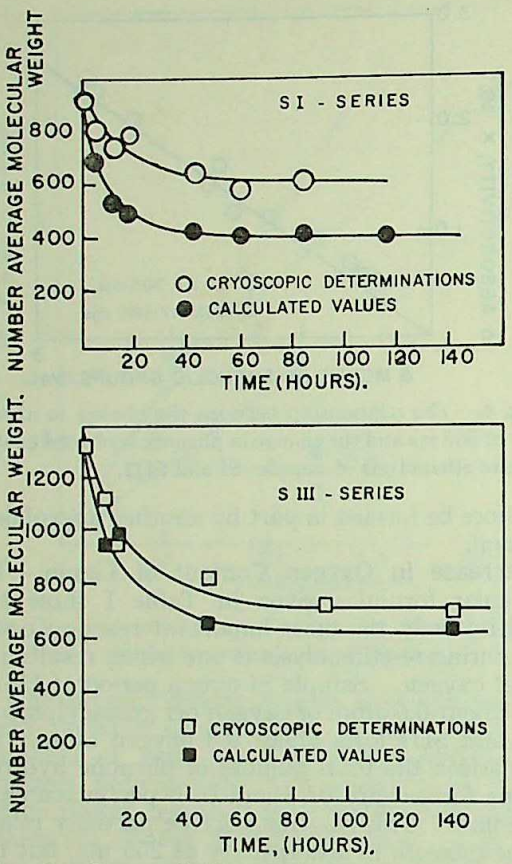

Fig. 5.—Cryoscopically determined number-average molecular weights compared with a hypothetical curve calculated from the change in phenolic group content.

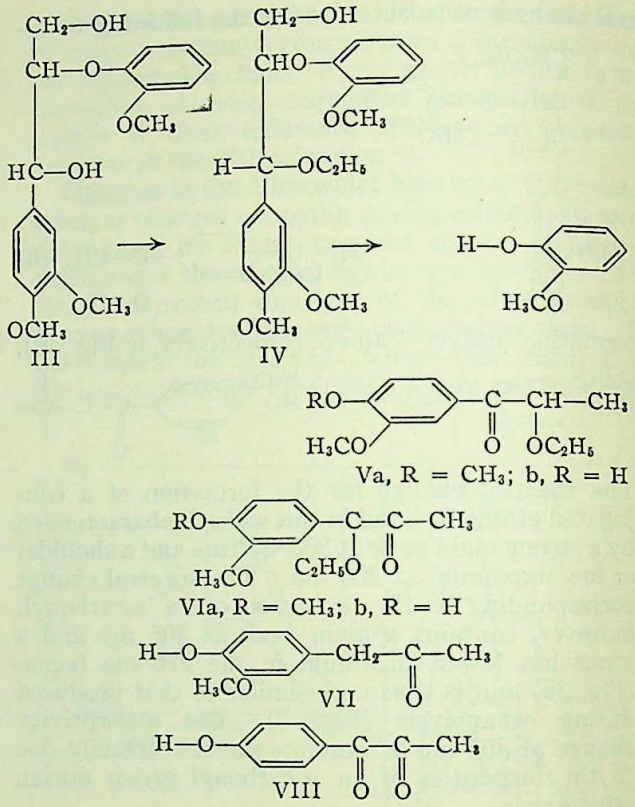
experimental molecular weights of the starting materials SI and SIII and from the corresponding increase in phenolic content using the above equation and thus assuming that each liberation of a phenolic group resulted in the formation of two molecules from one. The calculated values were consistently lower than the experimental values (Fig. 5) although the changes followed each other closely. There may therefore be some cyclic structures initially present or new bonds formed during degradation. In any case, this method of gaining evidence of cyclic structures in lignin should be applied further as our knowledge of lignin reactions develops and molecular weight determinations of lignin are improved.

Discussion

The behavior of ethanol–spruce lignins on re-ethanolysis is rather closely analogous to that of guaiacylglycerol-β-aryl ethers. Compounds of this general structure have been proposed as the structural elements of lignin responsible for the formation of the ethanolysis monomers,[5-8] and they now appear to be satisfactory models for at least two of the reactions occurring on the amorphous portion of lignin.

Veratrylglycerol-β-guaiacyl ether (III) reacts with ethanolic hydrogen chloride first to form an ethyl ether, presumably IV, and later to form small amounts of guaiacol and the two phenylpropane derivatives V_a and VI_a and an amorphous product containing carbonyl groups.[6]



Veratrylglycerol reacts similarly.[8] From the ethanolysis products of guaiacylglycerol (Vb, R = H), VII and VIII have been isolated and probably VIb also is formed.[8] The careful work of Gardner[26] shows that ethanolysis of oxyconiferyl alcohol, a compound which may well exist as a reaction intermediate from guaiacylglycerol, produces all four lignin ethanolysis monomers V_b, VI_b, VII and VIII. Furthermore, the two compounds (Vb and VIII) with α-carbonyl groups amount to 83% of the monomeric products of ethanolysis.

This research shows that lignin re-ethanolysis gives results similar in many respects to the above. The ethoxyl content of lignin rises sharply during the initial phase of the ethanolysis (compare references 22 and 23). The ethoxylation of lignin is accompanied by a slower reaction in which a phenolic hydroxyl and an α-carbonyl group are formed in nearly equimolar proportions. The ethoxyl content of the lignin decreases slightly during re-ethanolysis as might be expected if a conversion like that giving rise to VII and VIII were occurring.

It is reasonable to assume that the same reactions here shown to be occurring on about one-fifth of the units in SI, SII and SIII on re-ethanolysis must have occurred throughout the extraction process as well, that a very substantial fraction of the phenolic groups liberated must have been liberated by the same reaction and that the liberation of monomers by ethanolysis followed a similar course. The best present model for these reactions of ethoxylation and cleavage seems to be the guaiacylglycerol-β-aryl ether system.

The fact that the liberation of phenolic groups was not kinetically homogeneous does not necessarily mean that the reacting structures were origi-

nally different, for a change in the side chain structure of a monomer unit could affect the rate of liberation of its phenolic group.

While it has been implied that the amorphous ethanol lignins are analogous to the reversion products produced on ethanolysis of III,[6] our results indicate that they are nearer to being incompletely reacted fragments of the original lignin since we obtained no direct evidence of an increase in molecular weight during ethanolysis.

There is, however, an unexplained loss of oxygen (0.6 atom per C_9 unit in SI) in the re-ethanolysis. The proposed cleavage of IV produces no over-all change in oxygen content, and therefore it seems likely that the oxygen loss may be occurring in those monomer units which do not react to produce a free phenolic hydroxyl group. If this is the case, these units lose nearly one atom of oxygen per C_9 unit. Since the formation of a conjugated ethylenic bond appears to be excluded by the ultraviolet spectra and the molecular weight data seem to exclude repolymerization, we postulate an intramolecular condensation reaction to account for this oxygen loss.

The Constitution of Corn Starch Dextrin[1]

BY J. D. GEERDES, BERTHA A. LEWIS AND F. SMITH

RECEIVED JANUARY 16, 1957

Commercial corn starch dextrins have been fractionated and subjected to periodate oxidation studies and one of them has been examined by methylation. Periodate oxidation shows that the amount of glucose stable to oxidation is higher (5%) in the dextrin than in the parent starch. The hydrolyzate of the methylated dextrin has been shown to contain: 2,3,4,6-tetra-*O*- (16.5%); 2,3,6-tri-*O*- (57.3%), 2,3,4-tri-*O*- (2.6%), 2,4,6-tri-*O*- (1.2%), 2,3-di-*O*- (6.3%), 2,6-di-*O*-(10.0%), 3,6-di-*O*- (3.2%), 2-*O*- (1.5%), 3-*O*- (0.8%) and 6-*O*-methyl-D-glucose (0.5%). From the periodate and methylation data it is deduced that dextrinization is accompanied by considerable transglycosidation and the development of a highly branched structure.

In spite of the industrial importance of starch dextrins, prepared from native starches by roasting usually in the presence of acidic reagents, little is known about the detailed structural changes that the starch undergoes during the dextrinization process. In the early work[2,3] it was suggested that dextrins are formed by cleavage of the starch chains with concomitant anhydro-ring formation to give smaller molecules terminated by non-reducing units of the levo-glucosan type. Dextrinization of amylose and amylopectin also has been investigated by adsorption chromatography[4] whereby it was shown that amylopectin undergoes dextrinization more readily than amylose.[4,5] Methylation studies[5] enabled the deduction to be made that the dextrinization process caused breakdown of the starch molecules to smaller fragments which were much more highly branched than the original starch. This was recognized from the increased percentage of 2,3,4,6-tetra-*O*-methyl-D-glucose obtained from the methylated dextrin as compared with the yield from the methylated derivative of the parent starch.

This paper deals with periodate oxidation studies on a number of acid converted corn starch dextrins and methylation studies on one of them.

Four commercial corn starch dextrins were fractionated from aqueous solution with ethanol and the various fractions (see Table II) were examined by a procedure[6] involving periodate oxidation, reduction and hydrolysis. This procedure not only provides the usual information on the periodate consumption and formic acid production, but it also determines the percentage of glucose residues in the dextrin that are immune to periodate cleavage. Since the native starches contain less than 1% of glucose residues that are immune to periodate oxidation, it was tentatively concluded that the relatively high percentage of glucose residues in the dextrin that survived periodate oxidation was an indication of the structural rearrangements that occur during the dextrinization process.

On the basis of these periodate oxidation studies (see Tables I and II), the dextrin fraction chosen for further investigation by the methylation technique was one which was found[6] to contain the largest percentage of glucose units that were immune to periodate oxidation.

none:water azeotrope as the solvent,[8] is given in Table III (see later). The identity of these components was established by preparing suitable crystalline derivatives.

Since the commercial dextrin was produced from native starch, which contains amylopectin and amylose, a detailed structural discussion is not warranted. However, it is possible to make certain deductions concerning the structural changes that occur during the dextrinization process by an inspection of the nature and amounts of the components of the hydrolyzate of the methylated dextrin (see Table III).

Of the ten components in Table III only 1, 2 and 5 are obtained in quantity from methylated amylopectin and only components 1 and 2 from methylated amylose. The characterization of the other seven components, 3, 4 and 6–10, derived from the methylated dextrin coupled with the isolation of a relatively high percentage of component 1 (2,3,4,6-tetra-*O*-methyl-D-glucose), indicates that the dextrin has a much more complicated structure than either the amylose or the amylopectin of the parent corn starch.

The highly branched character of the dextrin molecule is shown by the complexity of the mixture of the di-*O*- and mono-*O*-methyl derivatives of glucose (Table III) and also by the fact that one out of every 6 glucose units occupies a terminal non-reducing position as revealed by the yield of 2,3,4,-6-tetra-*O*-methyl-D-glucose. This last finding is in agreement with that derived from a previous methylation study of a dextrin.[5] Support for this highly branched structure for the dextrin as revealed by the methylation studies is also provided by the results of the periodate oxidation studies which showed that 1.14 moles of periodate were consumed per anhydroglucose unit with the concomitant formation of 1 mole of formic acid for every 4.5 moles of anhydroglucose.

The identification of the 2,4,6-tri-*O*-, 2,6- and 3,6-di-*O*- and the 2-, 3- and 6-*O*-methyl-D-glucose also agrees with the observation that the dextrin contains a considerable number of glucose units that are stable to periodate oxidation.

While it is conceivable that certain of the partially methylated glucose derivatives obtained in small yield may have arisen as a result of incomplete methylation or demethylation during hydrolysis, it is not believed that this is the explanation for the isolation of the relatively large amount (10%) of 2,6-di-*O*-methyl-D-glucose. On the contrary, it is believed that the identification of the latter proves that the dextrinization process not only involves a shortening of the chains as shown by periodate oxidation and methylation studies and a decrease in molecular weight as revealed by viscosity studies, but also by a considerable amount of transglycosidation. This phenomenon which is probably one of the chief characteristics of the dextrinization process is most likely responsible for the formation of new glycosidic linkages and development of the highly branched structure as revealed by the identification of components 6–10 as well as components 3 and 4. This deduction is supported by the observation that starch dextrins are stable to β-amylase.[5] Although the possibility of anhydro-ring formation has been suggested,[2,3] a careful search of all the components of the hydrolyzate of the methylated dextrin failed to produce any supporting evidence for this hypothesis; no methyl derivatives of 3,6-anhydro-D-glucose were isolated and moreover there was no evidence for sugars other than D-glucose that might arise from ethylene oxide type sugar units.

Since transglycosidation is the characteristic reaction of "high conversion" dextrins, it would appear that the progress and control of dextrinization could be ascertained by determining the increase in the number of glucose residues in the dextrin that are resistant to periodate oxidation. It is also apparent that, inasmuch as dextrinization is accompanied by transglycosidation, it should be possible to bring about the synthesis of new carbohydrate polymers by a process of co-dextrinization (co-polymerization) with other substances such as sugars, oligosaccharides, polyhydric alcohols and also with other polysaccharides.

Experimental

Isolation of Dextrin Fractions.—The various "acid converted dextrins" (hereinafter called dextrins) were each extracted with 4 parts of water at room temperature and the solution centrifuged. To the supernatant liquid an equal volume of ethanol was added slowly with stirring to give one fraction, and after this had been removed (centrifuge) another volume of ethanol equal to the first was added to give a second fraction. Each fraction was redissolved in water and precipitated by pouring with stirring into about 4 volumes of ethanol. The white amorphous precipitates so obtained were washed successively with ethanol, ether, light petroleum ether and dried *in vacuo*. The two dextrin fractions so obtained were slightly reducing to Fehling solution while the product remaining dissolved in the aqueous ethanolic mother liquor from the initial precipitation was strongly reducing, doubtless due to the presence of glucose and oligosaccharides.

Acetylation and Fractionation of Dextrin.—The fraction (35 g.) of Dextrin #724, precipitated with two volumes of ethanol, was dissolved in formamide (250 ml.) with stirring at room temperature and acetylated by adding pyridine (250 ml.) followed by acetic anhydride (200 ml.), the latter

(8) L. Boggs, L. S. Cuendet, I. Ehrenthal, R. Koch and F. Smith, *Nature*, **166**, 520 (1950).

Digitized by Arya Samaj Foundation Chennai and eGangotri

being added over a 1-hr. period.[9] After standing at room temperature for 3 hr., the solution was poured into water (3 l.) with stirring. The precipitated acetate was filtered and washed with water. Further purification of the acetate was effected by dissolving it in chloroform, drying this solution with anhydrous magnesium sulfate, and reprecipitating the product by pouring the chloroform solution into light petroleum ether. The dry purified dextrin acetate was dissolved in chloroform (175 ml.) and fractionally precipitated in the usual way by adding increasing amounts of diethyl ether. Each fraction was separated, washed with petroleum ether and dried *in vacuo*. Examination of the 8 fractions so obtained showed that fractions 1–5 amounting to 7.1, 14.0, 11.3, 6.0 and 3.6 g., respectively, showed $[\alpha]^{25}D$ +140° (approx.) in chloroform (*c* 1), while fractions 6–8, amounting to 3.1, 1.3 and 1.9 g., respectively, showed $[\alpha]^{25}D$ +132° (approx.) in chloroform (*c* 1). Reacetylation of the second fraction caused no change in rotation (Found: OAc, 43.5).

Periodate Oxidation of Dextrin.—A portion (12.0 g.) of the dextrin acetate (composite of fractions 1–5) was deacetylated by treatment with a mixture of acetone (100 ml.) and *N* sodium hydroxide (150 ml.) for 1 hr. at 50°. The acetone was then removed under reduced pressure leaving an aqueous alkaline solution of the dextrin. The solution was neutralized with acetic acid and the dextrin precipitated by pouring the solution slowly with stirring into ethanol (4 volumes). The polysaccharide was dried as described above to give a fine white amorphous powder.

The dextrin (0.5000 g.) was dissolved in 0.1 *N* sodium periodate (500 ml.) and the oxidation allowed to proceed at 5° in the dark; at suitable intervals an aliquot (5 ml.) of the reaction mixture was withdrawn and added to 0.1 *N* As_2O_3 (5 ml.), sodium bicarbonate (2 g. approx.) and a crystal of potassium iodide. After standing for 0.5 hr. the excess arsenite was titrated with standard iodine solution in the usual way.[10] The periodate consumption was determined after correcting for a blank carried out under identical conditions.

An additional aliquot (20 ml.) was withdrawn and added to a solution containing 50% ethylene glycol (2 ml.) to destroy the excess of the periodate present and the formic acid was titrated with 0.01 *N* sodium hydroxide using methyl red as the indicator. A blank was carried out at the same time. The results are recorded in Table I.

Similar oxidations were carried out on other dextrin fractions with results given in Table II, the procedure being the same except that a 3-g. sample was oxidized in 2 liters of 0.05 *N* sodium periodate.

Determination of Anhydroglucose Units Not Oxidized by Periodate.—Following the periodate oxidation of the dextrin fractions, the number of anhydroglucose units not oxidized was determined by quantitative paper chromatography as previously described.[11] The results are recorded in Table II.

Methylation of Starch Dextrin.—The fraction of the "acid converted dextrin" No. 9533, precipitated from aqueous solution with 2 volumes of ethanol, was chosen for the methylation study since the periodate oxidation procedure showed that this was most highly branched and contained more periodate-stable glucose residues than the other dextrins examined (see Table II).

The dextrin (20 g.) was acetylated[9] as described above and freed from impurity by dissolution in acetone and precipitation with water (yield 26 g.). The acetate (20 g.) was dissolved in acetone and methylated with methyl sulfate (100 ml.) and 30% (w./w.) aqueous sodium hydroxide during 2 hr. in the usual way. The temperature was kept below 25° until the reaction mixture no longer reduced Fehling solution after which it was raised to 55°. The methylated product readily separated upon completion of the reaction. Seven further methylations were applied in the same manner at 55°, acetone being used as the solvent medium. The product from the final methylation was dissolved in chloroform and washed with water to remove inorganic impurities. After drying ($CaCl_2$) the chloroform solution was freed from solvent and the residual methylated dextrin further purified by extraction with diethyl ether followed by precipitation from ethereal solution with petroleum ether (b.p. 30–60°). Filtration and drying yielded the methylated dextrin as a white powder (yield 12 g. (approx.)). The material, which left no ash upon ignition, showed $[\alpha]^{25}D$ +173° (*c* 1.3) in chloroform, OMe, 43.0%; a sample examined after seven methylations had the same properties.

Fractional Precipitation of the Methylated Dextrin.—The methylated dextrin obtained above was dissolved in ether and subjected to fractional precipitation with light petroleum ether in the usual way. Examination of the 6 fractions so produced showed that the methylated dextrin was essentially homogeneous, the rotation ranging from $[\alpha]^{25}D$ +173 to +166° in chloroform (*c* 1) and the OMe from 43.2 to 42.8%.

Hydrolysis of the Methylated Starch Dextrin.—A composite sample (5.0 g., $[\alpha]^{25}D$ +173° in chloroform (*c* 1), OMe, 43.0) of the first 5 fractions of the methylated dextrin was dissolved in methanol (150 ml.) containing 2% hydrogen chloride and the solution refluxed until the rotation was constant, $[\alpha]^{26}D$ +169° (initial), +72° (7 hr.), +72° (12.5 hr.) (constant value). The solution was neutralized with ethereal diazomethane and evaporated *in vacuo* to a sirupy mixture of methyl glycosides (5.8 g.).

A solution of the mixture of glycosides in *N* sulfuric acid (110 ml.) was heated on a boiling water-bath until the rotation was constant, $[\alpha]D$ +74° (initial), +88° (constant value after 9 hr.). The solution was neutralized ($BaCO_3$), filtered and evaporated to a sirup. The sirup was dissolved in water and the solution, after treatment with a little charcoal, filtered and passed successively through a cation (Amberlite IR 120) and an anion (Duolite A4) exchange resin. Concentration of the effluent *in vacuo* gave a clear colorless sirup (yield 5.26 g.).

Separation of Component Sugars by Column Chromatography.—A portion (1.77 g.) of the sugar mixture from the hydrolysis above was separated into its component sugars by column chromatography using cellulose–hydrocellulose[7] and butanone:water azeotrope as the solvent.[8,12] The eluate from the column was collected in tubes automatically changed every 10 minutes for the faster moving components (1 to 4) and every 30 minutes for the rest. The location of sugars in the various tubes was determined by spotting a small amount of eluate from each tube on filter paper and spraying with *p*-anisidine–trichloroacetic acid reagent.[13] The eluates from any tubes which appeared to be free of sugars by this color test were first evaporated to dryness before discarding to check for possible non-reducing sugars. Fractions that showed overlapping were resolved by paper chromatography. The yields of the various methylated sugars obtained by this separation are recorded in Table III.

TABLE III

COLUMN CHROMATOGRAPHY OF THE HYDROLYZATE OF METHYLATED DEXTRIN

Component	Methyl derivative of D-glucose	Yield		
		Wt., g.	%	Mole ratio

and $[\alpha]_D$ +92° → +84° in water. *Anal.* Calcd. for $C_{10}H_{20}O_6$: OMe, 52.5. Found: OMe, 52.7.

(b) 2,3,6-Tri-*O*-methyl-D-glucose.—The sirupy component 2 (Table III, 0.979 g.) crystallized when nucleated with 2,3,6-tri-*O*-methyl-D-glucose and had m.p. 117–118° undepressed when mixed with an authentic specimen after recrystallization from ethyl ether, $[\alpha]^{24}D$ +92° → +68.7° in water (*c* 1.1); lit.[16–18] m.p. 122–123° and $[\alpha]_D$ +90.2° → +70.5° in water.

(c) 2,3,4-Tri-*O*-methyl-D-glucose.—The sirupy component 3 (Table III, 0.045 g.) had $[\alpha]^{24}D$ +61° in methanol (*c* 0.7) and was chromatographically identical with 2,3,4-tri-*O*-methyl-D-glucose when developed either with butanone:water azeotrope or with benzene:ethanol:water:ammonium hydroxide (200:47:14:1). Treatment of component 3 with aniline in ethanol yielded the crystalline anilide of 2,3,4-tri-*O*-methyl-D-glucose, $[\alpha]^{23}D$ −103° in ethanol (*c* 0.4), and m.p. 150°, undepressed by admixture with an authentic specimen; lit.[19] m.p. 145–146°.

(d) 2,4,6-Tri-*O*-methyl-D-glucose.—The sirupy product (0.065 g.) recovered from the mother liquors of the 2,3,6-tri-*O*-methyl-D-glucose was allowed to react with 0.5% methanolic hydrogen chloride (10 ml.) at room temperature for 20 hr. until the rotation became constant (final value, $[\alpha]^{23}D$ +20°). Neutralization (Ag_2CO_3), filtration and concentration gave a sirupy product which was resolved by paper chromatography using butanone:water azeotrope into two components. The faster moving component consisted of methyl 2,3,6-tri-*O*-methyl-D-glucofuranoside while the slower component (0.020 g.) proved to be 2,4,6-tri-*O*-methyl-D-glucose, $[\alpha]^{24}D$ +64° in methanol (*c* 0.3). Treatment of this slower moving tri-*O*-methyl-D-glucose with ethanolic aniline in the usual way afforded N-phenyl-D-glucopyranosylamine 2,4,6-tri-*O*-methyl ether, m.p. and mixed m.p. 156–158°, lit.[20] m.p. 162–166°.

(e) 2,3-Di-*O*-methyl-D-glucose.—Component 5 (Table III, 0.101 g.) yielded crystalline 2,3-di-*O*-methyl-D-glucose when nucleated with an authentic specimen. After recrystallization from ethyl acetate it had m.p. and mixed m.p. 117–119°, $[\alpha]^{26}D$ +51.3° in acetone (*c* 0.8); lit.[21] m.p. 110°, $[\alpha]_D$ +50.9° in acetone. Treatment of the 2,3-di-*O*-methyl-D-glucose with aniline in ethanol yielded the crystalline anilide of 2,3-di-*O*-methyl-D-glucose, m.p. 133–135°; lit.[22] m.p. 134°.

(f) 2,6-Di-*O*-methyl-D-glucose.—The sirupy component 6 (Table III, 0.160 g.) which had $[\alpha]^{23}D$ +65.5° in water (*c* 1.2)[23] was chromatographically identical with 2,6-di-*O*-methyl-D-glucose; lit.[22] $[\alpha]_D$ +63.3° in water. Treatment of the sirup with *p*-phenylazobenzoyl chloride in pyridine gave 2,6-di-*O*-methyl-D-glucose 1,3,4-tri-azobenzoate, m.p. 206–208°, $[\alpha]^{25}D$ −341° (*c* 0.4 in chloroform), after recrystallization from ethyl acetate–light petroleum ether. The mixed melting point with an authentic specimen (m.p. 200°, $[\alpha]^{25}D$ −329° in chloroform) was 205°; lit.[24] m.p. 205–207°.

(g) 3,6-Di-*O*-methyl-D-glucose.—Component 7 (Table III, 0.052 g.) was chromatographically identical with 3,6-di-*O*-methyl-D-glucose. When a portion (0.017 g.) of it was treated with methanolic hydrogen chloride (0.5%) at 20°, the rotation changed from $[\alpha]_D$ +75° to +22° in 2 hr. indicating furanoside formation and hence the presence of a free hydroxyl group at C_4 in the di-*O*-methyl-D-glucose. Component 7 crystallized completely when nucleated with an authentic specimen[25] of 3,6-di-*O*-methyl-D-glucose. After recrystallization from ethyl acetate, 3,6-di-*O*-methyl-α-D-glucose was obtained, m.p. 118–119°, $[\alpha]^{24}D$ +60° in water (*c* 0.6). Admixture with an authentic specimen (m.p. 111–112°)[25] gave m.p. 111–112°; lit.[26] m.p. 114–115°, $[\alpha]^{18}D$ +61.5° in water.

(h) 2-*O*-Methyl-D-glucose.—Component 8 (Table III, 0.022 g.) which crystallized spontaneously was chromatographically identical with 2-*O*-methyl-D-glucose. After recrystallization from ethanol the 2-*O*-methyl-β-D-glucose had m.p. and mixed m.p. 156–158°, $[\alpha]^{23}D$ +63° (equilibrium value) in water (*c* 0.8); lit.[27] m.p. 157–159° and $[\alpha]_D$ +66° (equilibrium value) in water.

(i) 3-*O*-Methyl-D-glucose.—Component 9 (Table III, 0.012 g.) which was chromatographically identical with 3-*O*-methyl-D-glucose, crystallized spontaneously as the β-anomer, m.p. and mixed m.p. 135°, $[\alpha]^{24}D$ +58° (equilibrium value) in water (*c* 0.4); lit.[28,29] m.p. 133.5–135° and $[\alpha]_D$ +55° (equilibrium value) in water.

(j) 6-*O*-Methyl-D-glucose.—Component 10 (Table III, 0.007 g.), which showed the same R_f and color on paper chromatograms when sprayed with *p*-anisidine–trichloroacetic acid as 6-*O*-methyl-D-glucose, crystallized when nucleated with the authentic specimen. The crystalline 6-*O*-methyl-α-D-glucose had m.p. and mixed m.p. 143–144° and $[\alpha]^{26}D$ +54° (equilibrium value) in ethanol (*c* 1.2); lit.[30,31] m.p. 143–145° and $[\alpha]_D$ +60° (equilibrium value) in water. The osazone prepared in the usual way had m.p. and mixed m.p. 175–180°.

Degradation of Glycogen to Isomaltotriose[1] and Nigerose

BY M. L. WOLFROM AND A. THOMPSON[2]

RECEIVED MARCH 11, 1957

Isomaltotriose and nigerose were found among the oligosaccharides in the acid hydrolyzate of beef liver glycogen, indicating that some of the α-D-(1 → 6) linkages in this molecule lie in adjacent positions and that a small amount of α-D-(1 → 3) linkages are present. Crystalline panose is shown to be dimorphous.

There are five predictable trisaccharides bound by α-D-glucopyranosyl-(1 → 4) or (1 → 6) linkages or combinations thereof. Three of these entities, *O*-α-D-glucopyranosyl-(1 → 6)-*O*-α-D-glucopyranosyl-(1 → 4)-D-glucopyranose (panose),[3–5] *O*-α-

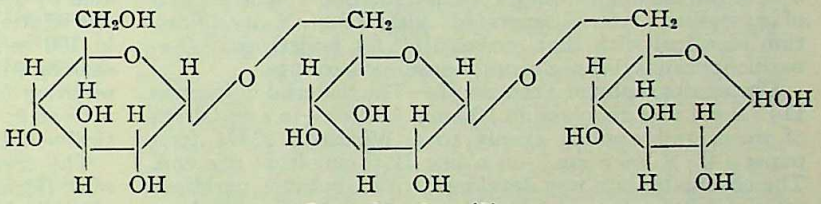
D-glucopyranosyl-(1 → 4)-*O*-α-D-glucopyranosyl-(1 → 4)-D-glucopyranose (maltotriose)[6-8] and *O*-α-D-glucopyranosyl-(1 → 6)-*O*-α-D-glucopyranosyl-(1 → 6)-D-glucopyranose (isomaltotriose, I)[9,10] have been isolated from natural sources and characterized on a crystalline basis. The remaining two trisaccharides, *O*-α-D-glucopyranosyl-(1 → 4)-*O*-α-D-glucopyranosyl-(1 → 6)-D-glucopyranose and *O*-α-D-glucopyranosyl-(1 → 4)-*O*-[α-D-glucopyranosyl-(1 → 6)]-D-glucose have not been described. All of these substances are of value as reference materials in the identification of polysaccharide linkages by fragmentation analytical methods. Maltose, isomaltose,[11] maltotriose[11] and panose[12] have been described as hydrolytic products of glycogens. We report herein that isomaltotriose and nigerose (3-*O*-α-D-glucopyranosyl-D-glucose) are likewise constituents of the glycogen molecule. Nigerose has been established as a constituent of amylopectin (waxy maize starch)[13] where it is encountered in larger amount than in glycogen. The hydrolytic conditions employed in our work were designed to reduce the formation of the isolated materials by reversion[14] to a negligible amount.

The sugars were isolated from the hydrolyzate of beef liver glycogen by a combination of carbon column chromatography, essentially as described by Whistler and Durso,[15] paper and silicate[16] column chromatography, and paper electrophoresis.[17,18]

The material (amorphous), which was identified as isomaltotriose, was chromatographically homogeneous, moving on paper at a rate slightly slower than panose but on paper electrophoresis moving at a rate much greater. A similar fast moving spot had been noted[12] in a yeast glycogen hydrolyzate but was not further investigated. The isomaltotriose displayed $[\alpha]_D$ +141°, which is in agreement with the reported value of +145°. The substance was further identified by molecular weight determination (on the dodecaacetate of its alditol) and by fragmentation analysis of the free sugar and its alditol. Paper chromatography and paper electrophoresis of a partial acid hydrolyzate of the alditol indicated the presence of only D-glucose, isomaltose, and unchanged material. Silicate chromatography of an acetylated partial hydrolyzate of the alditol (reduced trisaccharide) produced β-D-glucopyranose pentaacetate, D-glucitol (sorbitol) hexaacetate, β-isomaltose octaacetate and isomaltitol nonaacetate. These substances, which were fully identified by melting point and X-ray powder diffraction patterns, characterize the parent trisaccharide as isomaltotriose (I). The presence of this trisaccharide in a hydrolyzate of glycogen indicates that some of the α-D-(1 → 6) linkages occur in adjacent positions in the glycogen molecule.

In the course of this work, maltose, isomaltose, maltotriose and panose were again encountered and crystalline panose was shown to be dimorphous.



Isomaltotriose (I)

Experimental

Hydrolysis of Glycogen.—The glycogen used in this work was beef liver glycogen, $[\alpha]_D$ +198° (*c* 4, water). This material (92 g., dry basis) was hydrolyzed, in three portions, at a concentration of 0.4% in 0.1 *N* hydrochloric acid, by heating in a boiling water-bath. The hydrolysis was followed quantitatively by copper reduction and was stopped after 5.8 hr. at approximately 69% of completion. The hydrochloric acid was removed from the combined hydrolyzate by passage through a column of Duolite A4.[19]

Fractionation of the Glycogen Hydrolyzate on Carbon.—The sugars in the hydrolyzates were subjected to a preliminary separation on a carbon (Nuchar C unground[20]; no filter-aid added) column (800 × 65 mm., diam.) essentially according to the procedure of Whistler and Durso.[15] To prevent the accumulation of a large amount of D-glucose on the carbon, the neutralized hydrolyzate was placed on the same column in three portions, washing with water, after each addition, until the effluent exhibited a negative Benedict test. The water effluent, normally containing only D-glucose, was discarded. The developing solvent for the column was then changed to 5% ethanol and the addition continued (about 20 liters) until the effluent again showed a negative reaction toward Benedict solution. This effluent was evaporated to a sirup under reduced pressure; yield 15 g. (fraction I). The developer was changed to 10% ethanol and the washing continued until the effluent exhibited a negative reaction toward Benedict solution. Solvent was removed under reduced pressure; yield 7.2 g. of a sirup (fraction II).

Chromatography of Fraction I; Maltose, Isomaltose and Nigerose.—The sirupy fraction I (15 g.) was acetylated by heating to the boiling point with 100 ml. of acetic anhydride and 7 g. of anhydrous sodium acetate. The solution was then cooled and poured onto 300 ml. of ice and water. After the excess acetic anhydride was hydrolyzed, the solution was extracted with chloroform and the water-washed and dried extract was evaporated under reduced pressure; yield 25 g. of a sirup. The product was dissolved in ethanol and allowed to crystallize; yield 5.2 g.; after recrystallization from ethanol, m.p. 155–157° unchanged on admixture with known β-maltose octaacetate, $[\alpha]^{20}_D$ +62.7° (*c* 4, chloroform). The mother liquor was concentrated to a sirup; yield approx. 20 g.

The above sirup was dissolved in 200 ml. of benzene and chromatographed in four portions on Magnesol[16]–Celite[16] (5:1) columns (270 × 75 mm., diam.) using 4000 ml. of

Digitized by Arya Samaj Foundation Chennai and eGangotri

benzene–*t*-butyl alcohol (100:1 by vol.) as developer. The column was extruded and streaked with indicator (1% potassium permanganate in 10% aqueous sodium hydroxide). A zone appearing 145 to 215 mm. from the column top was excised and eluted with acetone. Upon evaporation of the combined acetone solutions from the four columns, a sirup was obtained which was crystallized from ethanol; yield 4.6 g., m.p. 145–146° unchanged upon admixture with an authentic sample of β-isomaltose octaacetate, $[\alpha]^{20}D$ +96° (*c* 4, chloroform). These constants are in agreement with those of β-isomaltose octaacetate.[21]

The material in a zone appearing at 90 to 125 mm. from the column top was eluted with acetone. After evaporation, the resulting sirup (2.95 g.) was rechromatographed, in the same manner, on a Magnesol[16]–Celite[16] (5:1) column (270 × 75 mm., diam.) with 4000 ml. of benzene–*t*-butyl alcohol (100:1 by vol.) as developer. The material obtained on solvent removal from the acetone eluate of a zone appearing 90 to 125 mm. from the column top yielded a small amount of a gel from ethanol. The gel was isolated by decantation and from its ethanol solution a small amount of crystalline material separated; yield 2 mg., X-ray diffraction identical with that recorded[13,14] for β-nigerose (3-*O*-α-D-glucopyranosyl-β-D-glucopyranose) octaacetate.

Chromatography of Fraction II.—The material in fraction II (7.2 g.) was dissolved in 100-mg. portions, in a few drops of water and applied evenly to a Whatman 3MM filter paper (47 × 56.5 cm.) on a line 12.5 cm. from one end. The chromatogram was developed with 1-butanol–pyridine–water (3:2:1.5 by vol.) for 40 hr. A pilot strip, cut from the edge of the paper, was sprayed with aniline phthalate (1.66 g. of phthalic acid, 0.93 g. of aniline in 100 ml. of 1-butanol saturated with water) and heated for a few minutes in an oven at 105° to indicate the positions of the zones on the paper. Two main zones, A and B, appeared with several smaller zones. These two main zones, which moved at rates approximating those of maltotriose and panose as determined by comparison with the known sugars, were cut out of the papers. A total of 72 papers were prepared in this manner and the respective zones were combined. The sugars were recovered by pulping the paper in water, filtering and washing with water. The combined filtrates and washings were evaporated under reduced pressure to sirups; yield 2.95 g. from zone A and 1.58 g. from zone B.

Panose and its Dimorphism.—The slower moving zone A material above (2.95 g.) crystallized from methanol on being maintained at 60° overnight; yield 1.2 g. Pure material (form 2) was obtained on recrystallization from methanol; yield 1.05 g., m.p. 220–221° dec., unchanged on admixture with an authentic specimen of panose (form 1) received from Dr. S. C. Pan (m.p. 220°), $[\alpha]^{25}D$ +160.4 → 150.6° (140 min., *c* 3.8, water); X-ray powder diffraction data of our isolated crystals (form 2): 6.88[22] vw,[23] 5.96w 5.38m, 5.11w, 4.84vs, 4.25m, 4.03vw, 3.90vw, 3.81w, 3.58w, 3.29w, 3.19w, 3.01m, 2.76vw, 2.71vw, 2.60 vw. These data are identical with those obtained on a sample of panose isolated from potato starch and submitted to us by Dr W. J. Whelan.

Anal. Calcd. for $C_{18}H_{32}O_{16}$: C, 42.85; H, 6.39. Found: C, 42.76; H, 6.44; sample dried before analysis 2 hr. at 78° and 1 mm. pressure over phosphoric anhydride, 0.55% loss, no loss on further heating for 4 hr. at 110°, X-ray powder diffraction pattern unchanged.

The above data on crystalline form 2 are in agreement with those for the sample of panose prepared by Dr. Pan with the exception of the X-ray powder diffraction data[22,23] which, for this modification (form 1) are: 9.51vw, 8.29vw, 6.09vw, 5.81vw, 5.48m, 5.18w, 4.87vs, 4.69w, 4.43vw, 4.27vw, 4.16vs, 4.01vw, 3.76w, 3.64vw, 3.49vw, 3.23m, 3.05w, 2.89vw, 2.73w. A sample of form 1 was heated over phosphoric anhydride for 2 hr. at 78° and 1 mm. and lost 0.26% with no further loss after 2 hr. at 110°.

Our infrared absorption spectrum for form 1 (Nujol mull) agrees with that published by Whiffen[24] in the range of 700 to 900 cm.$^{-1}$, but is slightly different from the spectrum (Nujol mull) of the new modification (form 2) in this range as well as in the range 1100 to 1400 cm.$^{-1}$.

Sirupy panitol (50 mg.), which had been prepared by reducing form 2 of panose with Raney nickel catalyst and 2000 p.s.i. of hydrogen at 80°, was acetylated with 5 ml. of acetic anhydride and 50 mg. of sodium acetate at the boiling point and the product was isolated as described above and crystallized from ethanol; yield 70 mg., m.p. 145–147° with no depression on admixture with a sample of known panitol dodecaacetate prepared from form 1; X-ray powder diffraction data[22,23]: 12.11vs, 10.43vw, 9.36vw, 8.63vs, 7.80w, 7.03w, 6.41vw, 6.07vw, 5.72vw, 5.29vw, 4.96vw, 4.62s, 4.44s, 4.14vw, 4.03vw, 3.89vw, 3.76w, 3.62w, 3.50w, 3.39m, identical with those of a sample of panitol dodecaacetate[4,25] prepared from a sample of panose (form 1) submitted to us by Dr. Pan.

An amount of 50 mg. of panose (form 1) was acetylated with hot acetic anhydride and sodium acetate in the manner described above for the disaccharide portion of the hydrolyzate. There resulted a sirupy acetate which was deacetylated by dissolving in 0.5 ml. of methanol and adding a drop of a solution of sodium methoxide (0.5 g. of sodium dissolved in 100 ml. of methanol). The sodium was removed by shaking with a small amount of Amberlite 120.[26] The sirup resulting on solvent removal was crystallized from boiling methanol; yield 25 mg., X-ray powder diffraction data identical with those of form 2.

The crystalline modification of panose isolated in this work (form 2) was recrystallized five times by dissolving in a small amount of water, filtering with carbon, removing the water by evaporation under reduced pressure and refluxing with methanol. The resulting material then gave an X-ray powder diffraction pattern identical with that of form 1.

These data indicate that the two crystalline forms are dimorphous and have indistinguishable melting points (decomposition points).

Isomaltotriose.—The mother liquors from the crystallization of panose were combined and evaporated under reduced pressure to an amorphous product; yield 1.79 g. This material was separated by means of paper zone electrophoresis with an apparatus similar to that described by Foster.[17] Whatman 3MM paper (14 × 57 cm.) was used and the material was applied in 75-mg. portions uniformly on lines 70 mm. and 225 mm. from the ground end of the plates. Three such papers were wet with borate buffer (*p*H 10) and clamped, one above the other, between the glass plates. In this way a total of 150 mg. of material could be separated in each run. A current of 400 volts and 45 milliamp. was applied for 4 hr. After the papers were removed from the apparatus, a pilot strip was removed from one edge and the zones were located therein by means of aniline phthalate indicator[17] and excised from the paper. Only two zones appeared. The faster moving zone had a M_G[17] value of 0.71 as compared with those of isomaltose 0.67,[17,27] maltose 0.37,[17,27] panose 0.33 and maltotriose 0.33. After 1.79 g. of amorphous material had all been subjected to this treatment, the papers holding the fast moving zone were pulped by stirring in water and the resultant suspension was filtered and washed with water. The filtrate and washings were combined and the sodium ion was removed by stirring the solution with Amberlite 120[26] until neutral. The solution was then evaporated to dryness under reduced pressure. The boric acid residue was removed as the volatile methyl ester by repeated distillation with methanol. The residue was dissolved in methanol, filtered with carbon and evaporated under reduced pressure to dryness; yield 0.67 g., $[\alpha]^{20}D$ +141°, a value comparable with that (+145°) found by Jeanes and associates[9] for isomaltotriose. A sample (50 mg.) of this material was dissolved in 2.5 ml. of 0.05 *N* hydrochloric acid and heated on a boiling water-bath for 5 hr. The acid was removed by shaking with a small amount of Duolite A4[19] ion exchange resin and the solution evaporated to dryness under reduced pressure. Paper chromatography, using 1-butanol, pyridine, water (3:2:1.5 by vol.) as developer, and electrophoresis, using a

borate buffer (*p*H 10), indicated the presence of only D-glucose, isomaltose and unhydrolyzed material.

The amorphous unhydrolyzed product (250 mg.) was dissolved in 30 ml. of water and reduced with hydrogen at 2000 p.s.i. and 80° with Raney nickel catalyst. The solution was filtered and evaporated to a sirup under reduced pressure; yield 200 mg., $[\alpha]^{20}D$ +114° (*c* 2.5, water). A 50-mg. sample of this material was acetylated with 3 ml. of hot acetic anhydride and 25 mg. of sodium acetate as described above; yield 60 mg. of sirup.

Anal. Calcd. for $C_{18}H_{22}O_6(CH_3CO)_{12}$: mol. wt., 1010.9. Found: mol. wt., 1018 (Rast).

Fragmentation Analysis of the Reduced Trisaccharide (Isomaltotriitol).—An amount of 134 mg. of the reduced and unacetylated product described above was dissolved in 10 ml. of 0.05 *N* sulfuric acid and heated on a boiling water bath for 7 hr. The excess acid was removed by shaking with a slight excess of Duolite A4[19] and filtering. The solution was evaporated under reduced pressure to a sirup which was acetylated with hot acetic anhydride (5 ml.) and sodium acetate (75 mg.) as described above. The resulting sirup was chromatographed on a column (235 × 35 mm., diam.) of Magnesol–Celite (5:1 by wt.) using 1000 ml. of benzene–*t*-butyl alcohol (100:1 by vol.) as developer. Three zones were located on the extruded column by streaking with the alkaline permanganate indicator. These were excised and eluted with acetone. The sirups obtained on solvent removal from the acetone eluates and from the column effluent were crystallized from ethanol. That from a zone located 25–40 mm. from the column top was identified as isomaltitol nonaacetate[28]; yield 3.8 mg. The material was crystallized from ethanol; m.p. 111–113°; X-ray powder diffraction pattern,[22,23] identical with that of authentic material: 10.98vs, 9.31s, 8.35w, 7.22vw, 6.86m, 6.39vw, 5.75vw, 5.14m, 4.72m, 4.43vw, 4.09s, 3.81w, 3.60vw. The product obtained from the zone 55–85 mm. from the column top was identified as β-isomaltose octaacetate[21]; yield 0.5 mg., m.p. 142–144°, X-ray powder diffraction data[14] identical with that of the authentic substance. The crystalline material found in the third zone located 240–290 mm. from the column top was identified as D-glucitol (sorbitol) hexaacetate; yield 0.8 mg., m.p. 95–96°; X-ray powder diffraction pattern,[22,23] identical with that of an authentic sample: 10.34w,, 8.43w, 7.58w, 7.02s, 6.56vw, 6.35vw, 5.96vw, 5.62vw, 5.05vs, 4.69w, 4.37w, 4.20vw, 4.01w, 3.89vw, 3.74m, 3.43s, 3.27vw, 3.18vw, 2.95m, 2.80vw, 2.72vw, 2.65w. The crystalline material from the column effluent was identified as β-D-glucopyranose pentaacetate; yield 25 mg., m.p. (on recrystallization from ethanol) 126–128° unchanged on admixture with an authentic specimen.

β-Maltotriose Hendecaacetate.—The material (1.58 g.) of the faster moving zone B from the paper chromatography of fraction II was placed upon paper and separated by electrophoresis, using a sodium borate buffer at *p*H 10, by the procedure described above for the separation of isomaltotriose. There resulted two zones, the slower of which had an M_G value of approximately 0.33 or that of maltotriose. The material in this zone was isolated; yield 950 mg. Acetylation of this product with hot acetic anhydride and sodium acetate was effected as described above for the acetylation of fraction I. This material failed to crystallize from ethanol and was chromatographed on a column (210 × 42, diam.) of Magnesol–Celite (5:1 by wt.) by development with 1000 ml. of benzene–*t*-butyl alcohol (100:1 by vol.). Two zones were located on the extruded column by streaking with the alkaline permanganate indicator. The amorphous material (180 mg.), obtained from the acetone eluate of a zone located 25–50 mm. from the column top, was not further investigated. The material obtained on solvent removal from the acetone eluate of a zone located 25–50 mm. from the column top, was crystallized from ethanol; yield 120 mg., m.p. 134–136° unchanged on admixture with authentic β-maltotriose hendecaacetate.[6,7]

The Synthesis of D-Gulosamine Hydrochloride[1a,b]

BY ZOFIA TARASIEJSKA AND ROGER W. JEANLOZ

RECEIVED MARCH 5, 1957

D-Gulosamine hydrochloride has been prepared in crystalline form from methyl 2-acetamido-4,6-*O*-benzylidene-2-deoxy-α-D-galactopyranoside and has been characterized through the following crystalline derivatives: *N*-(2′-hydroxynaphthylidene), methyl *N*-acetyl-α-D-glycoside and methyl *N*-acetyl-3,4,6-tri-*O*-acetyl-α-D-glycoside.

The isolation of a new aminosugar from streptothricin and streptolin B has been reported recently, and the structure of a 2-amino hexose, D-gulosamine (VII), has been proposed for it.[2] This appears to be the first isolation of a 2-amino hexose from natural sources since D-galactosamine was extracted from cartilage 40 years ago and the well known D-glucosamine from chitin nearly a century ago. It seems also to be the first isolation of a natural sugar with the D-gulose configuration.

Confirmation of the structure proposed by van Tamelen, *et al.*, by an unequivocal synthetic procedure seemed of interest. The preparation of D-allosamine from D-glucosamine has been accomplished in our laboratory.[3] In the present study a similar reaction sequence was applied to D-galactosamine and methyl 2-acetamido-4,6-*O*-benzylidene-2-deoxy-α-D-galactopyranoside (I)[4] was transformed into the 3-*O*-methylsulfonyl derivative II. Reaction with sodium acetate in methyl cellosolve[5] failed, however, to proceed in a similar way as described for the glucosamine derivative[3] and the starting material was recovered unchanged. This failure was unexpected, as the benzylidene derivative of galactosamine II possesses the general conformation of a *cis*-decalin, much more flexible than the *trans*-decalin confor-

mation of the glucosamine derivative, and consequently more favorable to the formation of the transient cyclic intermediate necessary for the inversion at C_3. After elimination of the benzylidene ring by hydrolysis of II into crystalline methyl 2-acetamido-2-deoxy-3-*O*-methylsulfonyl-α-D-galactopyranoside (III), it was then possible to obtain the transformation of III into a gulosamine derivative by heating with sodium acetate in methyl Cellosolve. To facilitate purification, the resulting product was acetylated and chromatographed. The crystalline acetyl derivative IX obtained was different from the crystalline diacetate IV of III which had been prepared previously. Alkaline hydrolysis of IX afforded a crystalline methyl 2-acetamido-2-deoxy-α-D-glycopyranoside (VIII), different from methyl 2-acetamido-2-deoxy-α-D-galactopyranoside, and consequently belonging to the D-gulosamine series. Acid hydrolysis of VIII gave in a 66% yield the crystalline α-form of 2-amino-2-deoxy-D-gulose hydrochloride (D-gulosamine hydrochloride) (VII). In view of the report of the formation of the 1,6-anhydro derivative of D-gulosamine hydrochloride by acid treatment of VII[2] the mother liquors of the preparation of VII were thoroughly studied. However, no trace of the anhydro compound could be detected by paper chromatography, using as standard of comparison D-galactosamine and 2-amino-1,6-anhydro-2-deoxy-β-D-galactopyranose hydrochloride.[6] The synthetic D-gulosamine exhibited a decomposition range of temperature, a starting and a final mutarotation identical to those of the natural product. It was definitely distinct from D-glucosamine, D-galactosamine and D-allosamine by direct paper chromatography. Degradation with ninhydrin in the presence of pyridine[7] gave rise to D-xylose (VI), identified by paper chromatography. As the free hydrochloride decomposes over a large range of temperature and the comparison of the mutarotation is an unsatisfactory method of identification, the preparation of crystalline derivatives was attempted in addition to the two crystalline glycosides described above. Starting from the hydrochloride VII, preparation of the *N*-acetyl derivative XI gave only a sirupy product. A sirup was also obtained when the *N*-acetyl derivative XI was obtained from the tri-*O*-acetylglycoside IX transformed by acetolysis to the sirupy pentaacetate XII, followed by alkaline *O*-deacetylation. However, the *N*-(2′-hydroxynaphthylidene) derivative X was crystalline. Another crystalline derivative was obtained by condensation of the glycoside VIII with benzaldehyde, to which the structure of a methyl 2-acetamido-4,6-*O*-benzylidene-2-deoxy-α-D-gulopyranoside (V) was ascribed by analogy; however, the possibility of a 3,4-*O*-benzylidene structure cannot be completely discarded.

After this work had been completed, a short note appeared in the literature describing a synthesis of D-gulosamine starting from D-xylose.[8] The structure of the final product is not unequivocally established by this work since two aminosugars,

D-gulosamine and D-idosamine, are formed. In addition, the value of the starting mutarotation of the aminosugar obtained differed significantly from the values of both the natural product and the synthetic product described above. Furthermore, no crystalline derivatives with definite melting point were reported.

Experimental[9]

Methyl 2-Acetamido-3-*O*-acetyl-4,6-*O*-benzylidene-2-deoxy-α-D-galactopyranoside.—This compound was obtained for identification purposes by conventional acetylation of methyl 2-acetamido-4,6-*O*-benzylidene-2-deoxy-α-D-galactopyranoside (I)[4] with pyridine and acetic anhydride. Crystallization from a mixture of acetone, ether and pentane gave elongated prisms, m.p. 219–220°, $[\alpha]^{23}D$ +186 ± 1° (in chloroform, *c* 0.74). *Anal.* Calcd. for $C_{18}H_{23}O_7N$: C, 59.17; H, 6.34. Found: C, 59.07; H, 6.39.

Methyl 2-Acetamido-4,6-*O*-benzylidene-2-deoxy-3-*O*-methylsulfonyl-α-D-galactopyranoside (II).—To a solution of 2.0 g. of methyl 2-acetamido-4,6-*O*-benzylidene-2-deoxy-α-D-galactopyranoside (I)[4] in 25 ml. of anhydrous pyridine previously chilled at −20° was added 1.0 ml. of methanesulfonyl chloride. After standing 3 days at 0°, ice was added, and the solution was extracted with chloroform. This extract was washed thrice each time with ice-cold 2 *N* sulfuric acid, saturated sodium bicarbonate and water and dried over sodium sulfate. After evaporation *in vacuo* the residue was dissolved in methanol, filtered through a layer of Darco G-60, and concentrated. Crystallization from mixtures of acetone and ether or acetone and pentane gave 2.14 g. (86%) of elongated prisms, melting at 205–207° dec., when started at room temperature, or at 219–220°, when started at 210°, $[\alpha]^{24}D$ +169 ± 1° (in chloroform, *c* 1.12). *Anal.* Calcd. for $C_{17}H_{23}O_8NS$: C, 50.86; H, 5.77; S, 7.99. Found: C, 50.93; H, 5.86; S, 7.90.

After heating in methyl Cellosolve solution in the presence of sodium acetate and extracting as previously described,[3] a recovery of approximately 90% of starting material was obtained.

Methyl 2-Acetamido-2-deoxy-3-*O*-methylsulfonyl-α-D-galactopyranoside (III).—A solution of 2.75 g. of II in 65 ml. of 60% acetic acid was heated a half-hour on a water-bath. The benzaldehyde and the solvents were removed by distillation *in vacuo*, followed by co-distillation with water then with absolute toluene. The residue was crystallized from a mixture of methanol and ether to give an almost quantitative yield of needles, m.p. 179–180° dec., $[\alpha]^{22}D$ +132 ± 1° (in methanol, *c* 0.88). *Anal.* Calcd. for $C_{10}H_{19}O_8NS$: C, 38.33; H, 6.11. Found: C, 38.48; H, 6.22.

Acetylation of 51 mg. of III with acetic anhydride and pyridine in the usual way gave the 4,6-di-*O*-acetyl derivative IV. Crystallization from a mixture of methanol and ether gave 59 mg. (91%) of short prisms, m.p. 163–164°, $[\alpha]^{24}D$ +96 ± 2° (in chloroform, *c* 0.83). *Anal.* Calcd. for $C_{14}H_{23}O_{10}NS$: C, 42.31; H, 5.83. Found: C, 42.22; H, 5.79.

Methyl 2-Acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-α-D-gulopyranoside (IX).—A solution of 1.0 g. of III and 0.9 g. of sodium acetate trihydrate in 25 ml. of 95% methyl Cellosolve was heated under reflux for 40 hours. After concentration to dryness *in vacuo*, the residue was acetylated with 10 ml. of anhydrous pyridine and 7 ml. of acetic anhydride overnight at room temperature. The mixture was filtered, the solution concentrated to dryness *in vacuo*, and the residue dissolved in chloroform and chromatographed on 50 g. of silicic acid. Pure ethyl acetate eluted crystalline fractions. Crystallization from a mixture of methanol and ether gave 0.65 g. of triangular prisms, m.p. 123–124°, $[\alpha]^{21}D$ +76 ± 1° (in chloroform, *c* 0.91). *Anal.* Calcd. for $C_{15}H_{23}O_9N$: C, 49.86; H, 6.42. Found: C, 49.71; H, 6.45. The yield based on the starting material III was 56%.

Methyl 2-Acetamido-2-deoxy-α-D-gulopyranoside (VIII).—To a cold solution of 300 mg. of IX in 2 ml. of methanol was added 0.3 ml. of 1.5 *N* barium methylate. After standing overnight at 0°, the solution was neutralized with carbon dioxide and diluted with water at the same time. After filtration through a double layer of Celite and Darco G-60, the last traces of barium were removed by filtering through a short column of Dowex 50 and the solution evaporated *in vacuo*. The residue was crystallized from a mixture of acetone and ether to give 142 mg. (72%) of short prisms, m.p. 79–82°, $[\alpha]^{25}D$ +72 ± 1° (in methanol, *c* 0.74). *Anal.* Calcd. for $C_9H_{17}O_6N$: C, 45.95; H, 7.29. Found: C, 45.80; H, 7.22.

VIII (49 mg.) was shaken overnight with 80 mg. of zinc chloride and 0.3 ml. of benzaldehyde. After addition of 2 ml. of water, the solution was extracted with hexane to remove the benzaldehyde in excess. The water solution was then extracted exhaustively with chloroform. This extract was dried over sodium sulfate, concentrated and chromatographed on 2 g. of silicic acid. After elution of benzoic acid with ether, a crystalline product was eluted with methanol. Crystallization from a mixture of methanol and acetone gave 38 mg. (57%) of prisms, m.p. 111–114°, $[\alpha]^{25}D$ +71 ± 2° (in methanol, *c* 0.90). *Anal.* Calcd. for $C_{16}H_{21}O_6N$: C, 59.43; H, 6.55. Found: C, 59.08; H, 7.07. The structure of **methyl 2-acetamido-4,6-*O*-benzylidene-2-deoxy-α-D-gulopyranoside** (V) was attributed to this compound.

2-Amino-2-deoxy-α-D-gulose Hydrochloride (α-D-Gulosamine Hydrochloride) (VII).—A solution of 227 mg. of VIII in 2.2 ml. of 2 *N* hydrochloric acid was heated on the water-bath for two hours. After evaporation *in vacuo*, the last traces of hydrochloric acid, water and acetic acid were removed by codistillation *in vacuo* with absolute ethanol. The residue was dissolved in aqueous methanol, filtered through a double layer of Celite and Darco G-60 and the solution concentrated. Crystallization from aqueous ethanol gave 138 mg. (66%) of prisms decomposing between 150 and 170°; the largest prisms started to decompose only at 162°. The product showed a complex mutarotation: $[\alpha]^{22}D$ +6.0° (10 minutes), −11° (30 minutes), −21° (one hour); −26° (2 hours), −26° (4 hours), −18 ± 1° (at equilibrium, after 36 hours, in water, *c* 0.90).[10] *Anal.* Calcd. for $C_6H_{14}O_5NCl$: C, 33.26; H, 6.48; N, 6.50; Cl, 16.44. Found: C, 33.47; H, 6.56; N, 6.32; Cl, 16.52. The reaction with ninhydrin was positive. In a descending paper chromatography on Whatman #54 paper in the mixture of *n*-propyl alcohol–water–ammonia 21:9:0.1, VII migrated 1.18, compared to D-glucosamine 1.00, D-galactosamine 0.91, and D-allosamine[3] 1.03. A small amount degraded with ninhydrin and pyridine as previously described[7] gave a spot migrating in paper chromatography with a R_f identical to the one of D-xylose (VI).

The rotation of the mother liquors of VII was $[\alpha]^{24}D$ +5°, showing that a maximum amount of 30% of 1,6-anhydro derivative could be present in it. However, any amount of untransformed starting material could be responsible for this figure. Before crystallization of VII, the crude mixture had an $[\alpha]^{24}D$ −10°, showing the presence of at least 90% of VII. Chromatographed in the mixture *n*-propyl alcohol–ammonia no spot faster than VII could be detected. A small amount of recrystallized VII was heated in 2 *N* hydrochloric acid solution at 100° for 7 hours in a sealed tube. After drying in a desiccator in presence of soda lime, the residue was chromatographed on paper in the mixture *n*-propyl alcohol–ammonia. No spot faster than VII could be detected. By comparison, 2-amino-1,6-anhydro-2-deoxy-β-D-galactopyranose hydrochloride[6] migrated 1.45.

2-Acetamido-2-deoxy-D-gulose (XI) (from IX).—To a mixture of 2.7 ml. of acetic anhydride and 0.05 ml. of concentrated sulfuric acid was added 273 mg. of IX. After standing one hour at room temperature, ice was added. The solution was neutralized with solid sodium bicarbonate, and extracted with chloroform. This solution was dried over sodium sulfate, concentrated and chromatographed on 10 g. of silicic acid. Elution with a mixture of ethyl acetate and acetone 4:1 gave 235 mg. of the sirupy **2-acetamido-1,3,4,6-tetra-*O*-acetyl-2-deoxy-D-gulopyranose (XII)**, which has thus far failed to crystallize; $[\alpha]^{24}D$ +51 ± 1° (in chloroform, *c* 1.08). *Anal.* Calcd. for $C_{16}H_{23}O_{10}N$: C, 49.35; H, 5.95. Found: C, 49.66; H, 5.74.

To a cold solution of 215 mg. of XII in 2.5 ml. of methanol was added 0.2 ml. of 1.5 *N* barium methylate. After 48 hours at 0°, it was diluted with water, neutralized with carbon dioxide, filtered and the solution passed through a short column of Dowex 50. After concentration, a quantitative yield of XI was obtained as a colorless sirup, $[\alpha]^{23}D$

$-47 \pm 2°$ (in methanol, *c* 1.32). *Anal.* Calcd. for $C_8H_{15}O_6N$: C, 43.44; H, 6.83. Found: C, 43.26; H, 6.99.

From VII.—To a solution of 19.5 mg. of VII in 1.5 ml. of methanol were added 30 mg. of silver acetate and 0.022 ml. of acetic anhydride. After standing at room temperature overnight, the solution was filtered. One drop of dilute hydrochloric acid was added and after two hours the solution was filtered through a double layer of Celite and Darco G-60. After concentration, a quantitative yield of sirup was obtained; $[\alpha]^{27}D$ $-50 \pm 1°$ (in methanol, *c* 1.82).

2-Deoxy-2-(2′-hydroxynaphthylidenamino)-D-gulose (X).—A solution of 48 mg. of VII and 32 mg. of sodium acetate trihydrate in 1 ml. of water was treated as previously described[11] with 100 mg. of 2-hydroxynaphthaldehyde in 10 ml. of methanol. Purification was carried out by chromatography on 5 g. of silicic acid. The substance was eluted by a mixture of acetone and methanol 9:1. Crystallization from a mixture of methyl Cellosolve and acetone gave 36 mg. (49%) of small yellow crystals, m.p. 186–188° dec., $[\alpha]^{22}_{5461}$ $-150 \pm 5°$ (at equilibrium, in methyl Cellosolve, *c* 0.60). *Anal.* Calcd. for $C_{17}H_{19}O_6N$: C, 61.26; H, 5.75. Found: C, 61.16; H, 5.86.

An Acyl Migration in Acetohalogenoglucosamines[1]

BY YOSHIYUKI INOUYE, KONOSHIN ONODERA, SHOZABURO KITAOKA AND HIDEO OCHIAI

RECIVED AUGUST 20, 1956

The acetobromoglucosamine (2-acetamido-2-deoxy-3,4,6-tri-*O*-acetyl-D-glucosyl bromide) described in the literature was proved to be 1,3,4,6-tetra-*O*-acetyl-α-D-glucosamine hydrobromide, in support of the finding of Micheel, *et al.* However, methyl β-D-glucosaminide and 1-*p*-tolyl-2-amino-2-deoxy-β-D-glucosylamine tetraacetates could be prepared by the Koenigs–Knorr reaction using the freshly prepared chloroform solution obtained from the reaction mixture of *N*-acetyl-tetra-*O*-acetyl-D-glucosamine with hydrogen bromide in acetic acid. A new disaccharide acetate of the trehalose type which consisted of two molecules of D-glucosamine tetraacetate also was prepared from this chloroform solution with silver oxide as the condensing agent. These results indicate that acetobromoglucosamine is actually formed by the usual method of preparation and then rapidly undergoes an acetyl migration. Additional evidence was obtained as well in the case of a crystalline analog, acetochloroglucosamine, which was converted into 1,3,4,6-tetra-*O*-acetyl-α-D-glucosamine hydrochloride, partially upon refluxing in moist chloroform and completely upon refluxing in acid-containing moist chloroform.

Micheel, van de Kamp and Wulff[2] recently have reported that the acetobromoglucosamine (2-acetamido-2-deoxy-3,4,6-tri-*O*-acetyl-D-glucosyl bromide) (IIa) prepared by the method of Moggridge and Neuberger,[3] (in which N-acetyl-tetra-*O*-acetyl-D-glucosamine (Ia) is treated with hydrogen bromide in acetic acid and the reaction mixture is dissolved in chloroform, washed with sodium bicarbonate solution, and the product is crystallized by concentrating the dried chloroform solution *in vacuo*), is actually 1,3,4,6-tetra-*O*-acetyl-α D-glucosamine hydrobromide (IVa). We had been engaged in some synthetic work starting from acetobromoglucosamine and had independently reached the same conclusion. The so-called acetobromoglucosamine obtained by the methods of Moggridge and Neuberger[3] and Baker, Joseph, Schaub and Williams,[4] the latter of which is a modification of the former, was 1,3,4,6-tetra-*O*-acetyl-α-D-glucosamine hydrobromide (IVa), which was identified by conversion into N-acetyl-tetra-*O*-acetyl-α-D-glucosamine (Ib), 2-*N*-(*o*-carboxybenzoyl)-1,3,4,6-tetra-*O*-acetyl-α-D-glucosamine (V) and 2-*N*-anisilydene-1,3,4,6-tetra-*O*-acetyl-α-D-glucosamine (VI). IVa was also converted into 1,3,4,6-tetra-*O*-acetyl-α-D-glucosamine (VII). Our attempts to synthesize the D-glucosaminides and disaccharides containing D-glucosamine as a component starting from IVa had resulted in failure. Similar failures have been described by the above authors.[2–4] However, Kuhn and Kirschenlohr[5] successfully prepared a series of alkyl-β-D-glucosaminide tetraacetates[5a] and 6-*O*-(2-amino-2-deoxy-β-D-glucosyl)-D-glucose and 6-*O*-(2-amino-2-deoxy-β-D-glucosyl)-D-galactose octaacetates[5b] from their acetobromoglucosamine preparation by the use of mercury cyanide as the condensing agent, and Bertho and Koziollek[6] obtained arylamine-*N*-β-D-glucosaminide tetraacetates from their acetobromo compound. However, these authors have given no detailed description of their acetobromoglucosamine preparations.

In our investigations, some of these D-glucosaminides were obtained by employing a slightly modified reaction procedure: *N*-acetyl-tetra-*O*-acetyl-D-glucosamine (Ia) was treated with hydrogen bromide in acetic acid in the usual manner. The reaction mixture was added to chloroform, washed quickly with an aqueous sodium bicarbonate solution and then with water and dried over anhydrous sodium sulfate. *This fresh chloroform solution* could be used to prepare D-glucosaminides. The reaction of this solution with methanol in the presence of silver oxide gave rise to methyl-β-D-glucosaminide tetraacetate (IIIa),[5a] and the reaction with *p*-toluidine yielded *p*-toluidine-*N*-β-D-glucosaminide tetraacetate (IIIb).[6,7]

Attempts to prepare 1-*O*-(2-amino-2-deoxy-β-D-glucosyl)-D-glucoside octaacetate by shaking the above chloroform solution of acetobromoglucosamine with 2,3,4,6-tetra-*O*-acetyl-D-glucose, silver oxide, iodine and anhydrous sodium sulfate resulted in the isolation of a small yield of a disaccharide containing two molecules of D-glucosamine acetate in the trehalose type linkage. This new disaccharide, presumably 1-*O*-(2-amino-2-deoxy-β-D-glucosyl)-2-amino-2-deoxy-β-D-glucoside octaacetate or 2,2′-diamino-2,2′-dideoxy-isotrehalose octaacetate, also was prepared by shaking the acetobromoglucosamine solution with silver oxide and drying agents. It did not reduce Fehling solution until after heating in 3 *N* hydrochloric acid for 5 hr. The corresponding glucose–glucose disaccharide, isotrehalose octaacetate, was obtained from acetobromoglucose in moist ethereal silver carbonate in 1% yield as the by-product of 2,3,4,6-tetra-*O*-acetyl-D-glucose.[8] Sharp and Stacey[9] prepared α-D-glucopyranosyl-β-D-glucopyranoside octaacetate from β-acetofluoroglucose.

It is noted that in the above *O*-glucosaminide synthesis silver oxide, one of the usual condensing agents in the Koenigs–Knorr reaction, is able to catalyze the reaction. Kuhn and Kirschenlohr[5a] reported that the synthesis was first achieved by the use of mercury cyanide. They cited the results of Moggridge and Neuberger[3] who reported that silver oxide, silver carbonate and pyridine were ineffective. This latter result is understandable since it is supposed that the synthetic work was started from tetra-*O*-acetyl-D-glucosamine hydrobromide (IVa). Lloyd and Stacey[10] found that silver carbonate catalyzed the synthesis of alkyl 2-(2,4-dinitrophenyl)-amino-2-deoxy-3,4,6-tri-*O*-acetyl-β-D-glucosides from 2-(2,4-dinitrophenyl)-amino-2-deoxy-3,4,6-tri-*O*-acetyl-α-D-glucosyl bromide.

The above success in our laboratory in the D-glucosaminide synthesis indicates that acetobromoglucosamine (IIa) is formed by the reaction of *N*-acetyl-tetra-*O*-acetyl-D-glucosamine (Ia) with hydrogen bromide in acetic acid and, in fact, exists in the fresh chloroform solution. It appears to be very unstable[11] and rapidly undergoes an acetyl migration to form IVa. Attempts to crystallize acetobromoglucosamine have hitherto resulted in failure. This rearrangement was also observed for the much stabler analog, acetochloroglucosamine (2-acetamido-2-deoxy-3,4,6-tri-*O*-acetyl-α-D-glucosyl chloride) (IIb),[4] from which Baker, Joseph, Schaub and Williams[4] prepared a puromycin analog in which 3-amino-3-deoxy-D-ribose is replaced by *N*-acetyl-D-glucosamine. The crystalline acetochloroglucosamine was converted into 1,3,4,6-tetra-*O*-acetyl-α-D-glucosamine hydrochloride (IVb), partially upon refluxing for 1 hr. in moist chloroform and completely upon refluxing in acid-containing moist chloroform. IVb was converted to 2-*N*-(*o*-carboxybenzoyl)-1,3,4,6-tetra-*O*-acetyl-α-D-glucosamine (V) and 2-*N*-anisilydene-1,3,4,6-tetra-*O*-acetyl-α-D-glucosamine (VI) for identification. It is noteworthy that refluxing IIb in absolute chloroform for the same period did not induce the acetyl migration.

Sugihara[12] has reviewed the literature on acyl group migration in the carbohydrate field. The migration is understood to proceed *via* an ortho acid ester as an intermediate. The intramolecular N→O and O→N acyl migrations in a variety of partially acylated amino alcohols have been reported,[13] and the reaction mechanism has been extensively studied. It has been established that the N→O and O→N acyl migrations are reversible, depending upon the presence of hydrogen and hydroxyl ions, respectively, and that they also proceed *via* an ortho acid ester intermediate (A). In some cases, oxazolines were isolated, but Phillips and Baltzly[14] preferred the ortho acid ester (A) to the oxazoline intermediate (B) in the conversion of various ethanolamides into the corresponding aminoethyl ester hydrochlorides.

van Tamelen[15] suggested that the ortho acid ester is also the intermediate to the formation of the oxazoline structure. Stereochemical studies have been made of the acyl migrations in inosamine[13b,16] and ephedrine and other amino alcohols.[17] It might be noted that White[18] was the first to observe an acyl migration in D-glucosamine in which 1,3,4,6-tetra-*O*-acetyl-D-glucosamine hydrochloride was converted into *N*-acetyl-D-glucosamine by the action of methanolic ammonia. Foster and Stacey[19] interpreted that this migration proceeded *via* an orthoacetate. Our present acetyl migration from II to IV should also proceed through the orthoacetate structure.

The results herein reported do not agree with the proposal made by Micheel, van de Kamp and Wulff[2] that the reaction of *N*-acetyl-tetra-*O*-acetyl-D-glucosamine (Ia) with hydrogen bromide–acetic acid produces primarily tetra-*O*-acetyl-D-glucosamine hydrobromide (IVa), which they showed is converted into 3,4,6-tri-*O*-acetyl-2-amino-2-deoxy-D-glucosyl bromide hydrobromide by further reaction with hydrogen bromide–acetic acid. These German researchers also stated that in the hydroxyl group-containing solvents 1,3,4,6-tetra-*O*-acetyl-D-glucosamine formed an oxazoline ring. This kind of conversion could occur under certain conditions, and further investigations are highly desirable.

Experimental[20]

hydrogen bromide at 0°, and to this was added 10 g. of *N*-acetyl-tetra-*O*-acetyl-D-glucosamine (Ia).[21] The mixture was allowed to stand overnight at room temperature; 80 ml. of chloroform was added with ice-cooling. The mixture was shaken, poured into ice-water, the aqueous layer was extracted with 20 ml. of chloroform and the extract was combined to the main chloroform layer. The chloroform solution was washed with three 20–30-ml. portions of ice-cold, saturated aqueous sodium bicarbonate, then with two portions of ice-cold water and dried over anhydrous sodium sulfate. The dried chloroform solution was concentrated under reduced pressure to a pale-yellow sirup, which on addition of a small volume of ethyl acetate and then of ether gave 5.5 g. (50%) of IVa. Repeated recrystallization from methanol by adding ether yielded colorless needles which charred gradually between 210 and 230°, $[\alpha]^{13}D$ +129° (*c* 1, water).

Anal. Calcd. for $C_{14}H_{22}NO_9Br$: C, 39.26; H, 5.18; N, 3.27. Found: C, 39.44; H, 5.41; N, 3.21.

IVa was soluble in water and methanol but not in chloroform. Concentration of the aqueous layer of the reaction mixture under reduced pressure to approximately one-tenth volume, followed by addition of methanol and keeping at ice-box temperatures, gave crystalline D-glucosamine hydrobromide.

N-Acetyl-tetra-*O*-acetyl-α-D-glucosamine (Ib).[22]—Two grams of IVa, dissolved in 10 ml. of water, was treated with 0.8 g. of anhydrous sodium acetate and 20 ml. of chloroform, and the mixture was well shaken. Acetic anhydride (1 g.) was added and the mixture was stirred for 30 minutes. The chloroform layer was separated, washed with a small volume of water and dried over anhydrous sodium sulfate. Crystallization occurred upon concentration under reduced pressure followed by treatment with ether. Recrystallization from an acetone–ether–petroleum ether mixture gave 1.3 g. (71%) of needles, whose m.p. and mixed m.p. with authentic Ib[23] were 137°, $[\alpha]^{22}D$ +92° (*c* 1, chloroform).

Anal. Calcd. for $C_{16}H_{23}NO_{10}$: C, 49.35; H, 5.95. Found: C, 49.47; H, 5.65.

2-*N*-(*o*-Carboxybenzoyl)-1,3,4,6-tetra-*O*-acetyl-α-D-glucosamine (V).—IVa (2 g.) was dissolved in 10 ml. of water, and to this was added 0.8 g. of anhydrous sodium acetate. This solution was extracted with three portions (8 ml. each) of chloroform. The extract was washed with a small volume of water and dried over anhydrous sodium sulfate. After filtration the dried chloroform extract was added to 0.7 g. of phthalic anhydride, and the mixture was refluxed for 1 hr. on a water-bath. The reaction solution was cooled to room temperature and extracted with three 10-ml. portions of saturated aqueous solution of sodium bicarbonate. The combined extract was passed through a Celite layer and acidified with *N* hydrochloric acid to give 1.5 g. (65%) of V, m.p. 176° after thorough washing with cold water and drying.

Anal. Calcd. for $C_{22}H_{25}NO_{12}$: C, 53.33; H, 5.09; N, 2.83. Found: C, 53.05; H, 5.09; N, 2.88.

The β-isomer was described by Baker, Joseph, Schaub and Williams.[4]

2-*N*-Anisilydene-1,3,4,6-tetra-*O*-acetyl-α-D-glucosamine (VI).[2]—To two grams of IVa in 10 ml. of water was added 0.8 g. of anhydrous sodium acetate, and the mixture was extracted with three 8-ml. portions of chloroform. The combined extract was washed with cold water, dried over anhydrous sodium sulfate and filtered. The filtrate was treated with 1.5 g. of anisaldehyde with stirring and was allowed to stand overnight. An excess of ether and petro-

leum ether was then added and the mixture was kept at ice-box temperatures for crystallization. Colorless needles were collected by filtration and washed with ether; yield 0.7 g. (32%) (after recrystallization from acetone–ether–petroleum ether), m.p. 174°, $[\alpha]^{24}D$ +123° (*c* 0.4, chloroform).

Anal. Calcd. for $C_{22}H_{27}NO_{10}$: C, 56.77; H, 5.85; N, 3.01. Found: C, 56.91; H, 6.03; N, 3.20.

The β-isomer was described by Bergmann and Zervas.[24]

1,3,4,6-Tetra-*O*-acetyl-α-D-glucosamine (VII).[2,24]—1,3,4,6-Tetra-*O*-acetyl-α-D-glucosamine hydrobromide (IVa) (1 g.) was dissolved in water which contained 0.38 g. of sodium acetate. The solution was extracted three times with 10-ml. portions of chloroform. The extract was washed with water, dried over anhydrous sodium sulfate and concentrated to 1 ml. The addition of ether gave crystals which were recrystallized twice from acetone–ether–petroleum ether, needles, yield 350 mg. (43%), m.p. 132°, $[\alpha]^{11}D$ +157° (*c* 0.5, chloroform). The substance easily was soluble in acetone, chloroform and methanol and was soluble in water. It was insoluble in ether and petroleum ether. The reported constants[2] are m.p. 118–119° and $[\alpha]D$ +145.5° (*c* 1, chloroform).

Anal. Calcd. for $C_{14}H_{21}NO_9$: C, 48.41; H, 6.09; N, 4.03. Found: C, 48.34; H, 6.39; N, 4.00.

The β-isomer of this compound was reported by Bergmann and Zervas.[24]

Acetochloroglucosamine (IIb).[4]—To 10 g. of *N*-acetyl-tetra-*O*-acetyl-D-glucosamine (Ia) dissolved in 150 ml. of anhydrous chloroform was added with stirring 6.2 g. of titanium tetrachloride dissolved in a small volume of anhydrous chloroform. After thorough shaking, the mixture was refluxed with exclusion of moisture for 3.5 hr., cooled, washed three times with ice-water and dried over anhydrous sodium sulfate. Concentration under reduced pressure followed by treatment of the resulting sirup with ether and then with petroleum ether produced 2.1 g. (22%) of IIb, which was recrystallized from a small volume of chloroform by adding ether and petroleum ether; m.p. 127° (dec.), $[\alpha]^{24}D$ +117.5° (*c* 1, chloroform).

Anal. Calcd. for $C_{14}H_{20}NO_8Cl$: C, 45.97; H, 5.51; N, 3.83. Found: C, 45.97; H, 5.47; N, 3.81.

1,3,4,6-Tetra-*O*-acetyl-α-D-glucosamine Hydrochloride (IVb).—IIb (0.1 g.) in 10 ml. of anhydrous chloroform was refluxed for 1 hr. with the addition of one drop of 0.1 *N* hydrochloric acid. After cooling, the solution was concentrated under reduced pressure, and to the resulting sirup was added a small volume of methanol and then ether to give 0.1 g. (95%) of IVb as colorless needles, soluble in water and methanol and insoluble in ether, decomposition point 185° after gradual charring, $[\alpha]^{11}D$ +140° (*c* 1, water).

Anal. Calcd. for $C_{14}H_{22}NO_9Cl$: C, 43.81; H, 5.79; N, 3.65. Found: C, 44.05; H, 5.77; N, 3.41.

The β-isomer is known.[24]

Refluxing IIb in anhydrous chloroform with addition of one drop of water yielded 30–40% of IVb, and unreacted IIb was recovered from the filtrate. When IIb was refluxed in anhydrous chloroform for the same period, no IVb was obtained, but the original amount of IIb was recovered.

IVb was converted into V and VI in the same manner as described above for the conversions from IVa.

In one experiment, IIb (6 g.) was dissolved in acetone (25 ml.), and to this was added freshly prepared silver carbonate (7 g.). The mixture was shaken for 10 min. and after dilution with 1 ml. of water was refluxed for one hour. Freshly prepared silver oxide (5.7 g.) was added and the reaction mixture was refluxed for another hour. The procedure was repeated. The reaction mixture which had a negative chlorine test was filtered, and the filtrate was treated with active carbon, dried over anhydrous sodium sulfate, and then concentrated under reduced pressure. The sirup was extracted with an excess amount of ether, and the extract was concentrated under reduced pressure to dryness; yield 4 g. (70%), m.p. 55–70°. It was recrystallized from ether; m.p. 70–80°, $[\alpha]^{11}D$ + 63° (final) (*c* 1, chloroform). The substance had a negative chlorine test and reduced the Fehling solution. It was soluble in water, methanol, chloroform and acetone.

(24) M. Bergmann and L. Zervas, *Ber.*, **64**, 975 (1931); **65**, 1201 (1932).

Anal. Calcd. for $C_{14}H_{21}NO_9$: C, 48.41; H, 6.09; N, 4.03. Found: C, 48.27; H, 6.22; N, 4.15.

It is noted that this compound has the same composition as that for VII.

The substance was dissolved in a small volume of methanol, and hydrogen chloride was added to the solution. The reaction mixture was allowed to stand at room temperature for 20 min. Upon addition of ether it yielded crystals, m.p. 185° (dec.). The yield was almost quantitative. The melting point of a mixture with a sample of 1,3,4,6-tetra-*O*-acetyl-α-D-glucosamine hydrochloride (IVb) obtained above was not depressed.

Methyl *N*-Acetyl-3,4,6-tri-*O*-acetyl-β-D-glucosaminide (IIIa).[5a]—Twenty grams of acetic acid was saturated at 0° with dry hydrogen bromide, and to this was added in the cold 5 g. of *N*-acetyl-tetra-*O*-acetyl-D-glucosamine (Ia).[21] The mixture was allowed to stand for 24 hr. in the dark at room temperature. Chloroform (50 ml.) was added to the reaction mixture in the cold and quickly washed with 50 ml. of ice-water. The combined washing was extracted with 10 ml. of cold chloroform and the extract was combined to the main extract. The extract was then washed, as quickly as possible, with three 15-ml. portions of ice-cold saturated aqueous solution of sodium bicarbonate and then with 30 ml. of ice-water. The chloroform extract was immediately dried with anhydrous sodium sulfate with shaking. After filtration it was immediately used for the glycosidation. When kept for a time in the cold or when ether was added, crystallization of IVa occurred.

To the above chloroform extract of acetobromoglucosamine were immediately added 15 g. of anhydrous sodium sulfate, 5 g. of anhydrous methanol, 10 g. of silver oxide and 0.2 g. of iodine. The mixture was shaken for 48 hr. at room temperature in the dark. The reaction mixture was filtered to remove solid matter, which was washed with chloroform and the washings were combined to the filtrate. The chloroform solution was washed repeatedly with water until it no longer gave turbidity with silver nitrate solution, and then dried over anhydrous sodium sulfate. Upon concentration, a sirup that contained amorphous matter was obtained. Treatment with petroleum ether gave a colorless powder which was recrystallized repeatedly from methanol with ether and petroleum ether; m.p. 160°, $[\alpha]^{18}D$ −24° (*c* 1, chloroform). The yield was 2.1 g. (45% based on *N*-acetyl-tetra-*O*-acetyl-D-glucosamine); it was dependent on the conditions under which the chloroform extract of IIa was prepared.

Anal. Calcd. for $C_{15}H_{23}NO_9$: C, 49.86; H, 6.42; N, 3.88. Found: C, 49.86; H, 6.41; N, 3.89.

***p*-Toluidine *N*-(*N*-Acetyl-3,4,6-tri-*O*-acetyl)-β-D-glucosaminide (IIIb).**[6,7]—To a fresh chloroform solution of acetobromoglucosamine (IIa), prepared from 5 g. of *N*-acetyl-tetra-*O*-acetyl-D-glucosamine (Ia) in the same way as above, was added 10 g. of *p*-toluidine. A precipitate appeared immediately. The mixture was shaken and allowed to stand at room temperature for 24 hr. The precipitate was filtered, washed with a small volume of chloroform, and the washings were combined to the filtrate. The combined filtrate was then concentrated under reduced pressure to a small volume to precipitate unreacted *p*-toluidine, which was dissolved in a large excess of ether, and the insoluble *p*-toluidine hydrobromide was removed by filtration. Upon standing the filtrate at ice-box temperatures for a while, the solution yielded 3.4 g. (61% based on *N*-acetyl-tetra-*O*-acetyl-D-glucosamine) of IIIb, colorless leaves, m.p. 183° (from methanol), $[\alpha]^{18}D$ −2° (*c* 1, methanol).

Anal. Calcd. for $C_{21}H_{28}N_2O_8$: C, 57.79; H, 6.47; N, 6.42. Found: C, 57.45; H, 6.45; N, 6.38.

2,2′-Diamino-2,2′-dideoxy-isotrehalose Octaacetate (IIIc).—Dried fresh chloroform solution of acetobromoglucosamine (IIa), prepared from 10 g. of *N*-acetyl-tetra-*O*-acetyl-D-glucosamine (Ia), was immediately shaken in the dark with 10 g. of silver oxide, 0.5 g. of iodine and 20 g. of anhydrous sodium sulfate for 48 hr. The mixture was filtered and the solid matter was washed twice with hot chloroform. The washings were combined with the filtrate which then was washed repeatedly with cold water until no reaction with silver nitrate was observed in the washings. The chloroform solution was dried over anhydrous sodium sulfate, filtered and concentrated under reduced pressure to a thick pale-yellow sirup. Warm ether was added to

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar.

this sirup to dissolve it and then to yield a fine amorphous precipitate. This was collected by filtration, thoroughly washed with ether, dried in a vacuum desiccator and crystallized from hot methanol to give 0.2 g. (2.3% based on *N*-acetyl-tetra-*O*-acetyl-D-glucosamine) as colorless needles; decomposing point 324–326° (after gradual charring), $[\alpha]^{20}D$ +2.5° (*c* 0.2, chloroform).

Anal. Calcd. for $C_{23}H_{40}N_2O_{17}$: C, 49.70; H, 5.96; N, 4.14. Found: C, 49.58; H, 6.03; N, 4.23.

IIIc is soluble in hot water, hot methanol, chloroform and acetone and insoluble in ether and petroleum ether. It did not reduce Fehling solution under ordinary conditions, but after heating in 3 *N* hydrochloric acid for 5 hr., it reduced Fehling solution.

Attempted experiments to prepare 1-(D-glucosaminido)-D-glucose acetate (1-*O*-(2-acetamido-2-deoxy-β-D-glucosyl)-D-glucoside heptaacetate) by shaking the chloroform solution of acetobromoglucosamine from 10 g. of *N*-acetyl-tetra-*O*-acetyl-D-glucosamine with 10 g. of silver oxide, 0.5 g. of iodine, 5 g. of 2,3,4,6-tetra-*O*-acetyl-D-glucose[25] and 20 g. of anhydrous sodium sulfate resulted in the isolation of IIIc.

Acknowledgment.—The authors gratefully acknowledge the generous supply of D-glucosamine hydrochloride by Kaken-Yaku Kako Co., Ltd., Yamashina, Kyoto.

Heterocyclic Compounds. IV. The Structures of 2-Phenylpyrroline and 2,4-Diphenylpyrroline

BY MILTON C. KLOETZEL, JACK L. PINKUS AND ROBERT M. WASHBURN[1]

RECEIVED MARCH 2, 1957

Chemical and spectral evidence is presented for ascribing the Δ^1-structure to the 2,4-diphenylpyrroline obtained by reductive cyclization of 1,3-diphenyl-4-nitro-1-butanone and to the 2-phenylpyrroline obtained from the reaction of phenylmagnesium bromide with γ-chlorobutyronitrile.

The exact assignment of the position of unsaturation in pyrrolines has been the subject of repeated misinterpretation and contradiction. Much of the difficulty stems from the arbitrary assignment of a Δ^2-pyrroline structure (such as II) to the examples of these compounds reported in the earlier literature.[2–5] In at least one instance[6] such a structure was assigned to a compound which proved later not to be a pyrroline at all.[7]

It is conceivable that some of these earlier investigators silently entertained the opinion to which Sonn[8] eventually gave expression; that is, that Δ^1- and Δ^2-pyrrolines are chemically indistinguishable.

However, the application of both physical and chemical methods recently has provided evidence that many pyrrolines, such as myosmine[9] and those obtained from reactions of Grignard reagents with γ-chlorobutyronitrile[10–12] or from reduction of certain pyrroles,[12] are best represented by Δ^1-structures. Indeed, Witkop[9] has come to the conclusion that "there are probably no authentic secondary Δ^2-pyrrolines."

Evidence now is presented for ascribing the Δ^1-structure to the 2,4-diphenylpyrroline obtained by reductive cyclization of 1,3-diphenyl-4-nitro-1-butanone (I), and to the 2-phenylpyrroline prepared for parallel study by the reaction of phenylmagnesium bromide with γ-chlorobutyronitrile.

Kohler and Drake[13] reported that hydrogenation of 1,3-diphenyl-4-nitro-1-butanone (I) over platinum black gave disappointing results which depended on factors that could not be controlled. Reduction was not confined to a single step and gave only oily products. 2,4-Diphenylpyrroline was not reported to be among the reduction products.[14] However, by reducing the nitro ketone with acetic acid and zinc or iron, Sonn[8] was able to obtain a 42% yield of 2,4-diphenylpyrroline.

We now have found that low pressure hydrogenation of 1,3-diphenyl-4-nitro-1-butanone (I) over ordinary Raney nickel at 25° affords a 79% yield of 2,4-diphenylpyrroline. With freshly prepared Raney nickel the reaction proceeds further to give a 77% yield of 2,4-diphenylpyrrolidine. One may reasonably assume that stepwise reduction occurs,

(13) E. P. Kohler and N. L. Drake, *ibid.*, **45**, 2144 (1923).

(14) Kohler and Drake obtained a solid, m.p. 179–180°, by treatment of their mixture of reduction products with benzoyl chloride. They ascribed to this derivative the composition $C_{23}H_{19}NO_2$ and cited its formation as evidence that the reduction mixture contained an hydroxylated diphenylpyrroline. However, it is not unlikely that this benzoyl derivative is identical with 4-benzoylamino-1,3-diphenyl-1-butanone (VIII), $C_{23}H_{21}NO_2$, m.p. 180–181°, obtained by Sonn[8] from the reaction of benzoyl chloride with "2,4-diphenyl-Δ^2-pyrroline" (II), and by us (with m.p. 182–183°) similarly from 2,4-diphenyl-Δ^1-pyrroline (IV). Thus, the benzoyl derivative obtained by Kohler and Drake may have resulted from the presence of 2,4-diphenylpyrroline, rather than an hydroxylated pyrroline, in their mixture of reduction products.

It is likely, moreover, that the benzoyl derivative, m.p. 180°, obtained by Rupe and Gisiger[5] from "2,4-diphenyl-Δ^2-pyrroline" also is the aforementioned amido ketone. On the basis of an analysis for nitrogen, these authors ascribed to their derivative the structure 1-benzoyl-2,4-diphenylpyrroline. However, this analysis is an inadequate criterion since the cyclic and acyclic amides in question do not differ sufficiently in nitrogen content.

for the pure pyrroline also is hydrogenated smoothly to the pyrrolidine in the presence of fresh catalyst. None of the pyrrolidine results from disproportionation of the pyrroline[15] for the latter is not affected even by extended treatment at 42° with fresh Raney nickel in ethanol.[16]

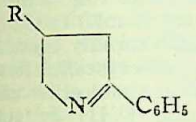
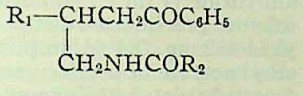
II



III, R = H
IV, R = C_6H_5



V, R_1 = H; R_2 = CH_3
VI, R_1 = H; R_2 = C_6H_5
VII, R_1 = C_6H_5; R_2 = CH_3
VIII, R_1 = R_2 = C_6H_5

The same 2,4-diphenylpyrroline is obtained, in yields up to 43 and 39%, respectively, when the nitro ketone I is reduced by hydrazine in the presence of Raney nickel or by zinc dust and aqueous ammonium chloride. In the latter instance, part of the product is isolated as a complex with zinc chloride unless all ionic zinc is first precipitated as the sulfide. The catalyzed hydrazine reduction of aromatic nitro compounds has been reported previously,[18,19] but the method does not appear to have been applied to aliphatic nitro compounds heretofore.[20]

The 2,4-diphenylpyrroline obtained from these reductions was characterized by formation of several solid salts and evidently is identical with that obtained by Rupe and Gisiger[5] and by Sonn.[8] There is no band in the NH region in its infrared absorption spectrum, although the general level of absorption at 2.5–3.5 μ is relatively high (Nujol mull). Moreover, changes in the infrared spectrum accompanying protonation of the basic nitrogen parallel those described by Witkop for the spectra of myosmine (2-β-pyridyl-Δ^1-pyrroline)[9] and other Schiff bases.[22] For example, the spectrum of 2,4-diphenylpyrroline hydrochloride shows a broad ammonium band at 3.80–4.08 μ with a maximum at 3.91 μ (compare 3.94 μ for myosmine monohydrochloride); immonium absorption occurs at 5.34 μ (at 5.30 μ for myosmine monohydrochloride); and the hypsochromic shift of the conjugated C=N band from 6.19 μ in the spectrum of the free base to 6.05 μ in the spectrum of the hydrochloride also is observed. These spectral characteristics are in harmony with the Δ^1-structure (IV) for this 2,4-diphenylpyrroline.

Zerewitinoff determinations at 25° and at 100° provided confirmatory evidence for the structure of 2,4-diphenyl-Δ^1-pyrroline (IV). Neither significant active hydrogen nor addition of methylmagnesium iodide was detected and the base was recovered in greater than 90% yield. Inertness of the azomethine group toward addition of Grignard reagent is to be expected, since the unsaturated carbon bears no hydrogen, but the compound might be expected to react through its enamine form.[23] The fact that no reaction occurs may be taken as evidence that 2,4-diphenyl-Δ^1-pyrroline is not readily tautomerized.

Acetylation and benzoylation of 2,4-diphenyl-Δ^1-pyrroline (IV) occur with concurrent rupture of the heterocyclic ring to yield acyclic amido ketones VII and VIII, respectively. As in the case of the benzoylation product,[14] amido ketone VII was erroneously assigned a cyclic structure (1-acetyl-2,4-diphenyl-Δ^2-pyrroline) by Rupe and Gisiger[5] on the basis of inadequate evidence. Their analysis for nitrogen failed to disclose the presence of the second oxygen atom in this compound, whose structure we have ascertained by means of analytical and infrared absorption data.

Dehydrogenation of 2,4-diphenyl-Δ^1-pyrroline (IV) was effected readily with sulfur or selenium, to produce 2,4-diphenylpyrrole in yields of 69 or 49%, respectively. Rogers[17] has obtained a 55% yield with selenium under similar conditions but reported that the use of sulfur gave inferior yields.

2-Phenylpyrroline, prepared by the method of Craig, Bulbrook and Hixon,[24] displayed spectral and chemical properties similar to those of 2,4-diphenyl-Δ^1-pyrroline. No unequivocal conclusion could be drawn from an examination of the 3 μ region in the infrared absorption spectrum of the free base.[25] However, conversion to the hydrochloride resulted in the appearance of broad ammonium absorption with a maximum at 3.88 μ, immonium absorption at 5.33 μ, and the hypsochromic shift of conjugated C=N band from 6.18 μ (in the base) to 6.06 μ in the infrared spectrum.

Consistent with a Δ^1-structure (III) for this pyrroline was the fact that a Zerewitinoff determination in anisole detected neither the presence of active hydrogen nor addition of methylmagnesium iodide.[26]

(25) In our experience, the NH region in the infrared absorption spectra of pyrrolidines and pyrrolines is difficult to interpret. Intensity of absorption in this region varies considerably, depending both upon the nature of substituents in the vicinity of the nitrogen atom and upon the medium in which the spectrum is determined.

(26) Maginnity and Cloke[11] reported that 2-phenylpyrroline caused no gas evolution upon contact with methylmagnesium iodide for 30 hours but "consumed" 1 mole of Grignard reagent. These authors referred to the product of this reaction as an "addition complex" and stated that "analysis of the reaction mixture demonstrated that a considerable portion of the original compound was recovered unchanged." Evidently the complex was decomposed by water and no addition of Grignard reagent to azomethine linkage had occurred. Under these circumstances it is difficult to understand how the complex could resist hydrolysis, during decomposition of excess Grignard reagent with water in the customary Zerewitinoff procedure, and so lead to the conclusion that Grignard reagent had been "consumed."

2-Phenyl-Δ^1-pyrroline (III) was characterized through its solid hydrochloride, picrate and methiodide. As in the case of its 2,4-diphenyl analog, acetylation and benzoylation of this base occur with simultaneous ring cleavage. The structures of the resulting amides (V and VI, respectively) have been confirmed spectroscopically.

Acknowledgment.—The authors are indebted to Parke, Davis and Co., Detroit, Mich., for generous financial aid which made this study possible, and to R. Bruce Scott, Research Department, Parke, Davis and Co., for his help in determining and interpreting infrared spectra during the initial stages of this investigation.

Experimental[27]

2,4-Diphenyl-Δ^1-pyrroline.—Catalytic hydrogenation of 1,3-diphenyl-4-nitro-1-butanone (I) was effected at room temperature by shaking a slurry of the ketone[28] (20 g.) and Raney nickel[29] (4 g.) in ethanol (200 ml.) for 28.5 hours under hydrogen at a pressure of 38–48 p.s.i. Distillation of the filtered solution yielded 13 g. (79%) of **2,4-diphenyl-Δ^1-pyrroline** (IV), b.p. 154–155° at 2 mm., which solidified in the receiver; m.p. 50–52°. Crystallization from ether furnished colorless needles, m.p. 52°; Sonn[8] reported a m.p. of 48–49°. Rupe and Gisiger[5] evidently obtained the same compound, m.p. 50°, by reduction of 2,4-diphenyl-4-oxobutanonitrile but designated it 2,4-diphenyl-Δ^2-pyrroline (II).

Anal. Calcd. for $C_{16}H_{15}N$: C, 86.84; H, 6.83; N, 6.33; mol. wt., 221. Found: C, 86.83; H, 6.82; N, 6.29; mol. wt., 225 (Rast method, in exaltone).

The infrared absorption spectrum determined on a Nujol mull of this base showed principal maxima at 6.19, 6.36, 6.71, 7.45, 9.26, 9.52, 9.80, 13.12 (broad) and 14.27 μ (broad).

The base decolorized a 3% solution of bromine in carbon tetrachloride but not a 1% solution of potassium permanganate in acetone

2,4-Diphenyl-Δ^1-pyrroline in anhydrous ether reacted with anhydrous hydrogen chloride to produce the insoluble **hydrochloride**, which subsequently crystallized from benzene in colorless, hygroscopic needles, m.p. 165–166.5° with slight decomposition (sealed tube).

Anal. Calcd. for $C_{16}H_{16}ClN$: C, 74.55; H, 6.25; N, 5.43. Found: C, 74.56; H, 6.36; N, 5.60.

The infrared absorption spectrum of the hydrochloride, determined on a Nujol mull, showed principal maxima at 3.91 (broad), 5.34, 6.05, 6.16, 6.25, 6.33, 6.68, 7.47, 7.76, 8.38, 9.75, 10.84 (broad) and 13.32 μ (broad).

2,4-Diphenyl-Δ^1-pyrroline perchlorate, prepared in a mixture of isopropyl alcohol and ether and crystallized twice from a similar mixture containing some ethyl acetate, melted at 110.5–111.5°

Anal. Calcd. for $C_{16}H_{16}ClNO_4$: Cl, 11.02. Found: Cl, 10.73.

The picrate formed readily in ethanol and separated from a mixture of chloroform and ether in green-yellow needles, m.p. 160–161° with sintering beginning at 157°. Rupe and Gisiger[5] and Sonn[8] reported 156° and 155–156°, respectively, for their picrates.

Anal. Calcd. for $C_{22}H_{18}N_4O_7$: C, 58.66; H, 4.03; N, 12.44. Found: C, 58.38; H, 4.32; N, 12.66.

The oxalate was prepared by adding a saturated acetone solution of anhydrous oxalic acid to an acetone solution of 2,4-diphenyl-Δ^1-pyrroline until no further precipitation occurred. After three crystallizations from ethyl acetate the colorless crystals sintered at 160° and melted at 168° with gas evolution. Rupe and Gisiger[5] reported 157–158°.

Anal. Calcd. for $C_{18}H_{17}NO_4$: C, 69.44; H, 5.50; N, 4.50. Found: C, 69.19; H, 5.31; N, 4.40.

Zerewitinoff determinations on 2,4-diphenyl-Δ^1-pyrroline were conducted in anisole in the usual manner[11,30] and unused methylmagnesium iodide was back titrated by addition of water. At 25° the base evolved no methane and added no Grignard reagent. After completion of the determination, solid ammonium chloride and water were added to the reaction vessel and the contents were extracted with chloroform. Evaporation of the dried extract and addition of picric acid in ethanol yielded 90.4% of 2,4-diphenyl-Δ^1-pyrroline picrate which did not depress the m.p. of authentic picrate.

At 100°, 2,4-diphenyl-Δ^1-pyrroline likewise added no methylmagnesium iodide and evolved 0.09 mole of methane.

Acetylation of 2,4-diphenyl-Δ^1-pyrroline (822 mg.) was accomplished by heating for 2.5 hours at 100° with acetic anhydride (1 ml.). Addition of water (5 ml.) to the cooled mixture precipitated the product which rapidly crystallized; yield 882 mg. (84%), m.p. 91–101°. Recrystallization from ethyl acetate or a mixture of chloroform and ether afforded 4-acetylamino-1,3-diphenyl-1-butanone (VII) in colorless platelets (624 mg.), m.p. 100–104°. A final crystallization raised the m.p. to 105°, the m.p. of Rupe and Gisiger's product.[5]

The infrared absorption spectrum determined on a Nujol mull of VII showed principal maxima at 3.06 μ (N—H), 5.95 μ (ketone C=O), 6.08 μ (amido C=O) and 6.47–6.50 μ (amide).

Anal. Calcd. for $C_{18}H_{19}NO_2$: C, 76.84; H, 6.81; N, 4.98. Found: C, 76.55; H, 7.11; N, 4.69.

Benzoylation of 2,4-diphenyl-Δ^1-pyrroline (616 mg.) was accomplished by shaking with benzoyl chloride (1 ml.) and 10% aqueous sodium hydroxide (10 ml.) until excess benzoyl chloride was hydrolyzed. Crystallization of the crude product from ethyl acetate yielded 673 mg. (70%) of 4-benzoylamino-1,3-diphenyl-1-butanone (VIII) in colorless needles, m.p. 180–182°. The m.p. was raised to 182–183° by further crystallization.

A Nujol mull of VIII displayed infrared absorption maxima at 3.06 μ (N—H), 5.97 μ (ketone C=O), 6.12 μ (amido C=O) and 6.58 μ (amide).

Anal. Calcd. for $C_{23}H_{21}NO_2$: C, 80.44; H, 6.16; N, 4.08. Found: C, 80.42; H, 6.14; N, 4.11.

Dehydrogenation of 2,4-diphenyl-Δ^1-pyrroline (IV) was accomplished by heating 2.0 g. of the base with 2.2 g. of selenium at 250° for 3 hours in a slow stream of nitrogen. From a benzene extract of the cooled product 980 mg. (49%) of 2,4-diphenylpyrrole was obtained, m.p. 175–178°. Recrystallization from ethanol yielded colorless microcrystals, m.p. 178–179°, the m.p. reported by Rogers.[17]

When a mixture of 440 mg. of IV and 64 mg. of sulfur was heated, evolution of hydrogen sulfide began at 180°. The temperature was then raised to 260° over a period of 7 minutes. A decolorized toluene solution of the reaction product yielded 2,4-diphenylpyrrole in colorless needles, m.p. 176–178°, yield 300 mg. (69%).

Hydrogenation of 2,4-diphenyl-Δ^1-pyrroline (2.21 g.) in ethanol (20 ml.) was effected in 5 hours at 25° and 45 p.s.i. in the presence of 1 g. of freshly prepared Raney nickel. The oily product (1.92 g.) distilled at 150–155° at 1 mm. pressure and was treated with 1.8 ml. of phenyl isothiocyanate in the usual manner. The resulting phenylthiourea (2.06 g.) formed colorless plates, m.p. 188–189°, which did not depress the m.p. of the phenylthiourea prepared from authentic 2,4-diphenylpyrrolidine.[28]

When 15 g. of 1,3-diphenyl-4-nitro-1-butanone (I) in 150 ml. of anhydrous ethyl acetate was hydrogenated for 26 hours under similar conditions in the presence of 5 g. of freshly prepared Raney nickel, 2,4-diphenylpyrrolidine was again the product; yield 9.5 g. (77%), b.p. 155° at 1 mm. pressure. A liquid film of this base showed an infrared absorption maximum at 2.96 μ; in chloroform solution, at 2.98 μ. The phenylthiourea melted at 189–190° and did not depress the m.p. of a sample prepared from authentic 2,4-diphenylpyrrolidine.

A solution of 2,4-diphenyl-Δ^1-pyrroline (368 mg.) in absolute ethanol (10 ml.) was stirred with Raney nickel (1 g.) for 17.5 hours at 42°. Unchanged pyrroline (81%) was

(27) Microanalyses are by William Schenck and Joseph Pirie, both formerly of the University of Southern California, and by Dr. Adalbert Elek, Elek Microanalytical Laboratories, Los Angeles, Calif. Infrared spectra were obtained with a Perkin–Elmer model 13 double beam spectrophotometer with sodium chloride prism and cells. Melting points are uncorrected.

recovered as the picrate, m.p. 159–160°, and the residual oily material, after being washed with aqueous sodium hydroxide to remove excess picric acid, gave no phenylthiourea when treated with phenyl isothiocyanate.

Reduction of 1,3-Diphenyl-4-nitro-1-butanone (I) with Hydrazine and Raney Nickel.—During a period of 3 hours, a solution of 8 ml. of 85% hydrazine hydrate in 12 ml. of methanol was added to a mechanically stirred mixture of 10 g. of the nitro ketone I, 100 ml. of methanol and 2 g. of Raney nickel (4 months old) maintained at 35–40°. Stirring was continued for 3 hours after all nitro ketone had dissolved and the catalyst was then removed by filtration. Evaporation of the filtrate yielded an oil (from which a small amount of solid was filtered) which distilled at 150–158° at 12–13 mm. to give 3.53 g. (43%) of 2,4-diphenyl-Δ^1-pyrroline (IV), m.p. 47–50°. Recrystallized material did not depress the m.p. of the pyrroline obtained from the aforedescribed hydrogenation of nitro ketone I.

Reduction of 1,3-Diphenyl-4-nitro-1-butanone (I) with Zinc and Aqueous Ammonium Chloride.—To a mechanically-stirred mixture of 20 g. of nitro ketone I, 24 g. of ammonium chloride, 80 ml. of water and 330 ml. of methanol, maintained at a temperature of 10–15°, were added 4-g. portions of 90% zinc dust every 15 minutes until a total of 96 g. had been added. Stirring and cooling were prolonged for an additional period of 2 hours and the solids were then removed by filtration and washed with methanol. The combined filtrates were concentrated to a volume of 75 ml. under reduced pressure and the aqueous layer was decanted.

The residual oil partially solidified and was extracted with 50 ml. of ethyl acetate. The colorless insoluble solid (5.88 g.) melted at 202–212°; recrystallization from ethanol gave small needles, m.p. 227°.

Anal. Calcd. for $(C_{16}H_{15}N)_2ZnCl_2$: C, 66.39; H, 5.22; N, 4.84. Found: C, 66.30; H, 5.31; N, 4.35.

Distillation of the ethyl acetate solution yielded 5.25 g. (32%) of 2,4-diphenyl-Δ^1-pyrroline (IV), b.p. 162–165° at 3 mm., m.p. 45–47°. Recrystallized material did not depress the m.p. of the pyrroline obtained from hydrogenation of nitro ketone I.

In another instance, all zinc was removed from the filtered aqueous methanol reduction solution by precipitation with hydrogen sulfide. The filtered solution was then concentrated and extracted with ether continuously for at least 36 hours. Benzene was added to the ether extract to redissolve some oil which had separated. Distillation of the dried solution under reduced pressure then yielded 6.5 g. (39%) of 2,4-diphenyl-Δ^1-pyrroline.

2-Phenyl-Δ^1-pyrroline.—A sample of the base prepared by the method of Craig, Bulbrook and Hixon[24] distilled at 88–89° at 3 mm. and then separated from petroleum ether (b.p. 30–35°) in large colorless plates, m.p. 41–42°. Gabriel and Colman[3] reported 44–45°.

Anal. Calcd. for $C_{10}H_{11}N$: C, 82.71; H, 7.64; N, 9.65. Found: C, 82.53; H, 7.59; N, 9.61.

The infrared absorption spectrum determined on a liquid film of the base showed principal maxima at 3.22, 3.36, 6.18, 6.34, 6.68, 6.90, 7.47, 9.54, 9.72, 10.10, 10.34, 10.85, 13.10 (broad) and 14.37 μ (broad).

The base decolorized bromine in carbon tetrachloride solution but not 2% potassium permanganate in acetone.

The hydrochloride was crystallized from a mixture of ethyl acetate and ether; m.p. 210.5–212.5° with sintering from 205°. Gabriel and Colman[3] reported 210–212° with sintering from 200°.

Anal. Calcd. for $C_{10}H_{12}ClN$: C, 66.12; H, 6.66; N, 7.71. Found: C, 65.57; H, 6.53; N, 8.14.

The hydrochloride showed infrared absorption maxima (Nujol mull) at 3.88 (broad), 5.33, 6.06, 6.25, 7.51, 7.60, 8.41, 8.67, 9.46, 10.16, 10.69 (broad) and 13.19 μ (broad).

The picrate of 2-phenyl-Δ^1-pyrroline separated from ethanol in glistening plates, m.p. 196.5–198.5° dec. Gabriel and Colman reported 198° and Sonn[3] 198° dec.

2-Phenyl-Δ^1-pyrroline Methiodide.—A mixture of 0.58 g. of the base, 5 ml. of 12% sodium hydroxide in aqueous methanol (2.5:1) and 1.0 g. of dimethyl sulfate was stirred at 62° for 1.5 hours and then allowed to stand at 25° for 12 hours. After being twice extracted with ether, the aqueous phase of the reaction mixture was made slightly acidic with hydrochloric acid. Dropwise addition of concentrated aqueous sodium iodide afforded colorless platelets of the methiodide in 44% yield, m.p. 221–224°. Recrystallization from ethanol raised the m.p. to 237–238°.

Anal. Calcd. for $C_{11}H_{14}IN$: C, 46.01; H, 4.91; N, 4.88; I, 44.20. Found: C, 45.71; H, 5.02; N, 4.59; I, 44.05.

Behavior of 2-Phenyl-Δ^1-pyrroline toward Methylmagnesium Iodide.—A Zerewitinoff determination in anisole at 29° showed 0.02 mole of active hydrogen and 0.01 mole of Grignard reagent addition. Unchanged pyrroline was recovered in 93.4% yield in the manner previously described for the 2,4-diphenyl analog.

An attempt was made to force a reaction between 2-phenyl-Δ^1-pyrroline and Grignard reagent in the following manner. Over a period of 45 minutes, a solution of 2.0 g. of the base in 25 ml. of anisole was added to the Grignard reagent prepared from 3.1 ml. of methyl iodide, 1.16 g. of magnesium and 25 ml. of anisole. The mixture was heated on a steam-bath during addition of the base and then for an additional period of 2.5 hours. Stirring was continued at 25° for 2.2 hours and then the mixture was decomposed with aqueous ammonium chloride. After removal of anisole the residual oil yielded 4.408 g. (85.4%) of the picrate of 2-phenyl-Δ^1-pyrroline which did not depress the m.p. of an authentic sample.

A slurry of the picrate in ether was shaken with 10% aqueous lithium hydroxide. The ether layer yielded 75.5% of 2-phenyl-Δ^1-pyrroline which did not depress the m.p. of an authentic sample and whose infrared absorption spectrum was identical with that of an authentic sample.

Acetylation of 2-phenyl-Δ^1-pyrroline, as described for the 2,4-diphenyl analog, produced 4-acetylamino-1-phenyl-1-butanone (V) in 73% yield, m.p. 89–93.5°. Recrystallization from aqueous ethanol or from ethyl acetate furnished colorless platelets, m.p. 94–95°.

Anal. Calcd. for $C_{12}H_{15}NO_2$: C, 70.22; H, 7.36; N, 6.82. Found: C, 70.04; H, 7.27; N, 6.54.

The infrared absorption spectrum determined on a Nujol mull of V showed principal maxima at 3.00 μ (N—H), 5.97 μ (ketone C=O), 6.07 μ and 6.12 μ (amido C=O), 6.26 μ (phenyl) and 6.41–6.46 μ (amide).

Benzoylation of 2-phenyl-Δ^1-pyrroline, as described for the 2,4-diphenyl analog, yielded 64% of crude product, m.p. 120–123°. Recrystallization from acetone or ethanol gave pure 4-benzoylamino-1-phenyl-1-butanone (VI) in colorless platelets, m.p. 124.5–125.5°. Gabriel and Colman[3] and Sonn[3] obtained benzoyl derivatives melting at 125–126 and 126°, respectively.

Anal. Calcd. for $C_{17}H_{17}NO_2$: C, 76.38; H, 6.41; N, 5.24. Found: C, 76.51; H, 6.23; N, 5.04.

A Nujol mull of VI displayed infrared absorption maxima at 3.05 μ (N—H), 5.97 μ (ketone C=O), 6.13 μ (amido C=O), 6.27 μ, 6.37 μ, and 6.45, 6.48 and 6.52 μ (amide triplet) and 6.73 μ; in chloroform solution at 2.93–2.99 μ (N—H), 5.95 μ (ketone C=O), 6.02 μ (amido C=O), 6.27 μ, 6.34 μ and 6.74 μ.

Heterocyclic Compounds. V. β-Pyridyl β-Styryl Ketone[1]

BY MILTON C. KLOETZEL AND FRANCIS L. CHUBB

RECEIVED MARCH 18, 1957

The base-catalyzed condensation of benzaldehyde with 3-acetylpyridine can be made to yield β-pyridyl β-styryl ketone (I) or 1,3,5-trinicotinoyl-2,4-diphenylpentane (VI). Michael type condensations of I with nitroalkanes, alkyl malonates, fluorene and 9-carboethoxyfluorene have been effected. The reaction with fluorene produced mixtures of the expected adduct XII and a trimolecular product. However the diethylamine-catalyzed condensation of I with 9-carboethoxyfluorene afforded a quantitative yield of the normal adduct XIII.

Reduction of γ-nitro ketones II–V by methods which have been explored in our laboratory[2,3] might be expected to yield a series of pyrrolidines and pyrrolines related to nicotine. Anticipating such studies, we have prepared the requisite β-pyridyl β-styryl ketone (I) and have investigated some of its reactions, including its conversion to the nitro ketones II–V.

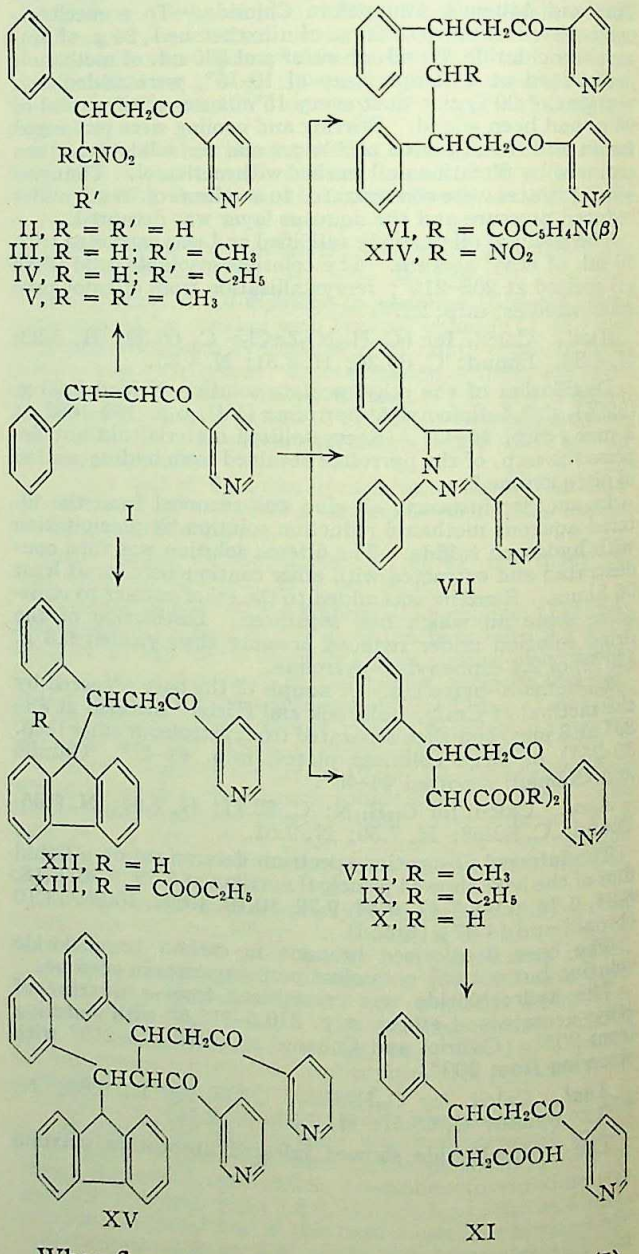
Ketone I was obtained in 92% yield when aqueous sodium hydroxide solution was added slowly to an equimolar mixture of benzaldehyde and 3-acetylpyridine in a large volume of water. Under more strongly basic conditions the condensation was more complex and yielded 1,3,5-trinicotinoyl-2,4-diphenylpentane (VI).[4] Effected in ethanol solution in the presence of benzyltrimethylammonium hydroxide, the reaction afforded two diastereoisomers of VI.

β-Pyridyl β-styryl ketone (I) reacted with phenylhydrazine in boiling acetic acid or in ethanol at room temperature under the catalytic influence of benzyltrimethylammonium hydroxide to yield the same product. Since hot acetic acid is known[5,6] to rearrange phenylhydrazones of α,β-unsaturated ketones, this substance has been designated 1,5-diphenyl-3-(3-pyridyl)-pyrazoline (VII). In dilute ethanolic acetic acid at room temperature, ketone I reacted with two molecules of phenylhydrazine, presumably producing the phenylhydrazone of 2-phenylhydrazino-2-phenylethyl 3-pyridyl ketone.

Diethylamine effectively catalyzed the Michael addition of nitro alkanes to β-pyridyl β-styryl ketone (I), affording nitro ketones II–V in 73–95% yields. Both nitroethane and 1-nitropropane yielded mixtures of diastereoisomeric nitro ketones.

The use of a 10:1 molar ratio of nitromethane to β-pyridyl β-styryl ketone effectively suppressed diketone formation and permitted the isolation of II in 75% yield. However, two diastereoisomers of 1,5-dinicotinoyl-3-nitro-2,4-diphenylpentane (XIV) resulted when the unsaturated ketone was employed in excess.

Diethylamine likewise promoted the reaction of β-pyridyl β-styryl ketone (I) with methyl and ethyl malonate to form adducts VIII and IX, respectively. These were hydrolyzed to the corresponding malonic acid X, which subsequently was decarboxylated at 180° to produce 5-oxo-3-phenyl-5-(3-pyridyl)-pentanoic acid (XI).



When fluorene and β-pyridyl β-styryl ketone (I), in molar ratio of 2 to 1, were allowed to react in aqueous pyridine containing sodium hydroxide (conditions which afforded[7] a quantitative yield of adduct in the case of benzalacetophenone), there was obtained 39% of the expected adduct XII, to-

gether with 55% of a trimolecular condensation product. The yield of XII was increased to 62% when the molar ratio of fluorene to I was 10 to 1 but still 11% of the trimolecular product was formed.

Neither 9-ethylfluorene nor 9-benzylfluorene will add to the highly reactive acceptor, acrylonitrile, in the presence of a strongly basic catalyst.[8] Therefore it is not likely that our trimolecular condensation product results from addition of a second molecule of I at the 9-position of the fluorene nucleus in XII. Accordingly, XV is proposed as the more probable structure of the trimolecular product.

To circumvent the formation of trimolecular products in the Michael condensation, we examined the reaction of I with the more reactive addendum, 9-carboethoxyfluorene. 9-Carboalkoxyfluorenes have been reported to add to unsaturated nitriles[9,10] or ketones[11] but always in the presence of potassium hydroxide. We now have found that the condensation of 9-carboethoxyfluorene with β-pyridyl β-styryl ketone (I) is efficiently catalyzed by diethylamine and affords a quantitative yield of adduct XIII.

Experimental[12]

Ethyl nicotinate was obtained consistently in yields of 67%[13] by the following procedure. A mixture of nicotinic acid (200 g.), absolute ethanol (400 ml.) and sulfuric acid (120 ml.) was heated to reflux for 3 hours and then concentrated by distillation of 200 ml. of ethanol. The cooled solution was added slowly, with stirring, to 2000 g. of 20% aqueous sodium carbonate and the ester was extracted with ether. Distillation of the dried extract yielded 166 g. of ester, b.p. 132–133° at 14 mm.

3-Acetylpyridine.—Rapid evolution of hydrogen began soon after ethyl nicotinate (50 g.), ethyl acetate (44 g.) and sodium hydride (12 g.) were mixed by stirring under a nitrogen atmosphere. After the initial violence of the reaction had subsided the mixture was warmed on a steam-bath for 3 hours and excess sodium hydride was then decomposed by the cautious addition of 10 ml. of ethanol and 200 ml. of water. Concentrated hydrochloric acid (100 ml.) was added to the cooled solution and the mixture was then heated to reflux for 2 hours. After removal of excess ethyl acetate by distillation, the cooled solution was made alkaline by addition of 50% aqueous sodium hydroxide and the precipitated oil was extracted with ether. Distillation of the dried extract under reduced pressure yielded 33.6 g. (84%) of colorless 3-acetylpyridine, b.p. 80° at 2–3 mm.

A similar condensation was effected when a mixture of ethyl nicotinate (198 g.), ethyl acetate (176 g.) and commercial sodium methoxide (102 g.) was heated on a steam-bath for 3 hours with continuous stirring. To the cooled mixture was added 800 ml. of water and 400 ml. of concentrated acid and the afore-described procedure was followed; yield 130 g. (82%) of 3-acetylpyridine.

The use of sodium ethoxide to effect this condensation afforded 81–85% yields of 3-acetylpyridine.[13,14]

β-Pyridyl β-styryl ketone (I) was obtained in 92% yield from the reaction of 3-acetylpyridine with benzaldehyde, following a procedure described by Engler and Engler[4b] for the preparation of the α-pyridyl isomer. The product, after distillation under reduced pressure, separated from ethanol or heptane in green-yellow needles, m.p. 84–85°.

Anal. Calcd. for $C_{14}H_{11}NO$: C, 80.36; H, 5.30. Found: C, 80.49; H, 5.27.

A picrate was formed in quantitative yield when equimolar ethanol solutions of ketone I and picric acid were mixed, and separated from ethanol in yellow needles, m.p. 199–200°.

Anal. Calcd. for $C_{20}H_{14}N_4O_8$: C, 54.79; H, 3.22. Found: C, 54.74; H, 3.56.

1,3,5-Trinicotinoyl-2,4-diphenylpentane (VI).—A solution of 3-acetylpyridine (6.0 g.) and benzaldehyde (5.4 g.) in ethanol (25 ml.), to which had been added 0.5 ml. of 40% benzyltrimethylammonium hydroxide solution, was allowed to stand at room temperature for 2 weeks. The solid precipitate was separated into two fractions by recrystallization from ethanol. The higher melting stereoisomer of VI (3.1 g.) formed colorless needles, m.p. 240–241°.

Anal. Calcd. for $C_{35}H_{29}N_3O_3$: N, 7.79. Found: N, 7.84.

A second isomer of VI (0.7 g.) also formed colorless needles but melted at 203–205°.

Anal. Calcd. for $C_{35}H_{29}N_3O_3$: N, 7.79. Found: N, 7.61.

When 10.8 g. of benzaldehyde and 12.1 g. of 3-acetylpyridine were allowed to react under the conditions employed by Kohler and Chadwell[15] for the preparation of benzalacetophenone, a yellow gum was obtained. Recrystallization from benzene afforded 8.1 g. of the stereoisomer of VI melting at 203–205°.

Reaction of β-Pyridyl β-Styryl Ketone with Phenylhydrazine.—Mild evolution of heat occurred when 0.1 ml. of 40% benzyltrimethylammonium hydroxide solution was added to a solution of ketone I (5.2 g.) and phenylhydrazine (2.7 g.) in ethanol (10 ml.). The solid which separated when the solution was allowed to stand for 12 hours at room temperature was crystallized from ethanol and afforded 5.4 g. (73%) of **1,5-diphenyl-3-(3-pyridyl)-pyrazoline (VII)** in green-yellow needles, m.p. 126–128°.

Anal. Calcd. for $C_{20}H_{17}N_3$: C, 80.23; H, 5.72. Found: C, 80.18; H, 5.79.

The same compound was formed when a mixture of β-pyridyl β-styryl ketone (5.2 g.), phenylhydrazine (2.7 g.) and acetic acid (25 ml.) was heated to reflux for 2 hours. The solvent was evaporated under reduced pressure and 6 ml. of concentrated hydrochloric acid was added. Crystallization of the residue from aqueous ethanol yielded the pyrazoline hydrochloride (3.9 g.) in yellow plates, m.p. 224–240° dec., from which VII was obtained by neutralization in ethanol with dilute aqueous sodium hydroxide.

When equimolar quantities of VII and picric acid were combined in hot ethanol, the **picrate of 1,5-diphenyl-3-(3-pyridyl)-pyrazoline** was obtained in quantitative yield. This substance sometimes separated from ethanol in orange-red leaflets, m.p. 195–196°, but from a mixture of ethanol and acetone in red crystals, m.p. 193–194°.

Anal. Calcd. for $C_{26}H_{20}N_6O_7$: C, 59.09; H, 3.83. Found: C, 58.96; H, 4.18.

Upon standing at room temperature for 3 hours, a solution of ketone I (1 g.), phenylhydrazine (600 mg.) and acetic acid (0.15 ml.) in 95% ethanol (10 ml.) deposited 600 mg. of crystalline solid, m.p. 145–148°. Several crystallizations from ethanol raised the m.p. of the presumed phenylhydrazone of 2-phenylhydrazino-2-phenylethyl 3-pyridyl ketone to 153–155°.

Anal. Calcd. for $C_{26}H_{25}N_5$: C, 76.62; H, 6.18. Found: C, 76.42; H, 6.35.

Reaction of β-Pyridyl β-Styryl Ketone with Nitro Alkanes. (a) With Nitromethane.—When a mixture of ketone I (10.4 g.), nitromethane (61 g.), methanol (30 ml.) and diethylamine (7.3 g.) was allowed to stand at room temperature for 12 hours and the solvents were then removed under reduced pressure, there remained a solid residue which crystallized from a mixture of ethanol and petroleum ether (b.p. 63–69°) to give 10.1 g. (75%) of **4-nitro-3-phenyl-1-(3-pyridyl)-1-butanone (II)** in colorless needles, m.p. 93–95°. Further crystallization raised the m.p. to 97–99°.

Anal. Calcd. for $C_{15}H_{14}N_2O_3$: C, 66.65; H, 5.22. Found: C, 66.33; H, 5.04.

The oxime of II[16] formed colorless needles, m.p. 113–114°.

Anal. Calcd. for $C_{15}H_{15}N_3O_3$: C, 63.14; H, 5.30; N, 14.73. Found: C, 63.23; H, 5.52; N, 14.52.

A solution of ketone I (5.2 g.), nitromethane (0.76 g.) and diethylamine (0.27 g.) in 95% ethanol (50 ml.) was allowed to stand at room temperature. After 4 days, the precipitate (2.1 g., m.p. 200–206°) was filtered and recrystallized from dioxane. 1,5-Dinicotinoyl-3-nitro-2,4-diphenylpentane (XIV) formed colorless needles, m.p. 215–216° dec., containing one molecule of dioxane of crystallization.

Anal. Calcd. for $C_{33}H_{33}N_3O_6$: C, 69.82; H, 5.86. Found: C, 69.74; H, 5.80.

A sample dried at 75° in vacuum for 2 hours still contained one-half molecule of dioxane of crystallization.

Anal. Calcd. for $C_{31}H_{29}N_3O_5$: C, 71.11; H, 5.58. Found: C, 71.06; H, 5.20.

Dioxane of crystallization was removed completely by heating the crystals to constant weight at 95° in vacuum. The substance then melted at 220–222° dec.

Anal. Calcd. for $C_{29}H_{25}N_3O_4$: C, 72.63; H, 5.25. Found: C, 72.57; H, 5.31.

The original reaction mixture from which XIV had been filtered was evaporated under reduced pressure. Crystallization of the residue from chloroform and then from a mixture of acetone and benzene afforded 1.4 g. of a second diastereoisomer of XIV in colorless needles, m.p. 198–199°, containing one molecule of acetone of crystallization.

Anal. Calcd. for $C_{32}H_{31}N_3O_6$: N, 7.82. Found: N, 7.48.

Solvent of crystallization was removed by heating to constant weight at 95° in vacuum.

Anal. Calcd. for $C_{29}H_{25}N_3O_4$: C, 72.63; H, 5.25; N, 8.76. Found: C, 72.70; H, 5.26; N, 8.63.

(b) With Nitroethane.—After standing for 12 hours at room temperature, a mixture of ketone I (5.2 g.), nitroethane (5.6 g.), diethylamine (0.55 g.) and methanol (10 ml.) was evaporated under reduced pressure and the residual liquid mixture of nitro ketones was dissolved in a mixture of ethanol (20 ml.) and concentrated hydrochloric acid (3 ml.). The solution gradually deposited 2.8 g. of **4-nitro-3-phenyl-1-(3-pyridyl)-1-pentanone hydrochloride** in colorless needles, m.p. 165–170°. Several crystallizations from absolute ethanol raised the m.p. to 178–179°. The hydrochloride was decomposed by addition of dilute aqueous sodium hydroxide in the presence of ether. Evaporation of the ether afforded **4-nitro-3-phenyl-1-(3-pyridyl)-1-pentanone** (III) which separated from a mixture of ethanol and petroleum ether in colorless needles, m.p. 91–92°.

Anal. Calcd. for $C_{16}H_{16}N_2O_3$: C, 67.59; H, 5.67. Found: C, 67.67; H, 5.03.

With an equivalent quantity of picric acid in 95% ethanol, this nitro ketone formed a **picrate** which separated from ethanol in yellow needles, m.p. 134–135°.

Anal. Calcd. for $C_{22}H_{19}N_5O_{10}$: C, 51.46; H, 3.73. Found: C, 51.69; H, 3.74.

The **oxime** of this isomer of III formed colorless needles, m.p. 152–154°.

Anal. Calcd. for $C_{16}H_{17}N_3O_3$: C, 64.20; H, 5.72; N, 14.04. Found: C, 64.33; H, 6.14; N, 13.98.

The original reaction mixture, from which the aforementioned hydrochloride had been filtered, was evaporated and the residue was shaken with aqueous sodium hydroxide and ether. Evaporation of the ethereal extract left a residue which, together with 3.7 g. of picric acid, was dissolved in the minimum volume of boiling 95% ethanol. Upon cooling, the solution deposited 4.9 g. of the picrate of a diastereoisomeric nitro ketone III which formed yellow needles when recrystallized from 95% ethanol, m.p. 155–156°.

Anal. Calcd. for $C_{22}H_{19}N_5O_{10}$: C, 51.46; H, 3.73. Found: C, 51.74; H, 3.68.

The diastereoisomeric **4-nitro-3-phenyl-1-(3-pyridyl)-1-pentanone** (III), formed by decomposition of this picrate with 3% aqueous ethanolamine in the presence of ether, separated from a mixture of ethanol and petroleum ether in colorless needles, m.p. 82–84°.

Anal. Calcd. for $C_{16}H_{16}N_2O_3$: C, 67.59; H, 5.67. Found: C, 67.97; H, 5.93.

(c) With 1-Nitropropane.—A solution of ketone I (10.4 g.), 1-nitropropane (13.4 g.) and diethylamine (1.1 g.) in methanol (20 ml.) deposited 12.7 g. (86%) of **4-nitro-3-phenyl-1-(3-pyridyl)-1-hexanone** (IV), melting above 142°, upon standing at room temperature. The ketone separated from methanol in colorless needles, m.p. 145–146°.

Anal. Calcd. for $C_{17}H_{18}N_2O_3$: C, 68.43; H, 6.08. Found: C, 68.56; H, 6.22.

The **oxime** of IV formed colorless needles, m.p. 143–144°.

Anal. Calcd. for $C_{17}H_{19}N_3O_3$: C, 65.16; H, 6.11. Found: C, 64.95; H, 6.20.

The original Michael condensation mixture, from which IV had been filtered, was evaporated under reduced pressure to yield a residue which was recrystallized from a mixture of absolute ethanol and petroleum ether. The resulting diastereoisomeric **4-nitro-3-phenyl-1-(3-pyridyl)-1-hexanone** (1.5 g., 10%) formed colorless needles, m.p. 84–85°.

Anal. Calcd. for $C_{17}H_{18}N_2O_3$: C, 68.43; H, 6.08. Found: C, 68.52; H, 5.95.

The **picrate** of this isomer formed yellow needles, m.p. 138–139°.

Anal. Calcd. for $C_{23}H_{21}N_5O_{10}$: C, 52.37; H, 4.01. Found: C, 52.66; H, 4.17.

The **oxime** separated from aqueous ethanol in colorless needles, m.p. 152–153° dec.

Anal. Calcd. for $C_{17}H_{19}N_3O_3$: C, 65.16; H, 6.11; N, 13.41. Found: C, 65.13; H, 6.20; N, 13.63.

(d) With 2-Nitropropane.—Pure **4-methyl-4-nitro-3-phenyl-1-(3-pyridyl)-1-pentanone** (V), m.p. 141–142°, separated in colorless needles when a solution of ketone I (10.4 g.), 2-nitropropane (6.7 g.) and diethylamine (0.55 g.) in methanol (20 ml.) was allowed to stand at room temperature for 3 days; yield 14.0 g. (95%).

Anal. Calcd. for $C_{17}H_{18}N_2O_3$: C, 68.43; H, 6.08. Found: C, 68.41; H, 6.52.

The **picrate** formed yellow leaflets, m.p. 189–190°.

Anal. Calcd. for $C_{23}H_{21}N_5O_{10}$: C, 52.37; H, 4.01. Found: C, 52.60; H, 4.33.

When 1 g. of V was warmed with 0.5 ml. of phenylhydrazine, 10 ml. of 95% ethanol and 2 drops of acetic acid, there were obtained two isomeric **phenylhydrazones**. One crystallized directly in yellow leaflets, m.p. 173–175°, when the reaction mixture was cooled; yield 600 mg. (46%).

Anal. Calcd. for $C_{23}H_{24}N_4O_2$: C, 71.11; H, 6.23. Found: C, 71.31; H, 6.38.

Concentration of the reaction yielded 300 mg. (23%) of an isomeric phenylhydrazone in colorless needles, m.p. 128–130°.

Anal. Calcd. for $C_{23}H_{24}N_4O_2$: C, 71.11; H, 6.23. Found: C, 71.42; H, 6.19.

Reaction of β-Pyridyl β-Styryl Ketone with Malonic Acid Esters.—After standing for 2 days at room temperature, a solution of ketone I (5.2 g.), dimethyl malonate (3.3 g.) and diethylamine (0.55 g.) in methanol (10 ml.) had deposited 7.8 g. of colorless needles. Concentration of the solution brought the total yield of **dimethyl 1-phenyl-3-(3-pyridyl)-3-oxopropylmalonate** (VIII) to 8.3 g. (98%), colorless needles, m.p. 95–96°.

Anal. Calcd. for $C_{19}H_{19}NO_5$: C, 66.85; H, 5.61. Found: C, 66.79; H, 5.46.

Ketone I reacted similarly with diethyl malonate in ethanol to give **diethyl 1-phenyl-3-(3-pyridyl)-3-oxopropylmalonate** (IX), m.p. 76–77°, in 68% yield.

Ester VIII (5 g.) was hydrolyzed readily when it was heated at 60–70° for 5 minutes with 20% aqueous potassium hydroxide (50 ml.). The resulting cooled solution was diluted with water to 100 ml. and any unhydrolyzed ester was separated. After acidification of the solution with concentrated sulfuric acid, aqueous sodium hydroxide was added as long as **1-phenyl-3-(3-pyridyl)-3-oxopropylmalonic acid** (X) precipitated; yield 3.6 g. (78%), m.p. 147–147.5°. The acid separated from aqueous ethanol in colorless needles, m.p. 149–150°.

Anal. Calcd. for $C_{17}H_{15}NO_5$: C, 65.17; H, 4.82. Found: C, 65.17; H, 4.83.

The same acid was obtained when ester IX was hydrolyzed.

When 5 g. of acid X was heated to 180° until evolution of carbon dioxide ceased, there remained 4 g. (93%) of 5-oxo-3-phenyl-5-(3-pyridyl)-pentanoic acid which separated from 95% ethanol in colorless needles, m.p. 147–148°.

Anal. Calcd. for $C_{16}H_{15}NO_3$: C, 71.36; H, 5.61. Found: C, 71.24; H, 5.68.

Reaction of β-Pyridyl β-Styryl Ketone with Fluorene Derivatives.—Ketone I (5.2 g.) was allowed to react with fluorene (8.4 g.) and 50% aqueous sodium hydroxide (5 ml.) in pyridine (50 ml.) for 12 hours at room temperature and the solvents were then removed under reduced pressure. Crystallization of the residue from benzene yielded 4.0 g. (55%) of 5-(9-fluoryl)-4-nicotinoyl-3,5-diphenyl-1-(3-pyridyl)-1-pentanone (XV), m.p. 258–260°.

Anal. Calcd. for $C_{41}H_{32}N_2O_2$: C, 84.22; H, 5.52. Found: C, 84.07; H, 5.72.

The mother liquor from crystallization of XV was evaporated and the residue was dissolved in hot 95% ethanol. Excess fluorene separated from the cooled solution. Addition of 3.0 g. of picric acid to the filtered ethanol solution produced 5.8 g. (representing 39% of XII) of the picrate of 9-(2-nicotinoyl-1-phenylethyl)-fluorene in yellow needles, m.p. 180–182°.

Anal. Calcd. for $C_{33}H_{24}N_4O_8$: C, 65.55; H, 4.00; N, 9.26. Found: C, 65.68; H, 3.87; N, 9.18.

When 2 g. of the picrate was shaken with 100 ml. of 3% aqueous ethanolamine there was obtained 1.0 g. of ketone XII, which melted at 105–106° after crystallization from ethanol.

Anal. Calcd. for $C_{27}H_{21}NO$: C, 86.37; H, 5.64. Found: C, 86.48; H, 5.74.

The yields of XV and XII were 11 and 62%, respectively, when this condensation was repeated with a 10-to-1 molar ratio of fluorene to ketone I.

A mixture of ketone I (5.2 g.), 9-carboethoxyfluorene (5.9 g.) and 95% ethanol (20 ml.) was warmed until all solids had dissolved and diethylamine (0.5 g.) was then added. After 2 days at room temperature the crystalline adduct was filtered. Concentration of the mother liquor afforded additional material making the yield of 9-carboethoxy-9-(2-nicotinoyl-1-phenylethyl)-fluorene (XIII) essentially quantitative; m.p. 87–91°. Recrystallization from ethanol raised the m.p. to 91–92°.

Anal. Calcd. for $C_{30}H_{25}NO_3$: C, 80.51; H, 5.63. Found: C, 80.48; H, 5.82.

The Preparation of Methyl-substituted DL-Phenylalanines

BY ROSS R. HERR, TAKASHI ENKOJI AND JOSEPH P. DAILEY

RECEIVED DECEMBER 26, 1956

A number of methyl-substituted phenylalanines and the corresponding diethyl acetamidomalonate intermediates have been prepared. The amino acids were evaluated as phenylalanine antagonists in the *E. coli* assay. The substituted malonates were prepared by the reaction between sodium diethyl acetamidomalonate and the appropriate benzyl bromide, benzyl chloride or benzyltrimethylammonium iodide. A modified procedure for the condensation of a quaternary iodide with sodium diethyl acetamidomalonate was devised. Hydrolysis and decarboxylation of these condensation products resulted in 2-methyl-, 3-methyl-, 4-methyl-, 2,3-dimethyl-, 2,4-dimethyl-, 2,5-dimethyl-, 2,6-dimethyl, 3,4-dimethyl-, 3,5-dimethyl- and 2,4,6-trimethylphenylalanines. Of these, only 3-methylphenylalanine will inhibit completely the growth of *E. coli*. Each of the compounds will reverse the growth-inhibiting effect of β-2-thienylalanine.

In view of the potential usefulness of compounds which are competitively antagonistic to specific amino acids, we have prepared a series of compounds which are chemically similar to phenylalanine. Each compound possesses the basic structure of phenylalanine with one or more methyl groups in different positions on the aromatic ring.

Previous investigators have shown that some *dl*-phenylalanines substituted in the phenyl ring act as competitive antagonists in the utilization of phenylalanine by microörganisms. Some of these compounds also are capable of replacing phenylalanine in reversing the inhibitory action of other competitive antagonists such as β-2-thienylalanine.[1–3]

The effect of methyl substituents in these phenylalanines would be expected to be more steric than polar. Information pertaining to the relationship between steric and polar effects and that between utilization and competitive antagonism could possibly be obtained by means of these methyl-substituted phenylalanines. Alkyl substitution in any position on the phenyl ring would hinder the hydroxylation of that position, and this, in turn, would block some of the possible pathways through which this amino acid could be metabolized.

Dakin[4] has prepared 4-methylphenylalanine and found it to cause a 35% inhibition of DOPA decarboxylase in dogs. In later studies,[3] it was found to reverse the inhibitory action of β-2-thienylalanine in *E. coli*. Burckhalter and Stephens[1] prepared 3-methylphenylalanine, and Harper, Furst and Morris[5] found that this compound did not inhibit the growth of *Leuconostoc mesenteroides* P-60, a lactobacillus, in concentrations up to 100 γ per cc. of medium.

The compounds listed in Table I were synthesized by condensing benzyl halides or benzyltrimethylammonium iodides with sodium diethyl acetamidomalonate, and the resulting substituted malonic esters were hydrolyzed and decarboxylated by refluxing with a halogen acid.[6]

Three methods were used for the preparation of the substituted malonic esters, and the data pertaining to these products are summarized in Table II. Method A consists of condensing diethyl acetamidomalonate with the methyl-substituted ben-

zyl halide, using sodium hydride as the condensing agent and toluene as the solvent.[6] The three xylyl bromides were obtained commercially. Side-chain bromination of mesitylene with N-bromosuccinimide resulted in 3,5-dimethylbenzyl bromide. Chloromethylation of *p*-xylene, *m*-xylene and mesitylene yielded 2,4-dimethyl-, 2,5-dimethyl- and 2,4,6-trimethylbenzyl chlorides, respectively.[7,8]

In Method B, a methyl-substituted benzyl chloride was condensed with diethyl acetamidomalonate in the presence of an equivalent amount of sodium ethoxide in ethanol. The starting 3,4-dimethylhexyl chloride was prepared by the chlorination of 3,4-dimethylbenzyl alcohol with thionyl chloride. The alcohol, in turn, was prepared by the reaction of the Grignard reagent from 4-bromo-*o*-xylene[9] with formaldehyde.[10]

A convenient method for the preparation of the 2,3-dimethyl- and the 2,6-dimethylbenzyl halides was not found, and the corresponding benzyl trimethylammonium iodides of these compounds were prepared. In Method C, these quaternary iodides were condensed with sodium diethyl acetamidomalonate in xylene by a procedure adapted from that used by Snyder and Smith.[11] The successive treatment of benzyltrimethylammonium iodide with sodium amide in liquid ammonia was used to prepare 2,3-dimethylbenzyltrimethylammonium iodide.[12] A Sandmeyer reaction of 2,6-dimethylaniline, using a mixture of sodium, potassium and cuprous cyanides yielded 2-cyano-*m*-xylene, which was reduced to 2,6-dimethylbenzylamine with lithium aluminum hydride. Methylation and quaternization of this amine with methyl iodide resulted in 2,6-dimethylbenzyltrimethylammonium iodide.

The methyl-substituted phenylalanines, which were prepared from the hydrolysis and decarboxylation of these condensation products, were evaluated as amino acid antagonists in the *E. coli* assay as described by Dittmer.[13] The concentrations of amino acids needed to reverse the effect of 5 γ of β-2-thienylalanine per 6 cc. of medium were also determined. These data are summarized in Table I.

Acknowledgments.—The authors wish to express their appreciation to Mrs. G. M. Robinson who conducted the microbiological assays and to Dr. T. J. Bardos for helpful discussions and suggestions.

Experimental

Side-chain Bromination of Mesitylene with N-Bromosuccinimide.—A mixture of 63.0 g. (0.53 mole) of mesitylene, 89.0 g. (0.50 mole) of N-bromosuccinimide, 0.5 g. of benzoyl peroxide and 200 ml. of dry carbon tetrachloride was refluxed

for 1 hr. under anhydrous conditions. After filtration, the solvent was removed under reduced pressure, and the residue was distilled at 10 mm. pressure. The material boiling up to 140° was redistilled at 8–10 mm., yielding 53.0 g. (53%) of 3,5-dimethylbenzyl bromide, b.p. 100–105°.

Chloromethylation of Mesitylene.—A stream of hydrogen chloride gas was bubbled through a stirred mixture of 120 g. (1.0 mole) of mesitylene, 100 g. (1.3 moles) of 38% aqueous formaldehyde and 450 ml. of concentrated hydrochloric acid for 1 hr. with the temperature maintained at 60–70°. The two layers were separated at room temperature, and after extracting the aqueous layer with ether, the organic layer and ether extracts were combined, washed with water and dried over anhydrous magnesium sulfate. After distillation of the ether, a crystalline material separated from the cooled residue. It was removed by filtration and recrystallized from *n*-hexane to give 40.0 g. (19%) of α^2,α^4-dichloropentamethylbenzene, m.p. 103–106°. The filtrate was fractionated at 16–18 mm. pressure and the material which distilled at 60–145° was redistilled at 15–16 mm. to give 46.0 g. (27%) of 2,4,6-trimethylbenzyl chloride, b.p. 125–126°.

Chlorination of 3,4-Dimethylbenzyl Alcohol.—A solution of 18.2 g. (0.15 mole) of thionyl chloride in 80 ml. of anhydrous ether was added dropwise with stirring to 9.8 g. (0.072 mole) of 3,4-dimethylbenzyl alcohol and 0.8 ml. of pyridine in 160 ml. of anhydrous ether. After 30 min., the mixture was washed with water, dried over anhydrous magnesium sulfate and distilled to remove the ether. The residue was distilled at 10 mm., and 3.8 g. (34%) of 3,4-dimethylbenzyl chloride was collected at 95–96°.[14]

2-Cyano-*m*-xylene.—A stirred mixture of 82.3 g. (0.68 mole) of 2,6-dimethylaniline in 400 ml. of 6 *N* hydrochloric acid was cooled to −5°, and a cold solution of 50.0 g. (0.73 mole) of sodium nitrite in 340 ml. of water was added dropwise. After 30 minutes, the mixture was neutralized with solid sodium bicarbonate and slowly added to a cold solution of 39.2 g. (0.80 mole) of sodium cyanide, 104.0 g. (1.6 moles) of potassium cyanide and 80.0 g. (0.89 mole) of cuprous cyanide in 500 ml. of water. After 30 minutes, the temperature was permitted to rise to 25° and maintained until the evolution of nitrogen had ceased. The mixture was steam distilled until 2 liters of distillate was collected in a well-cooled series of traps. The distillate was extracted with ether and washed with 2 *N* sodium hydroxide and water. After drying over anhydrous magnesium sulfate, the ether was removed by distillation and the residue crystallized upon cooling. The solid was recrystallized from *n*-hexane; yield 64.6 g. (66%), m.p. 89–91°.

Lithium Aluminum Hydride Reduction of 2-Cyano-*m*-xylene.—To a stirred suspension of 11.4 g. (0.3 mole) of lithium aluminum hydride in 30 ml. of anhydrous ether was added dropwise a solution of 26.2 g. (0.2 mole) of 2-cyano-*m*-xylene in 350 ml. of anhydrous ether. After 25 ml. of the nitrite solution was added, the reaction was heated until it was self-sustaining, and the addition was completed with occasional heating when necessary. The mixture was refluxed 30 minutes and, after cooling in an ice-bath, the excess lithium aluminum hydride was decomposed by the dropwise addition of 50 ml. of water. This was followed by 500 ml. of 20% sodium potassium tartrate solution and the aqueous emulsion was separated from the ether solution and re-extracted with ether. The ether layers were combined, washed with water, dried over anhydrous magnesium sulfate and the ether removed by distillation. The residue was distilled twice to yield 22.7 g. (84%) of 2,6-dimethylbenzylamine, b.p. 96–98°.

2,6-Dimethylbenzyltrimethylammonium Iodide.—To a stirred mixture of 72.6 g. (0.51 mole) of methyl iodide and 200 ml. of water was added 12.0 g. (0.3 mole) of sodium hydroxide pellets. A solution of 19.0 g. (0.14 mole) of 2,6-dimethylbenzylamine in 20 ml. of ethanol was added at a rate to maintain the temperature at approximately 50°. After stirring 2 hr., the mixture was cooled in ice and the precipitated solid was collected by filtration and dried. The dried solid was dissolved in 20 ml. of boiling methanol and the crystalline product which separated after addition of an equal volume of absolute ether was collected by filtration; yield 32.2 g. (75%), m.p. 197–201°. A sample for analysis was recrystallized from absolute methanol and the product partially decomposed at 194°, finally melting at 199–204.

Anal. Calcd. for $C_{12}H_{20}NI$: C, 47.2; H, 6.61; N, 4.59; I, 46.6. Found: C, 47.1; H, 6.27; N, 4.66; I, 42.4.

Preparation of Methyl-substituted Diethyl Benzylacetamidomalonates. Diethyl 4-Methylbenzylacetamidomalonate (IIIa) (Method A).—To a stirred solution of 65.0 g. (0.35 mole) of *p*-xylyl bromide in 50 ml. of dry redistilled toluene was added 8.4 g. (0.35 mole) of sodium hydride, followed by 72.0 g. (0.33 mole) of diethyl acetamidomalonate. The suspension was stirred and refluxed under anhydrous conditions for 8 hr., at which time the evolution of hydrogen, as indicated by a bubble counter, had almost ceased. The unreacted sodium hydride was decomposed by the addition of a few ml. of absolute ethanol, followed by a few ml. of 50% aqueous ethanol and then sufficient water to bring the volume of the aqueous layer to approximately 200 ml. The organic layer was separated and the aqueous layer was extracted with ether. The combined organic layer and ether extracts were washed thoroughly with water, dried over anhydrous sodium sulfate and filtered. Concentration of the filtrate to approximately 100 ml. and cooling in an ice-bath caused a crystalline product to separate. Two crops yielded 78.0 g. (74%), m.p. 108–110°.

Diethyl 3,4-Dimethylbenzylacetamidomalonate (VIIIa) (Method B).—To a solution of 1.3 g. (0.057 g. atom) of sodium in 70 ml. of dry absolute ethanol[15] was added 12.4 g. (0.057 mole) of diethyl acetamidomalonate, followed by 7.9 g. (0.051 mole) of crude 3,4-dimethylbenzyl chloride. The mixture was refluxed for 3 hr. under anhydrous conditions and filtered. The addition of 200 ml. of water caused the separation of an oil which crystallized upon cooling. The product was collected by filtration; yield 9.0 g. (53%), m.p. 106–109°.

Diethyl 2,6-Dimethylbenzylacetamidomalonate (VIIa) (Method C).—To a solution of 1.04 g. (0.045 g. atom) of sodium in 150 ml. of dry absolute ethanol was added 10.9 g. (0.050 mole) of diethyl acetamidomalonate, followed by 375 ml. of dry xylene. The mixture was distilled with stirring until the temperature reached 135° and approximately 200 ml. of distillate was collected. Crystalline sodium diethyl acetamidomalonate separated at this point.[16] The condenser was arranged for reflux and 13.6 g. (0.045 mole) of 2,6-dimethylbenzyltrimethylammonium iodide was added. The suspension was stirred and refluxed for 20 hr. and filtered. The xylene from the filtrate was removed under vacuum on the steam-bath. The last traces of the solvent were removed by adding 20 ml. of water and distilling to dryness. The residue was dissolved in 200 ml. of 95% ethanol, treated with charcoal and Celite and filtered. An equal volume of water was added to the filtrate, and cooling and scratching produced a crystalline solid which was collected by filtration; yield 13.2 g. (88%), m.p. 98–99°.

Hydrolysis and Decarboxylation of Methyl-substituted Diethyl Benzylacetamidomalonates. 3,5-Dimethylphenylalanine (IX).—A suspension of 33.5 g. (0.1 mole) of IXa in 400 ml. of 25% hydrochloric acid was refluxed for 8 hr., and the solid which separated was collected by filtration and extracted with 125 ml. of boiling water. The insoluble material from the extraction was separated by filtration to give 6.5 g. of unhydrolyzed starting material. The filtrate was concentrated to 100 ml., cooled in an ice-bath and the crystals collected; yield 18.5 g. (99%) based on recovery of 6.5 g. starting material. A solution of 5.0 g. (0.022 mole) of this amino acid hydrochloride in 200 ml. of hot water was neutralized to *p*H 7.0 with concentrated ammonium hydroxide, and the precipitate which formed upon cooling in an ice-bath was collected by filtration; yield 3.9 g. (92%), m.p. 229–231° dec.

2,3-Dimethylphenylalanine (IV).—A suspension of 4.0 g. (0.012 mole) of IVa in 40 ml. of concentrated hydrochloric acid was refluxed for 6 hr. and filtered. The filtrate was cooled in an ice-bath and the crystals were collected by filtration; yield 2.2 g. (80%), m.p. 234–235° dec. A solution of 1.0 g. (0.0043 mole) of the amino acid hydrochloride

(14) The bulk of the material appeared to decompose and polymerize during the distillation to give a fluorescent, viscous oil. In subsequent preparations, the crude 3,4-dimethylbenzyl chloride was used without distillation in the condensation with diethylacetamidomalonate with satisfactory results.

(15) H. Lund and J. Bjerrum, *Ber.*, **64**, 761 (1946).

(16) If the diethyl acetamidomalonate is not pure or if anhydrous conditions are not used, a brown viscous oil sometimes separates and this results in a poor yield. When this situation is encountered, we have found it advantageous to recrystallize the diethyl acetamidomalonate from toluene.

in 50 ml. of hot water was neutralized to *p*H 7 with concentrated ammonium hydroxide. The solution was concentrated under vacuum on the steam-bath until a precipitate began to form. The mixture was cooled in an ice-bath and the precipitate collected. Two crops yielded 0.84 g. (100%), m.p. 237–242° dec.

2-Methylphenylalanine (II).—A suspension of 33.5 g. (0.11 mole) of IIa in 400 ml. of 20% hydrobromic acid was refluxed for 6 hr., and the solution was concentrated under vacuum on the steam-bath until a solid began to form. The mixture was cooled in an ice-bath and the crystals collected by filtration; yield 21.0 g. (78%). A solution of 18.0 g. (0.069 mole) of the amino acid hydrobromide in 200 ml. of water was added to an aqueous slurry of 70.0 g. of Amberlite IR-4B ion-exchange resin (basic form). The mixture was stirred and filtered and the resin washed with an additional 100 ml. of water. The combined filtrates were concentrated under vacuum until a precipitate formed. The solid which separated upon cooling in an ice-bath was collected. Two crops yielded 10.5 g. (85%), m.p. 240–243° dec.

Analogs of Phenylalanine Containing Sulfur

BY ROBERT L. COLESCOTT, ROSS R. HERR AND JOSEPH P. DAILEY

RECEIVED DECEMBER 26, 1956

Analogs of phenylalanine containing a sulfur group in the *para* position have been synthesized and tested as growth inhibitors of *Escherichia coli*. The mercapto, symmetrical disulfide, methylmercapto, ethylmercapto, methylsulfinyl, methyl sulfonyl and sulfamyl analogs were prepared by hydrolysis and decarboxylation of the corresponding diethyl acylamidomalonates.

The substitution of various groups on the benzene ring of phenylalanine has often resulted in compounds that are competitive antagonists of phenylalanine or tyrosine, the *para* substituted compounds being the most active. Some of these *para* substituted analogs of phenylalanine that have been previously reported include the nitro,[1] amino,[1] fluoro,[2] chloro,[1] methyl,[3] dimethylamino,[4] mercapto,[5,6] sulfamyl[7,8] and the symmetrical disulfide.[5,6] Because of the potential usefulness of amino acid antagonists in chemotherapy, we have prepared a group of compounds related to phenylalanine wherein a sulfur containing group is substituted in the *para* position of this amino acid. In these compounds, variations in the oxidation state of the sulfur results in groups having a range of electronic effects, from the electron-donating mercapto group to the electron-withdrawing sulfonamide. In this way we hoped to obtain information about the relationship between electronic character of the substituent and antagonism or utilization of the amino acid. We have prepared the mercapto, disulfide, methylmercapto, ethylmercapto, methylsulfinyl, methylsulfonyl and sulfamyl substituted phenylalanines.

The general method of preparation of these amino acids was by way of the corresponding diethyl acetamidomalonate (Table I).

The amino acid was then prepared by hydrolysis and decarboxylation (Table II).

The preparation of *p*-mercaptophenylalanine was first reported by Johnson and Brautlecht[5] and later by Elliott and Harington.[6] A more direct route and one which resulted in higher yield was found in the reaction of potassium ethyl xanthate with diethyl *p*-diazobenzylacetamidomalonate. The diazo-compound was prepared readily from the corresponding amine and this, in turn, was obtained by hydrogenation of diethyl *p*-nitrobenzylacetamidomalonate.[1] The hydrolysis of the xanthate, the hydrolysis of the amide and ester groups, as well as the decarboxylation, were accomplished in one step to give the amino acid hydrochloride in 86% yield. Oxidation of the *p*-mercaptophenylalanine to the corresponding disulfide was carried out according to the procedure of Elliott and Harington using iodine in potassium iodide solution.

Chloromethylation of thioanisole or thioanethole with chloromethyl ether yielded the *para* substituted benzyl chloride. The thioanethole was prepared by the reaction of diethyl sulfate with thiophenol. Condensation of these benzyl halides with diethyl acetamidomalonate resulted in the production of the substituted acetamidomalonates which were then hydrolyzed and decarboxylated to yield *p*-methylmercaptophenylalanine and *p*-ethylmercaptophenylalanine.

Controlled oxidation of the diethyl *p*-methylmercaptobenzylacetamidomalonate with hydrogen peroxide resulted in the sulfinyl substituted malonate and hydrolysis of this yielded *p*-methylsulfinylphenylalanine. Oxidation with an excess of hydrogen peroxide gave the sulfone which was hydrolyzed to yield the corresponding sulfonyl amino acid.

Two methods were employed successfully in the preparation of *p*-sulfamylphenylalanine.[7] Chlorosulfonation of diethyl benzylacetamidomalonate followed by reaction with ethereal ammonia and hydrolysis and decarboxylation resulted in the sulfonamide in 16% yield. The alternate procedure utilized side chain bromination of *p*-toluene-

[a] Insoluble at higher concentrations. [b] Inhibition was reversed by 50 γ of tyrosine, not by phenylalanine up to 1000 γ. [c] Inhibition was reversed by 100 γ of tyrosine, not by phenylalanine up to 1000 γ. [d] 500 γ reversed the inhibition of B-2-thienylalanine. [e] No effect on β-2-thienylalanine inhibition. [f] Recrystallized from 20% HCl. [g] Recrystallized from water. [h] Recrystallized from water–ethanol mixture. [i] Recrystallized from water–acetone mixture.

sulfonyl chloride with N-bromosuccinimide followed by selective reaction of the sulfonyl chloride group with ammonia. The resulting sulfamylbenzyl bromide was condensed with diethyl formamidomalonate and subsequently hydrolyzed and decarboxylated. This method gave a 27% yield of product based on the amount of *p*-toluenesulfonyl chloride consumed.

The compounds were assayed in the *E. coli* microbiological system described by Dittmer, *et al.*,[9] and the results are shown in Table II.

Acknowledgments.—The authors wish to express their appreciation to Mrs. G. M. Robinson who conducted the microbiological assays and to Dr. T. J. Bardos for helpful discussions and suggestions.

Experimental

Diethyl *p*-Xanthylbenzylacetamidomalonate (Ia).—To a stirred suspension of 16.15 g. (0.045 mole) of diethyl *p*-aminobenzylacetamidomalonate·HCl[2] in 30 ml. of 6 *N* HCl at 0° was added slowly 4.1 g. (0.06 mole) of sodium nitrite in 8 ml. of water. After the addition was completed, the solution was adjusted to *p*H 7 by the addition of solid sodium carbonate. The temperature was maintained at 0°, and a solution of 9.3 g. (0.058 mole) of potassium ethyl xanthate was added slowly. The solution was allowed to reach room temperature and then stirred at 60° for 1 hr. The product was extracted from the aqueous layer with three 100-ml. portions of ether. The ether solution was dried over magnesium sulfate and the ether distilled, leaving a viscous oil. The product was obtained by crystallization from 70% ethanol; yield 8.5 g. (47%), m.p. 103–105°.

***p*-Mercaptophenylalanine Hydrochloride (Thiotyrosine) (I).**—A mixture of 1.0 g. (0.0028 mole) of Ia and 10 ml. of concentrated hydrochloric acid was refluxed for 5 hr. This solution was evaporated to 5 ml. under reduced pressure and chilled overnight. The product was collected and dried under vacuum over solid sodium hydroxide; yield 0.52 g. (86%), m.p. 243–246° dec. Recrystallization from 20% hydrochloric acid raised the melting point to 248–249° dec.[6]

***p,p'*-Phenylalanine Disulfide (II).**—A solution of 0.3 g. (0.0015 mole) of I in 10 ml. of water was treated with a slight excess of 2 *N* iodine in 5% potassium iodide. This solution was heated on the steam-bath and adjusted to *p*H 5 with ammonium hydroxide. The white solid that precipitated upon cooling was collected and dried under vacuum; yield 0.16 g. (66%), m.p. 276–278° dec.[5]

Diethyl *p*-Methylmercaptobenzylacetamidomalonate (IIIa).—To a solution containing 7.4 g. (0.32 gram atom) of sodium dissolved in 700 ml. of absolute ethanol was added 69.9 g. (0.32 mole) of diethyl acetamidomalonate. Fifty-five grams (0.32 mole) of *p*-methylmercaptobenzyl

chloride[10] was added and the mixture refluxed for 2.5 hr. Approximately 80% of the alcohol was removed by distillation and 750 ml. of water was added. The crude product was collected by filtration and crystallized from 95% ethanol; yield 113 g. (84%). A sample was recrystallized from 95% ethanol for analysis, m.p. 108.5–109.5°.

p-**Methylmercaptophenylalanine** (III).—The amino acid was obtained by refluxing 5.0 g. (0.0136 mole) of IIIa with 50 ml. of concentrated hydrochloric acid for 4 hr. Upon cooling, the hydrochloride salt separated and was removed by filtration. It was dissolved in 100 ml. of hot water and neutralized to *p*H 7 with concentrated ammonium hydroxide. The amino acid which crystallized upon cooling was collected by filtration, washed with acetone and dried; yield 2.87 g. (95%), m.p. 245–247° dec.

Thioanethole (IVa).—To 120 ml. of cold 20% sodium hydroxide was added 50 g. (0.455 mole) of thiophenol. The mixture was stirred and 71 g. (0.46 mole) of diethyl sulfate was added dropwise over a period of 30 minutes. Stirring was continued for 4 hr. at room temperature and then the solution was extracted with ether. The ether extract was dried over magnesium sulfate and the ether removed by distillation. The residue was distilled under reduced pressure and the thioanethole collected at 89° (15 mm.); yield 52.6 g. (83%).

p-**Ethylmercaptobenzyl Chloride** (IVb).—A mixture of 45 g. (0.32 mole) of IVa, 26 g. (0.32 mole) of chloromethyl ether and 260 ml. of glacial acetic acid was heated at 65–70° for 40 hr. The solution was cooled, poured into 500 ml. of ice-water and extracted with chloroform. The chloroform extract was dried over magnesium sulfate and the chloroform removed by distillation. The residue was distilled under reduced pressure and the *p*-ethylmercaptobenzyl chloride collected at 149° (15 mm.), yield 20.3 g. (34%).

Anal. Calcd. for $C_9H_{11}ClS$: C, 57.92; H, 5.90; S, 17.17; Cl, 19.04. Found: C, 57.82; H, 5.82; S, 17.02; Cl, 19.13.

Diethyl *p*-**Ethylmercaptobenzylacetamidomalonate** (IVc).—To a solution containing 1.93 g. (0.084 gram atom) of sodium dissolved in 210 ml. of absolute ethanol was added 18.2 g. (0.084) of diethyl acetamidomalonate. To this solution was added 15.6 g. (0.084 mole) of IVb and the mixture refluxed for 2 hr. Approximately 80% of the ethanol was removed by distillation and 400 ml. of water was added. The mixture was cooled and the crude product removed by filtration. Recrystallization from methanol–water yielded 19.7 g. (64%). A sample was recrystallized from 95% ethanol for analysis, m.p. 96–97°.

p-**Ethylmercaptophenylalanine** (IV).—The amino acid was obtained by refluxing 19 g. (0.0517 mole) of IVc with 190 ml. of concentrated hydrochloric acid for 4 hr. The hydrochloride salt crystallized on cooling and was collected by filtration. The salt was dissolved in 100 ml. of boiling water and adjusted to *p*H 7 by the addition of concentrated ammonium hydroxide. The amino acid crystallized on cooling and was collected by filtration; yield 7 g. (60%), m.p. 224–226° dec.

Diethyl *p*-**Methylsulfinylbenzylacetamidomalonate** (Va).—To a solution of 11 g. (0.03 mole) of IIIa in 20 ml. of acetic acid was added 3.1 ml. (0.03 mole) of 30% hydrogen peroxide. The solution was cooled under tap water for a few minutes, stirred at room temperature for 15 minutes and then at 90° for 15 minutes. After cooling, the solution was poured into 150 ml. of water and cooled in the refrigerator. The crude product was collected by filtration and dried *in vacuo;* yield 8.2 g. (90%), m.p. 141–143°. A sample was recrystallized from water for analysis, m.p. 142–143°.

p-**Methylsulfinylphenylalanine** (V).—The amino acid was obtained by refluxing 22 g. (0.06 mole) of Va with 220 ml. of concentrated hydrochloric acid for 4 hr. The solution was evaporated to dryness under reduced pressure and the solid dissolved in 100 ml. of water. The free amino acid was obtained by passing the solution of hydrochloride salt through a column of Duolite A-2 ion-exchange resin. The resulting solution was evaporated to 50 ml. under reduced pressure, diluted with 50 ml. of ethanol and then chilled in an ice–salt bath. The product was collected by filtration and dried *in vacuo;* yield 7.5 g. (55%), m.p. 246–250° dec. A sample was recrystallized from water–ethanol for analysis, m.p. 250–251° dec.

Diethyl *p*-**Methylsulfonylbenzylacetamidomalonate** (VIa).—A mixture of 10.6 g. (0.03 mole) of IIIa, 9 ml. (0.08 mole) of 30% hydrogen peroxide and 30 ml. of acetic acid was heated on the steam-bath for 1 hr. An additional 3 ml. of 30% hydrogen peroxide was added and the heating continued for 30 minutes. Ten ml. of water was added to the hot solution and then it was cooled in the refrigerator. The crude product was collected by filtration and recrystallized from 95% ethanol; yield 8.2 g. (71%), m.p. 174–176°.

p-**Methylsulfonylphenylalanine** (VI).—The amino acid was obtained by refluxing 8.0 g. (0.021 mole) of VIa with 80 ml. of concentrated hydrochloric acid for 4 hr. The solution was evaporated to dryness under reduced pressure and the remaining solid was dissolved in 200 ml. of water. The solution was heated to boiling and adjusted to *p*H 7 by the addition of concentrated ammonium hydroxide. After cooling, the product crystallized and was collected by filtration; yield 4.3 g. (85%), m.p. 264–267° dec. A sample was recrystallized from water for analysis, m.p. 266–267° dec.

p-**Sulfamylphenylalanine** (VII). **Method A. Diethyl** *p*-**Chlorosulfonylbenzylacetamidomalonate** (VIIa).—A 150-ml. portion of chlorosulfonic acid was stirred at 15° and to it was added slowly 103 g. (0.335 mole) of diethyl benzylacetamidomalonate[11] over a period of 1 hr. The mixture was stirred 1 hr. at room temperature, 1 hr. at 65° and then allowed to stand overnight at room temperature. The mixture was added slowly to 750 g. of crushed ice. The crude product precipitated as a viscous oil. It was washed twice with cold water and finally with cold water containing 2% ether. The product was placed in a desiccator over calcium chloride and dried *in vacuo*. It was recrystallized from anhydrous chloroform–hexane to yield 65 g. (54%), m.p. 123–124°.

Anal. Calcd. for $C_{16}H_{20}ClNO_7$: C, 47.35; H, 4.93; N, 3.45; S, 7.89; Cl, 8.75. Found: C, 47.38; H, 4.91; N, 3.86; S, 7.89; Cl, 8.37.

Diethyl *p*-**Sulfamylbenzylacetamidomalonate** (VIIb).—A large excess of anhydrous ammonia was passed into a solution of 28 g. (0.069 mole) of VIIa in 200 ml. of anhydrous ether. The solid which was formed was collected by filtration, washed with ether and recrystallized from methanol–water to yield 14.2 g. (53%), m.p. 240–241°.

p-**Sulfamylphenylalanine** (VII).—The amino acid hydrobromide was obtained by refluxing 3 g. (0.008 mole) of VIIb with 20 ml. of 20% hydrobromic acid for 4 hr. The free amino acid was obtained by passing the solution of hydrobromide salt through a column of Duolite A-2 ion-exchange resin. The resulting solution was evaporated to 10 ml. under reduced pressure, and 10 ml. of acetone was added. The crude product was collected by filtration and recrystallized from water–acetone, m.p. 251–252° dec., yield 1.2 g. (63%).

p-**Sulfamylphenylalanine** (VII). **Method B.** α-**Bromo-***p*-**toluenesulfonyl Chloride** (VIIc).—A mixture of 49 g. (0.252 mole) of N-bromosuccinimide, 48 g. (0.252 mole) of *p*-toluenesulfonyl chloride and 2.42 g. (0.01 mole) of benzoyl peroxide in 250 ml. of carbon tetrachloride was refluxed for 2 hr. The mixture was cooled to room temperature and the succinimide removed by filtration. The carbon tetrachloride was removed from the filtrate by distillation under reduced pressure, and the oil that remained was extracted with three 150-ml. portions of boiling heptane. Fifty-five grams of crude product was obtained from the cooled extract. It was recrystallized from heptane to yield 51.3 g. (76%), m.p. 74–76°.

α-**Bromo-***p*-**toluenesulfonamide** (VIId).—A large excess of anhydrous ammonia was passed into a solution of 10 g. (0.037 mole) of VIIc in 350 ml. of anhydrous ether. The resulting precipitate was removed by filtration, washed with ether and crystallized from acetone, yield 7 g. (73%). A sample recrystallized from methanol–water for analysis, m.p. 191–192°.

Anal. Calcd. for $C_7H_8BrNO_2S$: C, 33.60; H, 3.24; N, 5.60; S, 12.80; Br, 32.00. Found: C, 33.58; H, 3.75; N, 5.69; S, 12.61; Br, 31.60.

Diethyl *p*-**Sulfamylbenzylformamidomalonate** (VIIe).—To a solution containing 0.45 g. (0.0195 gram atom) of

sodium dissolved in 10 ml. of absolute ethanol was added 3.98 g. (0.0195 mole) of diethyl formamidomalonate. To this solution was added 4.92 g. (0.0195 mole) of VIId in 15 ml. of ethanol. The mixture was refluxed for 5 hr. and then evaporated to dryness under reduced pressure. One hundred ml. of water was added with stirring, the solid removed by filtration and recrystallized from ethanol; yield 4.6 g. (63%), m.p. 236–240°. A sample was recrystallized from dioxane–heptane for analysis, m.p. 239–240°.

p-Sulfamylphenylalanine (VII).—The amino acid hydrochloride was obtained by refluxing 21 g. (0.056 mole) of VIIe with 200 ml. of concentrated hydrochloric acid for 5 hr. The solution was evaporated to dryness under reduced pressure. The hydrochloride salt was dissolved in 100 ml. of water and the solution passed through a column of Duolite A-2 ion-exchange resin to obtain the free amino acid. The resulting solution was evaporated to 125 ml. under reduced pressure and 100 ml. of acetone added. The solution was cooled overnight and the crude product was collected; yield 10.5 g. (76%), m.p. 248–249° dec. A sample was recrystallized from water–acetone for analysis, m.p. 251–252° dec.

Organic Sulfur Derivatives. II.[2] Sulfides, Sulfoxides and Sulfones from Thiols and 10-Undecenoic Acid

BY N. H. KOENIG AND DANIEL SWERN

RECEIVED FEBRUARY 22, 1957

Sulfides are formed by the addition of thiols (RSH) to 10-undecenoic acid (equation 1). The reactions proceed moderately rapidly at temperatures below 100° under free-radical conditions, often with the assistance of ultraviolet light. The acids [$RS(CH_2)_{10}CO_2H$] have a terminal substituent R, which is alkyl (propyl, butyl, hexyl, heptyl, octyl, undecyl or dodecyl), hydroxyethyl, carboxymethyl, acetyl, benzyl, phenyl or 2-naphthyl. Some of the sulfides have been oxidized to sulfoxides by bromate–bromide solution; many have been oxidized to sulfones by peracetic acid. However, an attempt to prepare the sulfone of 11-(acetylthio)-undecanoic acid yielded 11-sulfoundecanoic acid. Other compounds prepared include diesters of 11-(carboxymethylthio)-undecanoic acid and a sulfonium salt, methyl-*n*-octyl-10-carboxydecylsulfonium iodide.

This investigation continues our systematic study of the preparation of long-chain sulfur compounds of known structure. In our first paper[2] it was shown that a high yield of 11-(carboxymethylthio)-undecanoic acid readily is obtained by the addition of an equimolar amount of mercaptoacetic acid to 10-undecenoic acid. We have now shown that this reaction is general. It has been extended to include many other thiols; the resulting (alkylthio)- and (arylthio)-undecanoic acids have been converted in many instances to sulfoxides, sulfones, esters and other derivatives. Aside from 11-(carboxymethylthio)-undecanoic acid,[3] 11-(*n*-dodecylthio)-undecanoic acid[3] and 11-sulfoundecanoic acid,[4] all of the compounds described in this paper are new. Some similar alkylthio, alkylsulfinyl and alkylsulfonyl acids, prepared in different ways, have been reported.[5,6]

Alkanethiols add moderately rapidly to 10-undecenoic acid as shown in equation 1. Previous evidence,[2] as well as infrared and X-ray diffraction studies to be reported separately, indicates that

$$RSH + CH_2{=}CH(CH_2)_3CO_2H \longrightarrow RS(CH_2)_{10}CO_2H \quad (1)$$

R = *n*-propyl, butyl, hexyl, heptyl, octyl, undecyl or dodecyl.

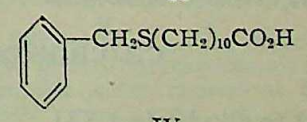
the addition products isolated have an unbranched structure, *i.e.*, the sulfur atom is attached at the 11-(terminal) rather than at the 10-position, and that they are formed *via* free-radical intermediates. The free-radical addition mechanism is also supported by the activating influence of ultraviolet light.

Other types of terminally substituted undecanoic acids, (I-VI) are formed by the addition of mercaptoethanol, mercaptoacetic acid, thiolacetic acid, α-toluenethiol, benzenethiol or 2-naphthalenethiol, respectively.

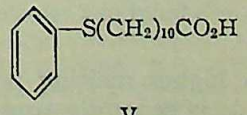
$HO(CH_2)_2S(CH_2)_{10}CO_2H$ I

$HO_2C(CH_2)S(CH_2)_{10}CO_2H$ II

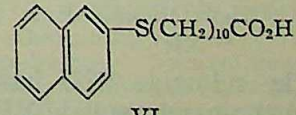
$CH_3CS(CH_2)_{10}CO_2H$ III



IV



V



VI

The pure acids, $RS(CH_2)_{10}CO_2H$, are odorless, white, crystalline solids. They are insoluble in water, sparingly soluble in petroleum ether at room temperature or 0° and moderately soluble in more polar solvents such as acetone and ethanol. Other characteristics of these compounds are given in Table I.

The chemical behavior of these sulfides is illustrated by some reactions of 11-(*n*-octylthio)-undecanoic acid, $CH_3(CH_2)_7S(CH_2)_{10}CO_2H$ (VII). Controlled oxidation with bromate–bromide solution gives the sulfoxide VIII, while excess peracetic acid forms the sulfone IX. Methyl iodide adds to

$CH_3(CH_2)_7SO_x(CH_2)_{10}CO_2H$ VIII, $x = 1$ IX, $x = 2$

VII to give the sulfonium salt, methyl-*n*-octyl-10 carboxydecylsulfonium iodide (X). The carboxyl

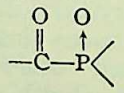
XII

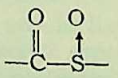
The sulfoxide VIII has a higher melting point than the parent sulfide VII, as is generally true for alkylsulfinyl aliphatic acids.[6] A lowering of melting point takes place, however, in forming the sulfoxide of II, *i.e.*, 11-(carboxymethylsulfinyl)-undecanoic acid, and of V, 11-(phenylsulfinyl)-undecanoic acid.

Sulfones have been prepared by peracetic acid oxidation of sulfides I, II, IV, V, VI, VII and 11-(*n*-heptylthio)-undecanoic acid. Characteristics of the sulfoxides and sulfones are given in Table II.

An attempt to prepare 11-(acetylsulfonyl)-undecanoic acid, the sulfone of III, led instead to the formation of 11-sulfoundecanoic acid ($HO_3S(CH_2)_{10}CO_2H$), a compound previously prepared by other methods. It seems plausible that a sulfoxide, sulfone or other intermediate is formed[7] but is readily cleaved because of the positive charges on neighboring carbon and sulfur atoms. This instability parallels that of acylphosphonates, in which the



group is analogous to the



group.[8] Furthermore, it is significant that the only α-ketosulfones we have found in the literature are probably special cases, since both the carbonyl and the sulfonyl groups are attached to benzene rings.[9]

Experimental

Starting Materials.—10-Undecenoic acid (b.p. 136° at 1.5 mm., $n^{30}D$ 1.4458) was purified by fractional distillation of the best commercial material. *n*-Octanethiol was purified by fractional distillation, taking a central cut, b.p. 77° at 33 mm. Other thiols were used as received. *n*-Dodecanethiol (b.p. 146–148° at 15 mm.) was obtained from Matheson, Coleman and Bell Division, The Matheson Co., Inc.[10] The *n*-undecanethiol was furnished by G. S. Sasin and R. Sasin of Drexel Institute of Technology. Benzenethiol (b.p. 71° at 15 mm.) was from Evans Chemetics, Inc. The remaining thiols were Eastman Kodak Co. White Label organic chemicals except for 2-mercaptoethanol

and α-toluenethiol, which were Practical Grade. Peracetic acid (approximately 40%) in acetic acid was used as received.

Sulfides (Table I). 11-(*n*-Heptylthio)-undecanoic Acid (XIII).—The following reaction conditions are typical. 10-Undecenoic acid (45.6 g., 0.25 mole) and *n*-heptanethiol (33.3 g., 0.25 mole) were mixed in a quartz flask. No noticeable change occurred in 16 hr. The solution was then irradiated at a distance of 1 inch by a 140 watt ultraviolet lamp (high pressure quartz mercury arc). Within 3 minutes, a precipitate formed on the walls of the flask (internal temperature, 35°). After 1 hr., during which the temperature rose to 80°, the extent of reaction was checked by cooling the solution to room temperature. Since the mixture was only about one-fifth solid, it was irradiated for 2 more hr. The reaction product, which appeared entirely solid at room temperature, was crystallized three times at 4° from 600-ml. portions of petroleum ether, yielding 49 g. of XIII as transparent crystals, m.p. 53–54° (62% yield). All melting points were obtained with a micro hot-stage.

Ultraviolet irradiation was unnecessary in the addition of mercaptoethanol, which resembles mercaptoacetic acid in being an unusually reactive thiol.[2] Compound I was formed simply by stirring mercaptoethanol and 10-undecenoic acid for 1.5 hr. at 60°. The crude product was recrystallized three times from acetone–petroleum ether and once from acetonitrile (m.p. 69°). An additional recrystallization from carbon tetrachloride yielded the analytical sample, m.p. 70°.

In the preparation of V, 1% of lauroyl peroxide catalyst was substituted for ultraviolet irradiation, and the mixture was heated overnight at 60° (yield 61%). This reaction was the only one conducted under a nitrogen atmosphere.

Methyl-*n*-octyl-10-carboxydecylsulfonium Iodide (X).—A solution of VII (1.0 g., 0.003 mole) in methyl iodide (4.9 g., 0.035 mole) was sealed and left in the dark for 8 days. The resulting precipitate was washed with ether and dissolved in 5 ml. of methanol. Addition of 85 ml. of ether precipitated an oil that changed to a solid when rubbed with a glass rod. Filtration and drying gave 0.55 g. of X as a pale yellow solid, m.p. 68–70°.

Anal. Calcd. for $C_{20}H_{41}IO_2S$: I, 26.9; S, 6.79; neut. equiv., 473. Found: I, 27.1; S, 7.07; neut. equiv., 453.

***p*-Bromophenacyl 11-(*n*-Octylthio)-undecanoate.**—VII was converted to the *p*-bromophenacyl ester by the conventional procedure.[11] Recrystallization of the ester from ethanol gave white platelets, m.p. 73°.

Anal. Calcd. for $C_{27}H_{43}BrO_3S$: Br, 15.2; S, 6.08. Found: Br, 14.9; S, 5.71.

Di-*n*-butyl 11-(Carboxymethylthio)-undecanoate.—II was esterified with *n*-butyl alcohol by a published procedure,[2] giving an 84% yield of product, b.p. 138° at 0.003 mm.

Anal. Calcd. for $C_{21}H_{40}O_4S$: C, 64.9; H, 10.4; S, 8.25. Found: C, 65.0; H, 10.9; S, 8.09.

Di-(2-ethylhexyl) 11-(Carboxymethylthio)-undecanoate.—Esterification of II with 2-ethylhexyl alcohol gave a 58% yield of product, b.p. 168° at 0.0005 mm.

Anal. Calcd. for $C_{29}H_{56}O_4S$: C, 69.5; H, 11.3; S, 6.40. Found: C, 69.6; H, 11.5; S, 6.13.

Sulfoxides.—The (sulfinyl)-undecanoic acids (Table II) were prepared by dissolving or suspending the sulfide in glacial acetic acid acidified with hydrochloric acid and adding 0.5 *N* bromate–bromide solution dropwise.[6]

11-(*n*-Octylsulfinyl)-undecanoic Acid (VIII).—Crude VIII (m.p. 79–86°, neut. equiv. 345, yield 91%) was dissolved in boiling acetone–petroleum ether (4:1) and crystallized at 4° to yield analytically pure VIII as white platelets, m.p. 88°.

11-(Carboxymethylsulfinyl)-undecanoic Acid.—This sulfoxide was fairly soluble in aqueous acetic acid and was recovered in low yield. The best material was a white powder or needles, m.p. 91–92°.

11-(Phenylsulfinyl)-undecanoic Acid.—The crude product was purified by dissolving it in acetone and adding 5 volumes of petroleum ether. The resulting oil, when rubbed with a glass rod, gave a white powder, m.p. 60–61°, in 90% yield.

Sulfones. 11-(*n*-Heptylsulfonyl)-undecanoic Acid (XIV).—Most of the sulfones (Table II) were prepared by slight modifications of the following procedure. XIII (15.8 g., 0.05 mole) was suspended in 100 ml. of acetic acid. Peracetic acid (20 ml. of 40% acid, 0.12 mole) was added, with stirring, over a 15-minute period. The rate of addition was controlled so that the maximum temperature of the resulting solution was 70°. Little or no heat was evolved during the addition of the last 5 ml. of peracetic acid. A positive starch–iodide paper test for excess peracetic acid was obtained a few minutes after its addition was completed. As the solution cooled, a heavy precipitate formed; it was stirred with 400 ml. of water, filtered through a coarse fritted disk, washed with water and vacuum dried. The product, a microcrystalline solid, weighed 17.1 g. (yield 98%), neut. equiv. 346, m.p. 110–111°. One gram of this solid was recrystallized from 80 ml. of acetonitrile, yielding 0.45 g. of white needles of analytically pure XIV, m.p. 111–112°.

11-(2-Hydroxyethylsulfonyl)-undecanoic Acid (XV).—The gel-like original product was dissolved in ethyl acetate, and the solution was dried with sodium sulfate. Addition of petroleum ether precipitated XV as a white powder, m.p. *ca.* 94–96°.

11-(Carboxymethylsulfonyl)-undecanoic Acid.—The solid that precipitated from aqueous acetic acid was gelatinous. It was difficult to filter and dry, and it melted at 122–126°. Three recrystallizations from acetonitrile gave the analytical sample, a granular crystalline solid, m.p. 140–141°.

11-(Benzylsulfonyl)-undecanoic Acid.—Water was not added after the peracetic acid. Instead, the mixture was evaporated to constant weight in a vacuum desiccator containing excess sodium hydroxide and a dehydrating agent. The crude solid (m.p. 104–112°) was recrystallized from acetone–petroleum ether, forming a white powder, m.p. 126–127° (93% yield).

11-Sulfoundecanoic Acid (XVI).—After adding peracetic acid to the acetic acid solution of III, the reaction mixture was dried over sodium hydroxide under vacuum at 25°. The crude product, m.p. 59–62°, neut. equiv. 141, corresponded to 11-sulfodecanoic acid hemihydrate, m.p. *ca.* 65°, neut. equiv. 138.[4] An ether-insoluble fraction was separated and discarded; the ether-soluble acid was purified by recrystallization from ether–benzene. Vacuum desiccation at room temperature gave anhydrous XVI, m.p. *ca.* 94° (reported[4] *ca.* 99° and 95–99° by two other methods of preparation).

Acknowledgment.—The authors thank C. L. Ogg, Ruth B. Kelly and associates for the elementary analyses.

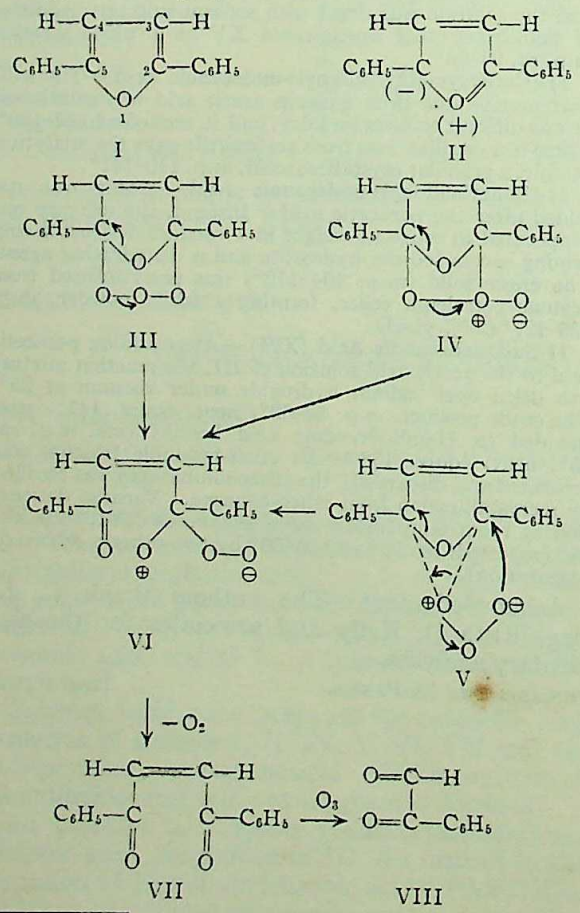
COMMUNICATIONS TO THE EDITOR

1,4-ADDITION OF OZONE TO FURANS AND PYRROLES

Sir:

Wibaut and co-workers[1,2] have obtained products from the ozonolyses of methylated pyrroles and furans which cannot be accounted for by cleavage of the double bonds in the normal structures of these substances. Similarly, we have obtained a 14% yield of phenylglyoxal (VIII) from ozonolysis of 2,5-diphenylfuran (I). The solvent was a methanol–acetone mixture, the temperature was −40°, two mole equivalents of ozone were absorbed, the peroxidic ozonolysis products were reduced with hydrogen over palladium catalyst and the other major product was benzoic acid (81% yield).

Wibaut and co-workers[1,2] have explained "abnormal" results such as these as being reactions of ionic structures such as II. It hardly seems likely, however, that ozone would polarize the molecule to, and attack, such an unstable structure as II, especially since the reactive positions of the furan and pyrrole ring systems are 2 and 5.[3] We have felt that the "abnormal" reactions are the result of the 1,4-addition of ozone. We wish now to report confirmatory evidence for this.



When the ozonolysis just described was stopped after the absorption of one mole equivalent of ozone and the reaction mixture was partially evaporated, a 12% yield of *cis*-1,2-dibenzoylethylene (VII) precipitated (m.p. 130–135°, identification by a mixture melting point with an authentic sample[4]). Similar results were obtained using a mixture of ozone and nitrogen instead of ozone and oxygen, showing definitely that the reaction is one of ozone and not of oxygen.

This material cannot arise from ozonolysis of II. The furan ring has been cleaved but the 3,4 bond is still intact. The *cis* configuration, which is that of the labile isomer,[5] proves that the double bond at the 3 and 4 positions was formed before the ring was cleaved. This can occur only by a 1,4-addition of ozone to the conjugated system of the furan. Any one of structures III, IV or V could have been the intermediate.

We believe a similar mechanism holds true for the reactions of Wibaut and co-workers.[1,2] Further, we believe ozone will attack the ends of other conjugated systems, if the ends are spatially close together. We have found previously that this holds true with anthracene.[6]

We wish to thank the University of Texas Research Institute and the Research Corporation for grants which made this work possible.

ISOLATION AND BEHAVIOR OF *spiro*[2,5]OCTA-1,4-DIENE-3-ONE

Sir:

Recently[1] spectroscopic evidence was reported for the formation of *spiro*[2,5]octa-1,4-diene-3-one (III) as a transient intermediate in solvolytic reactions of 2-*p*-hydroxyphenyl-1-ethyl bromide (I). We now report the successful isolation of this interesting reactive molecular species.

Passage of an ethereal solution of 2-*p*-hydroxyphenyl-1-ethyl bromide (I) through a column of a basic alumina[2] gives a *ca.* 10^{-3} *M* solution of *spiro*[2,5]-octa-1,4-diene-3-one (III) free from phenolic species.

If carefully treated glassware is employed, so as to ensure a dry neutral glass surface, ether solutions of this species can be evaporated at reduced pressure to give a crystalline solid, soluble in most

common solvents. Recrystallization from ether–pentane at low temperatures gives crystals, m.p. 43–46°, with the correct carbon–hydrogen analysis for dienone III, and which show strong absorption maxima for a highly conjugated carbonyl in the infrared at 1650 cm.$^{-1}$ in carbon disulfide and at 1640 cm.$^{-1}$ in chloroform. In the ultraviolet strong maxima are observed at 261 mμ in ether, 271 mμ in *t*-butyl alcohol, 274 mμ in methanol and *ca.* 282 mμ in water, the maxima in methanol and *t*-butyl alcohol being identical with those obtained previously.[1]

The dienone III at low concentrations reacts with a variety of reagents to open the 3-ring and restore the phenolic system. Reduction of the dienone III with lithium aluminum hydride or by catalytic hydrogenation gives *p*-ethylphenol (V) in good yield.

Solvolytic opening of the 3-ring occurs under basic, neutral and acidic conditions, a few spectroscopically measured rate constants being summarized in Table I. The rate of disappearance in methanol with added methoxide is within one per-

TABLE I

FIRST ORDER RATE CONSTANTS FOR SOLVOLYTIC CLEAVAGE OF DIENONE III AT 25°

Solvent	Added solute	10^4k (sec.$^{-1}$)
HOH	...	34.2
MeOH	...	3.87
MeOH	0.01 *N* NaOMe	9.14
MeOH	10^{-5} *N* $HClO_4$	>700

cent. of that reported previously[1] for the transient intermediate observed spectroscopically.

The opening of the dienone III is especially sensitive to acid catalysis, the half-life of III at 25° in 10^{-5} *M* methanolic perchloric acid being less than ten seconds. Under these conditions, and at least partly under neutral conditions, the solvolysis presumably involves the bridged-ion VI, also an intermediate in the solvolysis of suitable 2-*p*-hydroxyphenyl-1-ethyl derivatives.

The ion VI is attacked not only by solvent species, but by other nucleophiles such as bromide ion. Thus, treatment of the dienone III with excess ethereal hydrogen bromide gives rise to the parent bromoethylphenol I, m.p. and mixed m.p. with authentic I, 89–91.5°.

Although ether solutions of dienone III as concentrated as 5×10^{-3} *M* can be kept for about a week, the solid seldom is stable for more than 20 to 30 minutes, probably due to the presence of traces of stray catalysts. On standing, or more rapidly on warming above its m.p., dienone III is converted to a material melting in the range 160–200°, which is insoluble in the common solvents. The infrared spectrum (KBr), quite different from that of dienone III, resembles that of 2-*p*-anisylethyl bromide, especially with respect to the aromatic substitution patterns and the strong aromatic ether absorption band at 1235 cm.$^{-1}$. These data, along with carbon–hydrogen analyses, suggest the polymeric ether structure IX.

With respect to ionic mechanisms for polymerization of dienone III, different processes may be visualized which involve either attack of a growing aryloxide ion on dienone III, or attack of dienone III on a growing cation of the type of VIII. The

latter type is presumably involved in the stannic chloride-catalyzed polymerization of dienone III in ether.

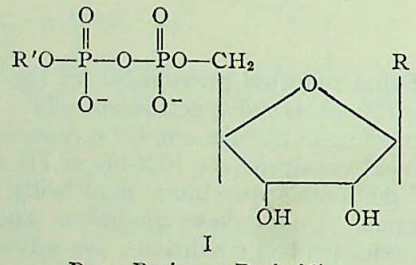
THE PREPARATION OF NUCLEOSIDE 5′-PHOSPHORAMIDATES AND THE SPECIFIC SYNTHESIS OF NUCLEOTIDE COENZYMES

Sir:

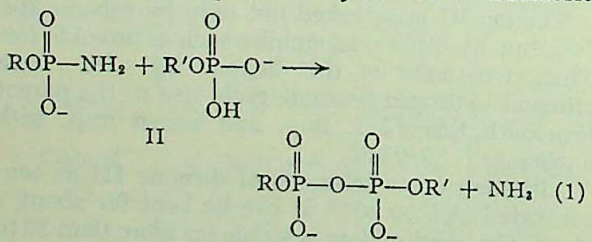
While the carbodiimide method[1] has been applied successfully to the syntheses of certain nucleotide coenzymes[2] (General Formula I) in good yield, the method is often unsatisfactory owing to its lack of specificity in effecting condensation between two dissimilar phosphate esters and frequently, to competing intramolecular cyclic phosphate formation.[3] In seeking to devise more specific methods for the synthesis of compounds of the type I, we have recently investigated[4] the use of phosphoramidates in reactions represented by equation 1. The application of this promising



I

R = Purine or Pyrimidine
R′ = Sugar, etc.

approach to the practical synthesis of nucleoside



R = nucleoside
R′ = H, sugar, etc.

pyrophosphate derivatives (I) was limited, however, by the relative inaccessibility of the key intermediates, nucleoside 5′-phosphoramidates[4] (II) and more direct methods for the preparation of these derivatives were, therefore, sought. In the present communication we outline a convenient one-step preparation of these compounds and record their use in highly improved syntheses of the unsymmetrical pyrophosphates, adenosine 5′-diphosphate (I, R = adenine; R′ = H; ADP) and uridine diphosphate glucose[5,6] (I, R = uracil; R′ = glucose; UDPG).

The direct preparation of nucleoside 5′-phosphoramidates by the condensation of readily available nucleoside 5′-phosphates with ammonia in the presence of an excess of dicyclohexyl carbodiimide (DCC) was examined and it was found that by the proper choice of reaction conditions, quantitative conversion of the nucleotides to the corresponding amidates could indeed be realized. Under the reaction conditions used, 1,3-dicyclohexylguanidine also is formed and the nucleoside 5′-phosphoramidates finally were obtained as the guanidinium salts. The general procedure may be illustrated by the preparation of adenosine 5′-phosphoramidate (AMP–NH_2): a mixture of adenosine 5′-phosphoric acid (3 mmoles), ammonia (7.5 ml. of 2*N*), formamide (5 ml.), *tert*-butyl alcohol (18 ml.) and DCC (3.0 g.) was heated at 80° for three hours. Paper chromatography at this stage showed a single strong spot corresponding to AMP–NH_2.[4] After a simple work up, which included removal of dicyclohexyl urea, ether extraction and subsequent evaporation, AMP–NH_2 was obtained as the crystalline dicyclohexylguanidinium salt (m.p. 240–241°, dec.) from formamide–acetone in 92% yield. *Anal.* Calcd. for $C_{23}H_{40}N_9O_6P\cdot 1H_2O$: C, 47.05; H, 7.21; N, 21.46; P, 5.27. Found: C, 47.46; H, 6.98; N, 21.92; P, 5.20; adenine phosphorus, 1.02. The addition of lithium hydroxide to an aqueous solution of the salt liberated the theoretical amount of free dicyclohexylguanidine (m.p. 181–182°; reported m.p. 182°).[7] Acidification of the above salt with hydrochloric acid liberated dicyclohexyl guanidinium hydrochloride; m.p. 296–297°, dec.

By the same procedure we have prepared the dicyclohexylguanidinium salts of the amidates derived from uridine 5′-phosphoric acid (75%) and monophenylphosphoric acid (68%).

In the previously reported experiments[4] on the synthesis of pyrophosphates from the phosphoramidic acids, formamide solutions of the free acids were used. In the present work, AMP–NH_2 reacted with orthophosphoric acid in *o*-chlorophenol to give 60% yield of ADP, which is easily separated from the other products of the reaction, AMP and orthophosphate, by ion exchange chromatography.[8] This new procedure should lead to more satisfactory syntheses of all the nucleoside 5′-diphosphates.[9] For the synthesis of the nucleoside pyrophosphate esters, it has now been found that pyridine solutions may be employed. In model experiments, dicyclohexylguanidium salts of uridine 5′- and adenosine 5′-phosphoramidates reacted in anhydrous pyridine with monophenylphosphoric acid to give, respectively, 87 and 70% yields of the corresponding pyrophosphates (I, R = uracil or adenine; R′ = phenyl). The application of this technique

to the synthesis of true nucleotide coenzymes was demonstrated by the following preparation of UDPG. Dicyclohexylguanidiniumuridine 5′-phosphoramidate (1 equiv.) and tri-*n*-octylammonium hydrogen glucose-1-phosphate[6] (4 equiv.) were allowed to react for three days in dry pyridine at room temperature and the products were then separated by ion exchange chromatography. UDPG was the major ultraviolet absorbing product (66%) and was isolated readily as the amorphous dilithium salt. This material, which was homogeneous by paper and ion exchange chromatography, had uridine to phosphorus to glucose ratios of 1:1.95:1.01 and was enzymatically active.[10] Its behavior to acid and alkali paralleled that reported for the naturally occurring substance.[11]

This work is being extended to the synthesis of other nucleotide coenzymes.

THE STABILITY OF POTASSIUM BOROHYDRIDE IN ALKALINE SOLUTIONS[1]

Sir:

In connection with an undergraduate research program to investigate some properties of KBH_4, it became necessary to determine its stability toward hydrolysis in alkaline solutions. It is generally stated in the literature that aqueous borohydride solutions are stable at a *p*H greater than 9,[2] but quantitative data on this point are meager. Pecsok[3] has presented a study on the hydrolysis of $NaBH_4$ solutions buffered at various *p*H values between 7.7 and 9.5. Jensen[4] has determined the stability of $NaBH_4$ in solutions buffered at *p*H 9.6 and 10.1 and of $NaBH_4$ dissolved in 1.00, 0.25 and 0.10 *N* sodium hydroxide.

Experimental.—0.10 *M* solutions of KBH_4 were prepared by dissolving the commercially available material[5] in a saturated $Ca(OH)_2$ solution[6] and placed in a water-bath thermostated at 25.0 ± 0.1°. At intervals of time, aliquot portions were analyzed for borohydride content by determining the volume of hydrogen liberated upon acidification.

Results and Discussion.[7]—A plot of the logarithm of borohydride content *vs.* time proved to be linear, indicating that the hydrolysis is first order with respect to borohydride at a constant *p*H. Likewise, it can be shown that Jensen's data fit the relation

$$-d(BH_4^-)/dt = k'(BH_4^-) \qquad (1)$$

where k' is a function of *p*H.

The relation between log k' and *p*H is shown in Fig. 1, indicating that the reaction is also first order in hydronium ion. The results shown in Fig. 1 support Pecsok's conclusion that the rate of hydrolysis of borohydride solutions is controlled by the formation of $HBH_4{\cdot}xH_2O$. This intermediate hydrolyzes immediately to an aquated borine radical which also hydrolyzes rapidly. It would appear from Fig. 1 that the rate of hydrolysis of the BH_4^- ion at any given *p*H is independent of the presence of Na^+, K^+, or Ca^{++} cations.

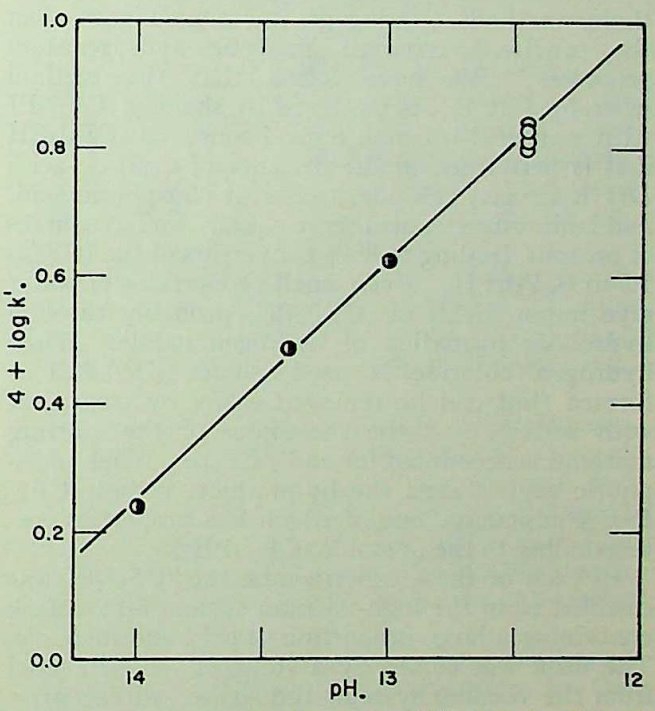

Fig. 1.—Rate constant of equation (1) as a function of *p*H: ○, KBH_4 in $Ca(OH)_2$ solutions at 25°; ◑, $NaBH_4$ in NaOH solutions at 24°.

Extrapolation of the line of Fig. 1 to lower *p*H values does not fit the data of Jensen or of Pecsok for the hydrolytic stability of the borohydride ion in buffered solutions. Nor do Jensen's data with the borate buffer lie on the same line as do Pecsok's

data for pyrophosphate buffer. This would indicate that the rate of hydrolysis is influenced by the presence of different anions, which is contrary to the conclusion of Hoekstra[2] that, in the *p*H range below 9, the hydrolysis is independent of the type of buffer system used.

A NEW SYNTHESIS OF BIS-TRIFLUOROMETHYL-PHOSPHINE, $(CF_3)_2PH$[1]

Sir:

Compounds of the type $(R_F)_2PH$ are important enough to the development of fluorocarbon–phosphorus chemistry to warrant a search for new synthetic methods offering greater convenience than the previously-reported catalytic hydrogenation processes.[2] We have found that the method whereby $P_2(CF_3)_4$ is produced by shaking $(CF_3)_2PI$ with mercury[3] becomes a good source of $(CF_3)_2PH$ if it is performed in the presence of a protic acid. Dry hydrogen chloride, technical phosphoric acid, and trifluoroacetic acid serve equally well as sources of protons, leading to 35% conversion of the $(CF_3)_2PI$ to $(CF_3)_2PH$. Even small proportions of water give minor yields of $(CF_3)_2PH$, probably through hydrolytic formation of hydrogen iodide. When hydrogen chloride is used, some $(CF_3)_2PCl$ is formed (but can be removed easily by treatment with water), and the remainder of the starting material is accounted for as $P_2(CF_3)_4$. When phosphoric acid is used the by-products include CF_3–P–O compounds, one of which has properties corresponding to the unstable $(CF_3)_2PHO$.

In each of these experiments, the $(CF_3)_2PI$ was distilled from the high-vacuum system into a flask containing a large proportion of acid and mercury. The flask was closed by a stopcock, disconnected from the vacuum system, and shaken while warming to room temperature, and for 15 minutes thereafter. The volatile products were brought into the vacuum system and separated by distillation methods. The $(CF_3)_2PH$ was identified by observation of a 760 mm. vapor tension at 2° (literature b.p. 1°) and a molecular-weight value of 170 (calcd., 170.00). The F^{19} nuclear magnetic resonance spectrum (obtained with the aid of Dr. Harden McConnell and Philip Bromberg at the California Institute of Technology) showed spin–spin interactions with one P^{31} and one H^1 nucleus to give a pair of doublets. The proton magnetic spectrum consisted of two groups of seven lines due to spin–spin splitting of one phosphorus nucleus and six equivalent fluorine nuclei. Quantitative data on the splittings and chemical shifts will be published elsewhere.

An insight into the course of the $(CF_3)_2PI$–Hg–acid reaction was obtained from an experiment in which 0.50 mmole of $(CF_3)_2PI$ was first shaken with mercury alone to give a 95% yield of $P_2(CF_3)_4$. Then the non-volatile residue was treated with dry hydrogen chloride, producing an amount of $(CF_3)_2PH$ which would account for the missing 5% of the original $(CF_3)_2P$ groups. Thus it would appear that a phosphorus–mercury bond had been established, possibly as $(CF_3)_2PHg_2I$, from which one could get either $(CF_3)_2PH$ by the action of acid or $P_2(CF_3)_4$ by further action of $(CF_3)_2PI$. It is proposed that a wide variety of new materials containing the $(CF_3)_2P$ group might be made by shaking $(CF_3)_2PI$ with mercury in the presence of halides of polyvalent metals or non-metals.

IDENTIFICATION OF RUTHENIUM SPECIES IN AQUEOUS SOLUTION

Sir:

We have used an ion-exchange technique for identifying aqueous ruthenium species. The method promises to be very useful in studies of this element where solutions usually contain a mixture of complex ions and polymers which do not equilibrate rapidly. The method will be applicable to other systems with similar characteristics.

Two experiments are performed: the first measures the ionic charge per ruthenium atom, *a*, while the second gives the net ionic charge of the species, *b*. The ratio *b*/*a* equals the number of ruthenium atoms per species, *i.e.*, the degree of polymerization. Using the oxidation number, the number of negatively charged groups in the complex can be inferred. If only one complexing anion is present, the stoichiometric formula of the species is fixed.

The charge per ruthenium atom is determined from the equivalents of charge with an ion-exchange resin per gram atom of ruthenium. It was convenient to use a column technique[1] because separation and concentration of the ruthenium species could be achieved simultaneously. A dilute solution of ruthenium species, primarily in the +3 oxidation state, was stirred with Dowex 50, 200–400 mesh resin in the hydrogen ion form until most of the ruthenium was taken up by the resin. This resin was added to the top of a tapered column already containing approximately one tenth as much resin in the hydrogen ion form. The column was eluted slowly with a dilute cerous perchlorate–perchloric acid solution. The cerous ion displaced most of the ruthenium species, which formed nearly pure bands as they descended. Several samples of a particular band were collected, analyzed for total ruthenium and hydrogen ion, and the spectra checked as an indication of purity. The value of *a* is equal to the molarity of hydrogen ion plus 3 times that of cerous ion in the elutriant, minus the molarity of hydrogen ion in the eluted

(1) Similar in principle to that of D. A. Everest and J. E. Salmon, *J. Chem. Soc.*, 1442 (1955).

Digitized by Arya Samaj Foundation Chennai and eGangotri

ruthenium solution, all divided by the gram atoms of ruthenium per liter in the eluted solution.

The charge per species is found from the concentration dependence of the exchange of ruthenium with a known ion—in our case hydrogen ion

$$Ru_{b/a}X^{+b} + bH^{+}_{R} = Ru_{b/a}X^{+b}_{R} + bH^{+}$$

$$Q = \frac{[RU_{b/a}X^{+b}]_R\,[H^+]^b}{[Ru_{b/a}X^{+b}]\,[H^+]^b_R}$$

where X denotes anions in the ruthenium species, R designates the resin phase and concentrations are indicated by brackets. The ratio of ruthenium concentrations is proportional to the ratio of hydrogen ion concentrations to the $-b$ power. From two equilibrations at different hydrogen ion concentrations b may be calculated. Conditions were chosen such that the great majority of the resin was in the hydrogen ion form and most of the ruthenium was present in the resin phase. There is an unpredictable change in activity coefficients in the aqueous phase but the method is believed to be sufficiently accurate in most cases because b must be an integer as well as a multiple of a.

It can be shown that any changes in hydrolysis on exchange do not affect the results.

This method has been used to establish the formulas of the species Ru^{+3} and $RuCl^{+2}$.

SEMI-QUANTITATIVE GAS CHROMATOGRAPHY

Sir:

We have found relationship (1) reasonably accurate in relating the fraction by weight of a component in a mixture to the corresponding area in a liquid–vapor chromatogram obtained using helium as the carrier gas and a tungsten wire thermal conductivity gage as detector

$$\left(\frac{m_i}{W}\right) = \frac{A_i\sqrt{M_i}}{\sum_i A_i\sqrt{M_i}} \qquad (1)$$

where (m_i/W) is the fraction by weight of the ith component, A_i the planimeter-determined area under the peak on the chromatogram corresponding to the ith component and M_i the molecular weight of the ith component.

Clearly the equation may be applied only to mixtures which are completely resolved and such that all components appear in the chromatogram.

Component	Known mole %	Known wt. %	Found area %	Calcd. wt. %
Ethanol	43.4	45.4	47.3	44.6
Water	46.6	19.1	31.1	18.3
1,8-Cineole	10.0	35.5	21.5	37.1

The equation has been applied with comparable results to chromatograms of several mixtures: α and β-pinene plus ethanol; α and β-pinene plus benzene; methyl ethyl ketone, n-propyl alcohol and p-xylene.

Although the expression was arrived at empirically, the appearance of the square root function is not unreasonable on the basis of kinetic theory. Further, it is apparent that the expression may be utilized to determine the molecular weight of a component from the chromatogram of a mixture of known weight composition of the material of unknown molecular weight with a known substance. Although the square root function through its leverage places a premium on accurate determination of the areas on the chromatogram, we have had some success in this utilization of the relationship.

TETRAACETYL DIBORATE AND SO-CALLED "BORON ACETATE"

Sir:

There has been considerable confusion in the literature over the constitution of the product obtained by the reaction between orthoboric acid and acetic anhydride. Two types of compounds have been reported at various times. One, said to melt around 121°, has been called boron triacetate, $(CH_3CO_2)_3B$,[1,2,3] and the other, m.p. 150–152°, pyroboron acetate, $(CH_3CO_2)_2BOB(O_2CCH_3)$.[4,5,6] Both have been supported by analytical data but, in several cases, the authors used identical procedures only to obtain different products.

We have repeated some of the previous preparations, our results agreeing with those of Gerrard and Wheelans[6]; no evidence was obtained for boron triacetate, although the methods described for its preparation[1,2] were carefully followed. The analytical data for $(CH_3CO_2)_2BOB(O_2CCH_3)_2$ were improved and extended and the name *tetraacetyl diborate* is proposed.

The reaction between orthoboric acid and acetic anhydride was found to occur according to the equation

$$2H_3BO_3 + 5(CH_3CO_2)_2O \longrightarrow (CH_3CO_2)_2BOB(O_2CCH_3)_2 + 6CH_3CO_2H$$

Orthoboric acid (0.534 mole) and acetic anhydride (1.96 mole) were heated together at 50–100° with vigorous stirring in a nitrogen atmosphere until all the solid had dissolved. On cooling, the product crystallized as colorless needles. One sample was purified by recrystallization from a benzene–chloroform mixture, another by precipitation from solution in dry acetic acid by the addition of ether. Both melted at 147–148°.

All filtrations were carried out using a pressure of dry nitrogen and the products were dried in vacuum at room temperature before being transferred to a dry box for subsequent handling.

The acetate content was determined by titration with standard base, the end-point (around pH 6.7)

being detected with a Beckmann *p*H meter. Boron was estimated, using the same solution, by further titration with base in the presence of excess mannitol to the phenolphthalein end-point. Analysis with the Karl Fischer reagent under anhydrous conditions caused the reaction

$$(CH_3CO_2)_2BOB(O_2CCH_3)_2 + 2MeOH \longrightarrow H_2O + 2(CH_3CO_2)_2BOMe$$

to be driven to the right, the reagent quantitatively removing the water.[7] The "hydroxyl equivalent" was calculated as mg. water/g. of sample. This reaction afforded unequivocal proof of the nature of the product, because boron triacetate could not react at all with the Karl Fischer reagent. The molecular weight measurement was carried out ebullioscopically in dry chloroform, the concentrations of the solutions being given in g. of sample per 1000 g. of solvent in parentheses after each value.

EXPERIMENTAL VALUES

Sample crystallized from	M.p., °C.	% CH_3CO_2	% B	Hydroxyl equiv. mg. H_2O/g.	CH_3CO_2/B ratio
Chloroform–benzene	147–148	85.0	7.86	67.2	1.98
		85.6	7.96	67.9	1.97

A sample of the tetraacetyl diborate was heated in acetic anhydride in an attempt to cause further acetylation, the product being precipitated by the addition of ether, m.p. 120–140°. Analysis showed that slight decomposition with decrease in acetate content occurred under these conditions, analogously to Dimroth's observation[4] that tetraacetyl diborate lost acetic anhydride on heating. However, an X-ray powder photograph was identical with the one we obtained for tetraacetyl diborate.

A further experiment in which we followed as closely as possible the method of Cook, *et al.*,[2] yielded a crystalline product, m.p. 149–150° (Cook gave m.p. 120°). This checks very well with the melting point of tetraacetyl diborate.

From the above evidence, we reach a conclusion similar to that of Gerrard and Wheelans.[6] Although it may be possible to prepare boron triacetate, our experience confirms the existence of only tetraacetyl diborate.

REACTIONS OF GASEOUS IONS. III. FORMATION OF PROTONATED METHANE

Sir:

Recent publications[1,2,3,4] have reported the formation of CH_5^+ (or CD_5^+) in a bimolecular reaction between CH_4^+ (or CD_4^+) ions and CH_4 (or CD_4) molecules taking place in the ionization chamber of a mass spectrometer. However, the formation of protonated methane by reactions involving methane ions and molecules other than methane has not been reported.

We have observed the formation of CD_4H^+ in mixtures of CD_4 with other hydrogen-containing substances. The formation of CD_4H^+ is first-order in CD_4^+ and first-order in the hydrogen-containing substance and appearance potential measurements of CD_4H^+ more closely correspond to the ionization potential of CD_4 than to any other possible ionic species in the system. We thus write for the formation of CD_4H^+

$$CD_4^+ + XH \longrightarrow CD_4H^+ + X \qquad (1)$$

We have calculated rate constants relative to the rate constant taking XH = CH_4 for several such reactions by the relationship

$$\frac{k_{XH}}{k_{CH_4}} = \frac{[CH_4]}{[XH]} \frac{\left(\frac{I_{CD_4H^+}}{I_{CD_4^+} + I_{CD_4H^+}}\right)_{XH}}{\left(\frac{I_{CD_4H^+}}{I_{CD_4^+} + I_{CD_4H^+}}\right)_{CH_4}} \qquad (2)$$

where the *I*'s are the observed ion-currents and $[CH_4]$ and [XH] are the ionization chamber gas concentrations. We assumed that the ratio of ionization chamber concentrations was equal to the ratio of gas reservoir partial pressures, an assumption well within experimental error. The values obtained (averages of replicate measurements) are shown in Table I.

Within experimental error the appearance potential of CD_4H^+ coincides with the ionization potential of CD_4. If we assume that (1) cannot be endothermic (any exponential term involving significant activation energy would so decrease the

Table I

Relative Rates of Formation of CD_4H^+

Reaction	k_{XH}/k_{CH_4}
$CD_4^+ + CH_4 \longrightarrow CD_4H^+ + CH_3$	1.00
$CD_4^+ + C_2H_6 \longrightarrow CD_4H^+ + C_2H_5$	0.11
$CD_4^+ + C_3H_8 \longrightarrow CD_4H^+ + C_3H_7$	.05$_6$
$CD_4^+ + \text{iso-}C_4H_{10} \longrightarrow CD_4H^+ + C_4H_9$	.04$_6$
$CD_4^+ + CH_3Cl \longrightarrow CD_4H^+ + CH_2Cl$	.04$_1$
$CD_4^+ + NH_3 \longrightarrow CD_4H^+ + NH_2$	.08$_3$
$CD_4^+ + H_2S \longrightarrow CD_4H^+ + HS$	.17
$CD_4^+ + HCl \longrightarrow CD_4H^+ + Cl$	.56

probability of a reactive collision that we could not observe the reaction), then the energetics of the reactions that do take place (Table I) lead us to the conclusion that the heat of formation of CD_4H^+ is $\Delta H_f \leq 234$ kcal/mole. On the other hand, we have not been able to find any evidence of CD_4H^+ formation in CD_4–H_2O and CD_4–H_2 mixtures. If these reactions are not observable for energetic reasons, one calculates the heat of formation of CD_4H^+ to be $\Delta H_f \geq 218$ and $\Delta H_f \geq 233$ kcal./mole, respectively. Thus, the implied value for the heat of formation of CD_4H^+ is 233–234 kcal./mole, and if this is correct, then the proton affinity of methane is 113 kcal/mole.

Although we have made no rate measurements, we have observed in the systems studied reactions (3), (4) and (5), which we believe have not been reported as yet

$$H_2S^+ + H_2S \longrightarrow H_3S^+ + HS \quad (3)$$

$$H_2S^+ + CD_4 \longrightarrow H_2DS^+ + CD_3 \quad (4)$$

$$HCl^+ + CD_4 \longrightarrow HDCl^+ + CD_3 \quad (5)$$

Relative rate measurements have indicated that (5) has about the same rate as the reaction between CD_4^+ and HCl shown in Table I.

THE REACTION OF TRIARYL PHOSPHITES WITH SULFONYL CHLORIDES

Sir:

Gilbert and McGough[1] reported that trialkyl phosphites react with sulfonyl chlorides to yield a mixture of the trialkyl phosphate, O,O-dialkyl-S-substituted thiophosphate and an alkyl chloride

$$3(RO)_3P + R'SO_2Cl \longrightarrow 2(RO)_3PO + (RO)_2P(O)SR' + RCl$$

This reaction has been confirmed recently by Hoffmann and his co-workers.[2] It is most likely that the reaction proceeds in three consecutive stages—the first two involving oxygen transfer

$$(RO)_3P + R'SO_2Cl \longrightarrow (RO)_3PO + R'SOCl \quad (1)$$

$$(RO)_3P + R'SOCl \longrightarrow (RO)_3PO + R'SCl \quad (2)$$

$$(RO)_3P + R'SCl \longrightarrow (RO)_2P(O)SR' + RCl \quad (3)$$

Reaction 3 which is analogous to the Michaelis–Arbuzov reaction can occur only if one of the R groups is labile; in the case of trialkyl phosphites, this has been amply demonstrated by Gilbert and McGough[1] and by Morrison.[3]

With triaryl phosphites, however, O,O,S-trisubstituted thiophosphates are not formed under the same mild conditions. Thus, refluxing a mixture of triphenyl phosphite and benzenesulfonyl chloride (mole ratio 3:1) in dry benzene under a nitrogen atmosphere, then fractionating *in vacuo* gave triphenyl phosphate, diphenyl disulfide, chlorobenzene and possibly diphenyl phosphorochloridite (not definitely identified). The results support the stoichiometric equation

$$6(PhO)_3P + 2PhSO_2Cl \longrightarrow 5(PhO)_3PO + (PhS)_2 + PhCl + (PhO)_2PCl$$

The phosphate and disulfide were obtained almost quantitatively.

Diphenyl sulfide and O,O-diphenyl-S-phenyl thiophosphate were not found, thus indicating that triphenyl phosphite does not react with diphenyl disulfide. This inference was confirmed by demonstrating that triphenyl phosphite and diphenyl disulfide are recovered quantitatively after refluxing a mixture of them in benzene. With triethyl phosphite under the same conditions, however, diphenyl disulfide reacts quantitatively in refluxing benzene solution

$$(PhS)_2 + (EtO)_3P \longrightarrow (EtO)_2P(O)SPh + PhSEt$$

This reaction had been observed previously with dialkyl disulfides by Jensen and his co-workers[4] and it now appears to be generally applicable to trialkyl phosphites and diaryl disulfides.

Our conclusion is that the first two stages (reactions 1 and 2) occur with both triaryl and trialkyl phosphites but the third stage (reaction 3), in contrast to phosphites bearing at least one alkyl group, does not take place with triaryl phosphites. This is demonstrated readily by carrying out a reaction of triphenyl phosphite with benzenesulfenyl chloride when diphenyl disulfide but not O,O,S-triphenyl phosphate is formed

$$(PhO)_3P + 2PhSCl \longrightarrow Ph—S—S—Ph + (PhO)_3PCl_2$$

Unstable quasi-phosphonium intermediates seem likely at each stage of the reaction; however, the nature of these phosphonium complexes, the manner in which oxygen transfer occurs, and the interpretation of disulfide formation requires critical examination to clarify the course of this reaction. Disulfone or disulfoxide intermediates are unlikely—both are expected to react giving other products. However, the mechanistic and experimental details of this novel and convenient reduction of sulfonyl chlorides to disulfides by triaryl phosphites will be presented in a forthcoming publication.

DEGREE OF IODINATION AND LOCALIZING ACTIVITY OF RABBIT ANTIKIDNEY γ-GLOBULIN

Sir:

The precipitation of chemically modified antibody γ-globulin by homologous antigen has been used by many workers as an index of residual biological activity.[1,2] Data obtained in this manner have been considered by analogy to hold for certain iodinated γ-globulins possessing *in vivo* localizing activity.[3,4,5,6] The danger in making this type of extrapolation is evident when one examines the results of a more direct approach.

Anti-rat kidney γ-globulin obtained from immunized rabbits was radioiodinated essentially as in ref. (6) and then was dialyzed exhaustively against large volumes of *p*H 8 borate buffer. The dialysates were counted as was the content of the bag. This gave the percentage of the original iodine bound to the protein. The amount of original protein was determined gravimetrically and the weight of insoluble residue found after dialysis was subtracted. As long as the starting γ-globulin solution was free from turbidity the insoluble fraction contained the same ratio of I^{131} as the rest of the solution. This fraction was always very minor. The values given for degree of substitution are considered accurate to not less than ±10%. The molecular weight of γ-globulin was taken as 160,000. Iodination and dialysis were performed at 0–5°.

The labeled γ-globulin was then injected into rats and the extent of localization determined three days later according to the method of Pressman.[7] The results are shown in the table and are all for the same preparation of γ-globulin.

Expt.	No. of rats	Atoms I / Molecule	% Injected dose bound to kidney, ±1 std. error
1	7	0.5	1.47 ± 0.07
2	6	0.6	1.68 ± .03
3	6	1.3	1.21 ± .05
4	4	2.7	1.15 ± .10
5	3	3.2	0.87 ± .08
6	4	4.0	0.82 ± .07

It would appear, therefore, that the conclusions of the workers earlier referred to (that antibodies can be substituted with from 2 to 9 atoms of iodine per molecule without apparent modification of activity) are based upon relatively insensitive criteria. In the experiments reported here, the extent of binding started to diminish at about 1 atom I/protein molecule. It was noted also that the cross localization in the liver fell off at a slower rate,[8] indicating a concomitant loss in the specificity of the γ-globulin. Since the specific activity of I^{131} is very high, a small degree of substitution such as is suggested by this work, could still yield a preparation of high radioactivity.

INTERMEDIATES IN THE SYNTHESIS OF DIPHOSPHOPYRIDINE NUCLEOTIDE FROM NICOTINIC ACID[1]

Sir:

A previous communication from this laboratory reported synthesis of DPN[2] by human erythrocytes at low concentrations of nicotinic acid.[3] Nicotinamide, at similar concentrations, did not elevate the pyridine nucleotide level significantly, presumably eliminating free NAm as an intermediate and suggesting that amidation may occur after NA is converted to some presently unknown derivative.

Incubation of 0.72 μmole of NA with glutamine, 0.1 *M* P_i buffer, *p*H 7.4, glucose and 3.5 ml. of defibrinated erythrocytes resulted in synthesis of 0.181 μmole of DPN. After incubation of 0.72 μmole of nicotinic acid-7-C^{14} (4.4×10^5 c.p.m.) under the same conditions and chromatographing aliquots of the deproteinized filtrate on Whatman No. 1 paper with a solvent system of 0.1 *M* PO_4 buffer *p*H 6.8, 600 g. of ammonium sulfate per liter, 2% 2-propanol, 3 radioactive spots could be detected. One corresponded to NA (25% of the total radioactivity). A second traveled between NR and NMN (Compound I-39% of the total radioactivity) and the third traveled with DPN (Compound II, 36% of the total radioactivity). Whereas omission of glutamine reduced DPN synthesis by 70%, glutamine had no effect on the amount of radioactivity in the two nucleotide spots, indicating that at least two NA derivatives other than DPN had been synthesized. Omission of glucose reduced the percentage of the total radioactivity of Compound I from 37 to 18% and Compound II from 63 to 27%.

Extracts of acetone powdered-eythrocytes, which cannot synthesize DPN from NA, do synthesize both Compounds I and II. Synthesis of Compound I requires Mg^{++}, P_i and either R5P or PRPP. NaF (0.02 *M*) inhibits synthesis of Compound I from R5P by 88% and from PRPP by only 25%. PRPP formation from R5P and ATP is known to be inhibited 60 to 70% by 0.02 *M* NaF in erythrocyte acetone powder extract.[4] Hypoxanthine, which is known to condense with PRPP to

(1) These studies were supported in part by contract AT-(40-1)-289 between Duke University and the United States Atomic Energy Commission and by Grant RG-91 from the National Institutes of Health.

(2) These abbreviations are used: NA, nicotinic acid; NAm, nicotinamide; GAm, glutamine; DPN, diphosphopyridine nucleotide; NMN, nicotinamide mononucleotide; NR, nicotinamide riboside; R5P, ribose 5-phosphate; ATP, adenosine triphosphate; PRPP, 5-phosphoryl-ribose 1-pyrophosphate; P_i, inorganic phosphate.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

form inosinic acid in these extracts,[4] inhibits Compound I formation by about 50%. These results suggest that Compound I is nicotinic acid mononucleotide and is formed by condensation of PRPP with NA.

To characterize these compounds, a large-scale incubation of erythrocyte acetone powder extracts with nicotinic acid-7-C^{14} was performed. A neutralized perchloric acid filtrate was then passed through a Dowex 1 formate column; 15-ml. aliquots were collected and assayed for radioactivity and absorption at 260 mμ. The various fractions were pooled and components identified by paper chromatography. Radioactive fractions were adsorbed on a Norit A column and, after washing with water, were eluted with 10% aqueous isoamyl alcohol. Ribose and phosphate analyses and absorption spectra suggested that Compounds I and II were the nicotinic acid analogs of NMN (desamido-NMN) and DPN (desamido-DPN), respectively. Compound II was not active with alcohol dehydrogenase and did not form a fluorescent acetone addition product.[5] Further work on the identification of these compounds is in progress.

TABLE I

SYNTHESIS OF DPN FROM DESAMIDO-DPN

Complete incubation system consisted of 1.7 μmoles of desamido DPN, 20 μmoles of glutamine, 2 μmoles of ATP, 5 μmoles of ATP, 40 μmoles of P_i buffer, *p*H 7.4, and 4 cc. of dialyzed yeast autolysate. Total volume 1.0 cc. after incubation of 100 minutes 1 cc. of H_2O was added and the protein denatured at 100° for 1.5 minutes; 1-cc. aliquots were taken for alcohol dehydrogenase assay of DPN formed.

Omission and/or Additions	μmoles DPN synthesized
None	0.116
−Desamido DPN	.028
−ATP	.011
$-Mg^{++}$	.014
−Glutamine	.026
−Glutamine + NH_4Cl 20 μm.	.015
−Glutamine + glutamate 20 μm.	.019
"0 time"	.007

Dialyzed yeast autolysates have been found slowly to synthesize DPN upon addition of glutamine, ATP, PRPP, Mg^{++}, F^- and NA but not NAm. With nicotinic acid-7-C^{14} in the medium, accumulation of compounds I and II was again observed. Compound II prepared with erythrocytes or yeast exhibited an R_f in 70% ethanol, 30% 1 *M* ammonium acetate, *p*H 5.0 identical to that of an authentic sample of the nicotinic acid analog of DPN kindly supplied to us by Dr. N. O. Kaplan. This solvent system adequately separates Compound II from DPN. Synthesis of Compound II from NA by yeast autolysate is dependent on ATP, PRPP and Mg^{++}. R5P is 10% as effective as PRPP. Glutamine, ATP and Mg^{++} are required for synthesis of DPN from desamido-DPN (Table I). NH_4^+ and glutamate are inactive as amide donors. Further investigations of the mechanisms of these enzymatic syntheses, purification of the enzymes, and a study of their distribution in bacterial and mammalian systems are in progress.

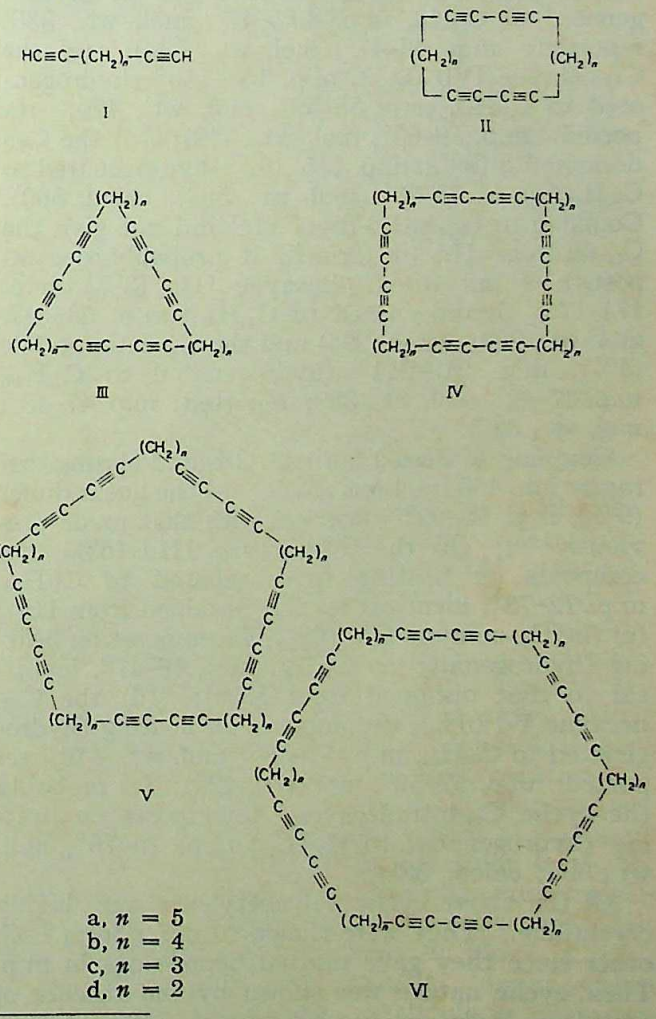
UNSATURATED MACROCYCLIC COMPOUNDS. V.[1] LARGE RING POLY-ACETYLENES

Sir:

We have shown recently that the oxidation of terminal diacetylenes of type I with oxygen in the presence of cuprous chloride and ammonium chloride in aqueous ethanol leads to the cyclic dimers II besides linear compounds.[1,2] We have studied this type of coupling of terminal diacetylenes under a variety of conditions, especially in homogeneous media. The surprising discovery has been made that when diacetylenes of type I in pyridine solution are simply heated with neutral cupric acetate,[3] not only the cyclic dimers II are formed, but also the cyclic trimers III, tetramers IV, pentamers V, hexamers VI and higher cyclic



(1) Part IV, F. Sondheimer, Y. Amiel and R. Wolovsky, THIS JOURNAL, in press.

(2) (a) F. Sondheimer and Y. Amiel, *ibid.*, **78**, 4178 (1956); *ibid.*, in press; (b) Y. Amiel, F. Sondheimer and R. Wolovsky, *Proc. Chem. Soc.*, 22 (1957).

(3) This sort of oxidation has been shown to result in the smooth coupling of simple acetylenes and to give the cyclic monomer, and dimer in the case of I, $n = 10$ (and of a diacetylenic diester) when carried out under conditions of high dilution (G. Eglinton and A. R. Galbraith, *Chem. & Ind.*, 737 (1956)).

polyacetylenes. Except in the case of Id, only small amounts of the linear coupling products result.

For example 1 part of nona-1,8-diyne (Ia) in 100 parts of pyridine was heated and stirred with 15 parts of neutral cupric acetate at 55° for 3 hours. The product on chromatography on 200 parts of alumina into *ca.* 300 fractions gave successively: (a) the C_{18}-tetrayne IIa (10%), m.p. 210–212° (identical with that made previously[1,2b]); (b) the C_{27}-hexayne IIIa (13%), m.p. 125–126° (hydrogenated to $C_{27}H_{54}$,[4] m.p. 47–48°, mol. wt., 374[5]; calcd. 378); (c) the C_{36}-octayne IVa (11%), m.p. 135–136° (hydrogenated to $C_{36}H_{72}$,[4] m.p. 70–71°, mol. wt., 517; calcd., 504); (d) the C_{45}-decayne Va (4%), m.p. 144–145° (hydrogenated to $C_{45}H_{90}$,[4] m.p. 78.5–79°, mol. wt., 618; calcd., 630); (e) probably the C_{54}-dodecayne VIa (4%), m.p. 144–145° (hydrogenated to $C_{54}H_{108}$,[4] m.p. 90–91°, mol. wt. not determined due to insolubility).

A similar coupling of octa-1,7-diyne (Ib) gave: (a) the C_{16}-tetrayne IIb (9%), m.p. 162–163° (identical with that made previously[2a]); (b) the C_{24}-hexayne IIIb (14%), m.p. 173–174° (hydrogenated to $C_{24}H_{48}$, m.p. 46.5–47°, mol. wt., 330; reported: m.p. 46–47°, mol. wt., 336); (c) the C_{32}-octayne IVb (8%), m.p. 154–155° (hydrogenated to $C_{32}H_{64}$, m.p. 58–59°, mol. wt., 429; reported: m.p. 59–60°, mol. wt., 448); (d) the C_{40}-decayne Vb (9%), m.p. 155–157° (hydrogenated to $C_{40}H_{80}$,[4] m.p., 74–75°, mol. wt., 568; calcd. 560). Coupling of hepta-1,6-diyne (Ic) did not give the C_{14}-tetrayne IIc (if formed, it probably decomposed),[1,2b] but the C_{21}-hexayne IIIc (3%), m.p. 174–175° (hydrogenated to $C_{21}H_{42}$,[4] m.p. 63–64°, mol. wt., 289; calcd. 294) and the C_{28}-octayne IVc (4%), m.p. 213–214° (hydrogenated to $C_{28}H_{56}$, m.p. 47–48°, mol. wt., 389; reported: m.p. 47–48°, mol. wt., 398).

Coupling of hexa-1,5-diyne (Id) and chromatography into 450 fractions gave: (a) the linear dimer (9%), m.p. 98–99° (identical with that made previously[1,2b]); (b) the C_{18}-hexayne IIId (6%), decomposes on heating (hydrogenated to $C_{18}H_{36}$, m.p. 72–73°, identical to that obtained from IIa); (c) the C_{24}-octayne IVd (6%), decomposes on heating (hydrogenated to $C_{24}H_{48}$, m.p. 46–47°, identical to that obtained from IIIb); (d) the C_{30}-decayne Vd (6%), decomposes on heating (hydrogenated to $C_{30}H_{60}$, m.p. 57–58°; mol. wt., 416; reported m.p. 57–58°, mol. wt., 420); (e) probably the cyclic C_{42}-tetradecayne, decomposes on heating (hydrogenated to $C_{42}H_{84}$,[4] m.p. 75–76°, mol. wt., 598; calcd., 588).

All the above cyclic polyacetylenes were highly crystalline. They were shown to differ from each other since they gave mutual depressions in m.p. Their cyclic nature was shown by the absence of acetylenic hydrogen (no band at *ca.* 3300 cm.$^{-1}$ in the infrared, no precipitate with silver nitrate) and by the absence of terminal methyl groups (no band at *ca.* 1380 cm.$^{-1}$) in the corresponding saturated compounds. The latter gave satisfactory analytical results, but most of the polyacetylenes exploded on attempted combustion and gave low carbon values. In all the four series studied, cyclic polyacetylenes of higher mol. wt. than those described were also obtained; their structures are now under investigation.

The present method makes available in one step highly unsaturated large ring alicyclic hydrocarbons (and by hydrogenation the corresponding saturated ones) over a wide range of size, including considerably larger ones than the thirty-four membered cycle which is the biggest alicyclic ring prepared previously.

THE CHANGE OF OPTICAL ACTIVITY OF POLY-γ-BENZYL-L-GLUTAMATE IN AN ELECTRIC FIELD

Sir:

The optical activity of a molecule is different along different directions. Therefore we expect the optical activity of a solution of these molecules to change if the molecules are oriented. However, this effect has not been described. We wish to report the change of optical activity of a solution of poly-γ-benzyl-L-glutamate (PBLG) caused by orientation of the molecules in an electric field.

An equation relating the change in optical activity to molecular parameters at infinite dilution has been derived.[1] For a helical molecule the

$$\frac{[\alpha]_E - [\alpha]_0}{E^2} = \frac{2}{45}([\alpha_{33}] - [\alpha_{11}])[p_3^2 + (q_{33} - q_{11})]$$

change in the specific optical activity in an electric field[2] E is proportional to the difference in optical activity for light incident parallel to the helical axis $[\alpha_{33}]$ and perpendicular to the helical axis $[\alpha_{11}]$. The proportionality factor is the electrical orientation term which involves the permanent and induced dipole moments of the molecule. The specific optical activity in the absence of a field $[\alpha]_0$ is just $(2[\alpha_{11}] + [\alpha_{33}])/3$.

In order to measure the change of optical activity in an electric field, the light must be incident parallel to the field. Only along this direction is the refractive index and optical absorption the same for all directions of the plane of polarization.[3]

A one-cm. cell with transparent conducting glass[5] electrodes was used. The optical rotation with the electric field off, then on, was measured from $\lambda = 330$ to 550 mμ in a Rudolph automatic spectropolarimeter[6] for two concentrations of $M_w = 64{,}000$ PBLG[7] in ethylene dichloride. The

rotatory dispersion in the absence of the field was in good agreement with the measurements of Doty and Yang.[8,9] In the presence of the electric field an increase in optical rotation was observed at all wave lengths. The change was found to be proportional to the square of the electric field strength as predicted; an easily measurable change of about 0.1° occurred for a field of about 2,000 volts/cm.

As the electrical orientation term is not known, quantitative values of $[\alpha_{33}]$ and $[\alpha_{11}]$ cannot be obtained. However, an estimate of this term from electrical birefringence studies[10] allows us to make the following conclusions. Both $[\alpha_{33}]$ and $[\alpha_{11}]$ are very large in absolute magnitude, but $[\alpha_{33}]$ is positive and $[\alpha_{11}]$ is negative. Both values increase in absolute magnitude as the wave length decreases; however $[\alpha_{11}]$ increases faster, thus leading to the change in sign of the average optical activity $[\alpha]_0$ at $\lambda = 425$ mμ. These conclusions are in good agreement with Moffitt's prediction.[11]

VITAMIN B_{12} AND PROTEIN BIOSYNTHESIS. II. EFFECT OF VITAMIN B_{12} ON AMINO ACID INCORPORATION IN MICROSOMAL PREPARATIONS

Sir:

It has been reported from this laboratory that, while vitamin B_{12} has no effect on nucleic acid biosynthesis,[1] there is a decreased incorporation of C^{14}-labeled amino acids into liver protein in vitamin B_{12}-deficient animals,[2,3] indicating that vitamin B_{12} is involved in the incorporation of amino acids into protein.

Following these findings with the whole animal, the incorporation of C^{14}-labeled amino acids into protein has been studied *in vitro* using the microsomal fraction of liver and of spleen from both B_{12}-deficient and normal rats.

The rats were killed by decapitation and the livers removed and microsomes prepared by the procedure of Zamecnik and Keller.[4] This microsome fraction was freed only of mitochondria and nuclei since, as Keller and Zamecnik[5] have reported, the supernatant fraction is essential along with microsomes for the incorporation of amino acids into protein. These preparations containing microsomes and supernatant were then incubated under oxygen (95% O_2, 5% CO_2) with fructose diphosphate, C^{14}-amino acid, ATP[6] and GTP[6] for one hour in the Dubnoff shaker. They were then inactivated by the addition of TCA,[6] and the proteins were isolated and counted at infinite thickness in a GM gas-flow counter. The results are given in Table I.

Table I

Incorporation of C^{14}-Amino Acids into Protein by Microsome Preparations[a] from the Liver and the Spleen of Vitamin B_{12}-Deficient and Normal Rats[b]

	Liver microsome preparation, c.p.m./mg. protein		Spleen microsome preparation, c.p.m./mg. protein	
B_{12} status	$-B_{12}$	$+B_{12}$	$-B_{12}$	$+B_{12}$
$C^{14}H_3$-Methionine	16	76	26	94
2-C^{14}-Alanine	12	57	21	69

[a] Complete system contained 0.1 μM. FDP (6), 0.5 μM. ATP, 0.25 μM. GTP, 0.5 ml. of microsome preparation and labeled amino acid, made to 1 ml. with 0.15 molar KCl. [b] Each figure is the mean for three rats and run in duplicate. Excellent agreement was obtained between replicate animals.

In another series of experiments, the enzyme preparations were supplemented with vitamin B_{12}. The results are given in Table II.

Table II

The Effect of Addition of Vitamin B_{12} to Liver and Spleen Microsome Preparations[a] on the Incorporation of C^{14}-Amino Acids into Protein[b]

B_{12} status of animals	B_{12} added to microsome prep.	Liver microsome preparation, c.p.m./mg. protein		Spleen microsome preparation, c.p.m./mg. protein	
		$-B_{12}$	$+B_{12}$	$-B_{12}$	$+B_{12}$
C^{14}-Methionine	None	19	64	14	81
C^{14}-Methionine	50 mμg	53	73	51	88
2-C^{14}-Alanine	None	12	44	21	67
2-C^{14}-Alanine	50 mμg	40	66	48	90

[a] See Table I. [b] Each figure is the mean for two rats, run in duplicate. Agreement was excellent between animals.

Table I clearly shows that there is much less incorporation of labeled amino acids into protein in the case of microsome preparations prepared from the livers and spleens of vitamin B_{12}-deficient rats than in those from normal animals. These results agree with our previous data on intact animals.[2] In an additional experiment, in which the effect of level of substrate (labeled amino acid) concentration on incorporation was studied, it was found that an increase in the incorporation of amino acids was obtained with microsome preparations (both liver and spleen) from B_{12}-normal animals, upon incubation with increasing levels of amino acid, but that these substrate increments had no effect in preparations from deficient animals. This indicates an enzymatic block in protein synthesis in deficient animals. Again, when the microsome preparations, particularly from the deficient animals, were supplemented with crystalline vitamin B_{12} increased incorporation of the amino acids occurred, bringing the incorporation almost to a normal level (the stepwise increase obtained with graded levels of vitamin B_{12} and also amino acid increment data will be reported in full

later). All these data indicate that vitamin B_{12} is a co-factor for the incorporation of amino acids into protein–protein biosynthesis. A study of the distribution of radioactivity among the liver subcellular fractions following injection of 1 microcurie of Co^{60}-labeled vitamin B_{12} showed a high percentage of radioactivity in the microsomes (46%) and the supernatant fraction (25%) as related to the radioactivity of all the fractions. This high percentage in these fractions most implicated in protein synthesis is in agreement with the hypothesis that vitamin B_{12} is a co-factor for protein synthesis indicated by the amino acid incorporation studies. Work on the isolation of the enzyme containing B_{12} is in progress.

This work was supported in part by a grant-in-aid from the National Vitamin Foundation, New York. We are grateful to Dr. C. Rosenblum of Merck and Co., Inc., for a generous gift of Co^{60}-labeled vitamin B_{12}.

BOOK REVIEWS

Lectures in Immunochemistry. By MICHAEL HEIDELBERGER, Emeritus Professor of Immunochemistry, College of Physicians and Surgeons, Columbia University, New York; Visiting Professor, Institute of Microbiology, Rutgers University, New Brunswick, New Jersey. Academic Press, Inc., Publishers, 111 Fifth Avenue, New York 3, N. Y. 1956. ix + 150 pp. 14.5 × 22 cm. Price, $4.00.

The author of this short volume is a chemist who began his distinguished scientific career at the Rockefeller Institute for Medical Research in 1912. It was he who, together with the great bacteriologist Oswald T. Avery, isolated the capsular polysaccharides of several pneumococcal types and showed that they were endowed with immunological specificity. This was an achievement of no small magnitude, as subsequent events revealed.

Immunology was a lively field of investigation during the two decades prior to this discovery. Although the science was relatively new, chemists were already beginning to make important contributions to an understanding of the processes involved in immune phenomena. The monumental work of Karl Landsteiner concerning the specificity of proteins, and his discovery of the specific blood groups, an achievement for which he later received the Nobel Prize, were but two of the great contributions of this period. The classical studies of Arrhenius and of Madson on the quantitative aspects of the toxin-antitoxin reaction had brought a new interpretation of a phenomenon which, but a few years before, had scarcely been conceived of as a chemical reaction.

The discovery in the early twenties of the specific bacterial polysaccharides and of the role which they played in antipneumococcal immunity added a new, imposing milestone to the progress which both the chemist and the bacteriologist have made to our understanding of immune reactions.

Six of the lectures found in this volume, delivered in 1954 at the University of Tokyo, are a summation of the contributions which the author has made to the modern field of chemical immunology. These lectures deal for the most part with his quantitative studies on the precipitin and agglutination reactions, with the chemical nature of complement, and its role in the hemolytic system, and with the relationship between the chemical constitution and specificity of proteins and of carbohydrates. Three other lectures are included in the volume. Two of these, delivered in Europe, have to do with an evaluation of antipneumococcal immunity in humans following administration of the pneumococcal polysaccharides, while the third, delivered in New Brunswick, New Jersey, presents a study of the serological properties of native and denatured proteins.

For those who wish to obtain a broad background in the field of chemical immunology and a knowledge of the developments which have occurred in this field during the past several decades, or for those who wish to gain a broad scope in this specialized and many faceted field of biochemistry, this is not the book. However, for those who wish to learn something of the individual contributions of a contemporary and distinguished biochemist in a rapidly expanding field the volume is to be recommended warmly, although it is regrettable that many of the statements in the lectures, and in particular those regarding the work of others, are not better documented.

WALTHER F. GOEBEL

Enzyme Antigen and Virus. A Study of Macromolecular Pattern in Action. By F. MACFARLANE BURNET, Kt., F.R.S., F.R.C.P. Cambridge University Press, American Branch, 32 East 57th Street, New York 22, N. Y. 1956. viii + 193 pp. 13 × 18.5 cm. Price $3.50.

This monograph is an extension and revision of the author's earlier monograph ("The Production of Antibodies"[1]). It is concerned with the process of biological replication of specific patterns. Burnet is primarily interested in the replication of active proteins and presents evidence for the thesis that protein is synthesized by or on a RNA template. The content of the monograph is best summarized by the titles of the chapters and their contents.

I. Introduction: Enzyme Action and Protein Synthesis. (1) Enzyme specificity; (2) Adaptive enzymes in microorganisms; (3) Chemical aspects of the biosynthesis of protein; (4) The nature of adaptive enzyme synthesis.

II. Antibody Production. (1) The self-marker concept; (2) Antibody production after the elimination of antigen; (3) The site of antibody production; (4) Theoretical approach to antibody production; (5) Weaknesses of the present hypothesis.

III. The Self-marker Hypothesis in Relation to Cellular Proliferation and Control. (1) Immunological aspects of tumour transplantation; (2) The implications of cutaneous sensitization to simple compounds; (3) Application of Weiss's concepts of cell control to the self-marker hypothesis; (4) Summary.

IV. Virus Multiplication. Influenza Virus Multiplication: (1) Nucleic acid in relation to influenza virus; (2) An attempted visualization of the structure of influenza virus particles; (3) Process of infection; (4) Interference; (5) Incompleteness; (6) The dynamics of influenza virus multiplication in the allantoic cavity; (7) Recombination phenomena; (8) Mutation; (9) Summary.

V. The Scope of Biological Generalization. (1) Information theory in biology; (2) The application of pattern concepts to biological problems.

The monograph outlines very effectively much of the current thought on protein synthesis, antibody production and virus multiplication and, as a monograph should, it presents

very strongly the views of the author himself. Burnet attempts to present both sides of arguments. He was not able, unfortunately, to include some very pertinent recent work. For example, in connection with the problem of whether or not antigen persists during the period of antibody production, as required by the template theory, he was not able to include the very important work of Garvey and Campbell[2] which indicated that immunologically active fractions of proteins containing S^{35}-labeled azobenzene sulfonate groups persist in the liver of injected animals for several weeks. This is contrary to the work in the same system quoted by Burnet, namely, that of Ingraham,[3] who was not able to find such active components.

The author presents a great deal of information on the important and currently popular phenomenon of tissue tolerance. Although the recognition unit concept as described by Burnet is an appealing one, it is difficult to see how all the component substances of an organism could have a certain self-marker unit which would be recognized by the cells. It is known that slight chemical alteration of an individual's own proteins will render them antigenic to the same individual, and it does not seem possible that any such slight alteration would always affect the recognition unit.

Burnet concludes with the statement that "the generalizations that are needed for the technical control of biological processes will not come from the elaboration either of structural chemistry or of information theory in its conventional sense. These can only provide a background against which effective working concepts can be oriented and rendered more intellectually appealing. The handling of biological material will always be the business of scientists using their own working concepts based essentially on a not very deeply analyzed concept of specific pattern with which we have been concerned."

Since many chemists require sound basis and deep structural analysis for their effective function and do not consider these factors as mere "intellectual appeal," they may be dismayed at the loose use of the term "Specific Pattern," without concern about the actual nature and configuration of the pattern.

Instead of adopting an open mind to the possible contribution of all fields to the study of living processes, *Burnet openly minimizes the past contributions of chemistry and he is pessimistic about future contributions from chemistry* as shown by the following quotations which are typical: "Without ever being able to state the precise point at which technique must break down, we can yet be quite certain that no conceivable development of organic chemistry will provide us with the detailed structure of trypsin or of the particular nucleic acid that can transfer a new antigenic quality from one pneumococcus to another." "The attempt to press the structural, physical and chemical approach to the understanding of living process seems to have reached the phase of diminishing return for the effort involved. We are approaching an asymptotic barrier and it may be that some modification in the outlook and approach of theoretical biology will soon be needed."

The Calculation of Atomic Structures. Based on lectures given under the auspices of the William Pyle Philips Fund of Haverford College, 1955. Structure of Matter Series. Maria Goeppert Mayer, Advisory Editor. By Douglas R. Hartree, John Humphrey Plummer, Professor of Mathematical Physics in the University of Cambridge, England, and Philips Visitor at Haverford College. John Wiley and Sons, Inc., 440 Fourth Avenue, New York 16, N. Y. 1957. xiii + 181 pp. 15.5 × 23.5 cm. Price, $5.00.

Calculation of accurate wave functions for atoms is an important undertaking, but it has proved to be very frustrating because of the tedious numerical work involved. Renewed interest in the problem has been stimulated recently by development of large digital computing machines, and we soon hope for improved functions for the normal and more important excited states of atoms, from which transition probabilities and energies may be derived. Methods developed and tested for atoms are also of obvious importance in the problem of molecular structure calculations.

It is fortunate that we have now, for the first time, a very detailed and complete account of methods used by Professor Hartree and others in the self-consistent field treatments of atomic structure, especially for atoms with many electrons. The present book is based on a series of lectures delivered at Haverford College and repeated later in Princeton University. The emphasis is on technical rather than on descriptive aspects of the problem, but one may obtain a general view of what has been done and see how calculations may be improved without working through the numerous mathematical results. However the book is especially valuable for the specialist who plans similar or improved computations. In this connection, Chapter 10, on "Better Approximations," is particularly important, and might well have been amplified.

The Appendix contains tables of new (and recalculated) results, and it is very convenient to have this material collected in one book. The numerous references appear to be complete and extend into 1956.

University of Rochester A. B. F. Duncan
Rochester, New York

Textbook of Polymer Chemistry. By Fred W. Billmeyer, Jr., University of Delaware and Polychemicals Department, E. I. du Pont de Nemours and Co., Inc. Interscience Publishers, Inc., 250 Fifth Avenue, New York 1, N. Y. 1957. viii + 518 pp. 16 × 23.5 cm. Price, $10.50.

This book, according to its author, was written as a text in the physical and organic chemistry of high polymers at the senior or graduate student level. It is intended that the text be expanded by lectures and supplementary reading.

The first third of the book deals with the physical chemistry of high polymers, including their physical and chemical structure, thermodynamic properties in solution, a discussion of molecular weight methods, and ends with a section on rheology and viscoelastic properties. The kinetics of polymerization occupies the next fifth of the text and includes such topics as linear condensation polymerization, addition polymerization, copolymerization kinetics and the reactivity of monomers and radicals. A short section on molecular weight distributions, and chapters on emulsion polymerization, ionic polymerization and polymer degradation follow.

The properties of plastics are next dealt with, starting with a section on polymer processing, including injection and compression molding, plasticization and reinforcement. This is followed by a series of chapters on polymers from polystyrene, the acrylates, vinyl polymers, halogen-containing polymers, linear and cross-linked condensates, cellulose and the silicone polymers. This is essentially the organic polymers section of the text, occupying about 20% of its space.

Chapters on the properties of fibers are concerned with the physical and chemical properties of synthetic and natural fibers, fiber fabrication, and after-treatment. The subject of elastomers completes the text with chapters on vulcanization and reinforcement, as well as ones on natural rubber, GRS and other synthetic elastomers. The book concludes with a complete list of symbols giving their dimensions, units, definitions and chapter where used, and an appendix of trade names and manufacturers.

The field of the physics and chemistry of polymers is so extensive in terms of fundamental work as well as applied work that no text of manageable size could possibly cover it completely. Since this text treats almost every aspect of the field, the author has been forced to present only its essentials. In this his achievements have been truly remarkable. Each of the many chapters (57 in all) had to be necessarily short (they average 8 pages), but they are all authoritative and written in an extraordinarily clear manner. This was made particularly difficult because many of the derivations depend upon a sophisticated knowledge of theory, particularly statistical thermodynamics. The bases of the derivations are explained and the important intermediate and final expressions alone presented; this is as it should be.

This text is extremely readable. The material is well organized, making it easy to locate topics. The appendices

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

are excellent, particularly the one listing the many symbols used, 179 in all.

It is probable that a specialist in the organic chemistry of polymers would like to see more of his field covered and the same will doubtless be true of the physical chemist and the applied chemist. Each, however, will find the essentials of his subject ably and authoritatively presented.

In the opinion of this reviewer, this book is the outstanding general text in this field. It should also serve as an invaluable reference book for the non-specialist. While more complete books are available on advanced topics and on limited, applied phases of the field, this text will serve as an "initiator" to the field of polymer chemistry.

Crystal Structures. Volume II. Chapter XI. Miscellaneous Inorganic Compounds. Chapter XII. Structure of the Silicates. By Ralph W. G. Wyckoff, Laboratory of Physical Biology, National Institute of Arthritis and Metabolic Diseases, Bethesda, Maryland. Interscience Publishers, Inc., 250 Fifth Avenue, New York 1, N. Y. 1957. 261 pp. 19.5 × 24.5 cm. Price, $7.00.

Previously issued sections of this very valuable loose-leaf reference work have already been reviewed.[1,2]

The present section includes detailed structure data on the silicates and on miscellaneous inorganic compounds: complex and basic halides, thio salts, complex sulfides, complex oxides, and a few other compounds not belonging in these or other categories previously included. Coverage of the results of detailed structure analyses of all classes of chemical substances is not complete, except for some figures and the most recent work, which will presumably be covered in supplements to be issued later.

The world owes Dr. Wyckoff and the publishers a big debt of gratitude for the preparation and publication of this monumental work.

Encyclopedia of Chemical Reactions. Volume VI. Samarium, Scandium, Selenium, Silicon, Silver, Sodium. Compiled by C. A. Jacobson, Late Professor of Chemistry, West Virginia University. Edited by Clifford A. Hampel, Manager, Chemical Equipment Division, Fansteel Metallurgical Corp., Editor, "Rare Metals Handbook." Reinhold Publishing Corporation, 430 Park Avenue, New York 22, N. Y. 1956. 438 pp. 16 × 23.5 cm. Price, $12.50.

Volume VI of the Encyclopedia covers the reactions of six elements, samarium, scandium, selenium, silicon, silver and sodium. In general this reviewer can simply repeat the same criticisms as were voiced by the reviewers of previous volumes (This Journal, 68, 1678 (1946); 71, 2278 (1949); 75, 5772 (1953)). The main objection is still the incompleteness of the coverage. To be sure, a compilation of a comprehensive encyclopedia is a Gargantuan and unenviable task; however, if such work is to have any usefulness, at least an attempt should be made at reasonable completeness.

In order to illustrate the extent of this work it is sufficient to mention that there is a total of 77 reactions listed for samarium, of which 52 date to 1883 and 1885, and 51 reactions are listed for scandium, 46 of which are taken from pre-World War I literature!

The appendix contains a list of 93 journals from which the abstracts were made. One cannot but wonder why journals such as *Oil and Soap* or *Soap and Sanitary Chemicals* are included, while *Acta Chem. Scand.*, *Canadian J. Chem.*, or *J. Ind. Chem. Soc.* are omitted and the only Russian journal listed is the *J. Russ. Phys. Chem. Soc.* which ceased publication in 1930?

One easily comes to the conclusion that the title "Encyclopedia of Chemical Reactions" is certainly too pretentious. It is rather a limited collection of chemical reactions. As such it may have some usefulness for a research worker. To claim that the work is encyclopedic is certainly unrealistic.

The Atomic Weights of Fluorine and Silver

BY ARTHUR F. SCOTT AND WILLIAM R. WARE

RECEIVED JANUARY 30, 1957

This is the first chemical determination of the atomic weight of fluorine by the Harvard method. Perfluorobutyryl chloride was prepared by the reaction between PCl_5 and carefully fractionated perfluorobutyric acid. The chloride was purified by fractional distillation in vacuum systems. Samples of the chloride were hydrolyzed in pyridine solution and the chloride was precipitated with a known amount of silver. The end-point was determined nephelometrically, the final adjustment being made after the precipitate had stood for two years. The atomic weight of fluorine is calculated to be 18.999 as the average result of six analyses. This new value is shown to be in excellent agreement with the best atomic weight values derivable from mass-spectrographic measurements and from nuclear reaction data. The question of unifying the chemical and physical atomic weight scales by assigning the value 19 to the mass of the anisotopic element F is discussed.

The present chemical value 19.00 of the atomic weight of fluorine is based upon a number of determinations[1] by two different methods: the chemical analysis of pure fluorine compounds; and the measurement of the gas density of fluorine compounds of carbon and silicon. In the case of this element the analytical determinations presented special difficulties and are generally regarded as inferior to those by the gas density method. By way of illustration of the status of the analytical determinations it may be noted that of the five determinations of this type the one which is given most weight is Smith and Van Haagen's[2] conversion of sodium fluoride to sodium sulfate, a determination which comprised only three experiments involving samples of sodium fluoride ranging in weight between 0.3 and 1.1 g. Obviously, this determination by Smith and Van Haagen leaves much to be desired in many respects. The atomic weight of fluorine derived from Smith and Van Haagen's measurements is 19.005.
